Table 1 shows statistics on these datasets. For TW, it displays the statistics for each annotator. The TW datasets are fairly small, containing only around 1,000 frame labels. The MASC dataset is of substantial size, but it constitutes a lexical sample and therefore a slightly artificial evaluation setup. There is another Twitter-based test set (Johannsen et al., 2015), which we do not use in our experiments, because it was created semi-automatically and is therefore of lower quality. We conclude that existing out-of-domain test sets for FrameNet SRL are insufficient, in particular for increasingly important domains like user-generated text, because available datasets are either small or of low quality.

**YAGS: a new FrameNet test set based on user-generated text** To address the need for new out-of-domain test datasets, we created YAGS, a new FrameNet-annotated evaluation dataset based on question-answer data from Yahoo! Answers (YA), a community-driven question-and-answer forum. The corpus is based on a random sample of 55 questions and their answers from the test split of the YA Manner Questions dataset used by Surdeanu et al. (2011) and published as part of the Yahoo! Webscope program (<https://webscope.sandbox.yahoo.com/>).

YAGS contains 1,415 sentences, 3,091 frame annotations, and 6,081 role annotations. Figure 1 shows a sentence from YAGS that demonstrates some non-standard properties of the user-generated question-answer data, such as typos (*mortal* instead of *mortar*). We publish the annotations as stand-off annotations to the original dataset.

**Annotation study** Each document was annotated by a two linguistically trained annotators provided with detailed guidelines and then curated by an experienced expert, all using WebAnno 2.0.0 (Yimam et al., 2014). Up to five predicates per sentence were pre-selected automatically based on lemma and POS, preferring verbal predicates to other POS, which leads to a larger proportion of verbs in YAGS. The annotation task was to identify the correct frame label for each predicate, if any, and then to identify the role spans as arguments and adjuncts of the frame, and to label them with the appropriate role. For reference, annotators accessed the FrameNet 1.5 definitions and examples with the FrameNet Explorer tool ([www.clres.com/FNExplorer.html](http://www.clres.com/FNExplorer.html)).

Inter-rater agreement for frame labels is Krippendorff’s  $\alpha=0.76$ ; agreement for role labels given matching spans is  $\alpha=0.62$ , and Krippendorff’s  $\alpha$  unitizing agreement for role spans is 0.7 – a good result for such a difficult task on user-generated text. Average pairwise F<sub>1</sub> agreement for frame labels is high at 0.96, higher than the 0.84 reported by Søggaard et al. (2015) for the TW sets. Our high frame agreement is a result of annotator experience and our elaborate annotation setup.

**YAGS statistics and properties** Table 1 presents dataset statistics for YAGS and the other test sets. Due to the predicate selection, YAGS contains a larger proportion of verbal predicates than the other sets, and has three times more frames and roles than TW, approximating the size of das-test. The proportion of core roles, roles that are obligatory for a frame and thus typically more frequent in datasets than non-core roles, in the out-of-domain test sets (TW, YAGS, MASC) is slightly smaller

data	s	f	a	n	v	r	cr
das-test	2,420	4,458	12	42	33	7,172	83
YAGS	1,415	3,091	5	18	75	6,081	74
MASC	8,444	7,226	25	42	33	11,214	78
TW <sub>1</sub>	236	1,085	10	47	40	1,704	77
TW <sub>2</sub>	236	1,027	11	46	39	1,614	79
TW <sub>3</sub>	236	1,038	11	47	39	1,399	89

Table 1: Text dataset statistics: sentences **s**; frames **f**; % of adjectives **a**, nouns **n** and verbs **v**; roles **r**, % of core roles **cr**. Subscripts for TW indicate the respective annotator.

compared to das-test. This goes along with a larger variance of roles in YAGS.

The user-generated aspect of YAGS manifests in spelling errors, and in the lack of punctuation and structure of the texts. The language is informal, but there are only few emoticons or other special words such as the hashtags typically found in tweets.

In the next section, we use the test sets from Table 1 to analyze the domain generalization capabilities of an open-source FrameNet SRL system.

#### 4 Domain generalization capabilities of open-source FrameNet SRL

To analyze the domain generalization capabilities of contemporary open-source SRL, we ran the frame identification from *Semafor* (Das et al., 2014) with the enhanced role labeler from Kshirsagar et al. (2015), both trained on the in-domain das-train set, on the four test sets das-test, YAGS, TW, and MASC. The systems receive text annotated with predicate spans as input, which has become the standard in recent evaluations.

**Evaluation script** The *Semafor* evaluation script (Das et al., 2014) provides precision P, recall R, and  $F_1$  scores for full SRL (SRL), and accuracy A for frame identification (frameId). Full SRL evaluation can be performed with and without using gold frames instead of predicted (auto) frames.

The script does not provide results on the role labeling (argument identification and labeling, roleId) alone: the scoring mechanism for *SRL/gold* also considers the by default correct gold frames. This is useful when comparing different SRL systems on the same test set, but not sufficient when 1) comparing role labeling performance on different test sets with a different ratio of frame labels to role labels (resulting from different annotation strategies), and 2) analyzing the contribution of frameId and roleId to full SRL performance across test sets.

data	frameId	roleId		SRL	
	auto	auto	gold	auto	gold
das-test	82.09	30.08	55.20	55.40	73.16
YAGS	59.62	18.60	56.99	37.22	72.58
MASC	39.52	19.46	51.74	29.05	71.08
TW-av	62.17	15.91	61.45	38.44	76.74

Table 2: *Semafor* performance on test sets in %: exact frameId A; then  $F_1$  for roleId and SRL with system frames (auto) and gold frames (gold).

We therefore evaluate the output of the script to retain the original counts for role labels and compute scores on the role labeling proper (roleId). Moreover, there are two evaluation settings for frameId: exact frame match and partial frame match. We use the exact match setting that does not credit related frames and roles.

**Results** Table 2 presents scores for exact match frameId and for SRL and roleId with automatic frames (auto) and with gold frames (gold). For TW, the results are averaged over the number of annotators. According to column *SRL/auto*, we observe best *Semafor* performance for full SRL on das-test, results for the other test sets are at least 16 percentage points  $F_1$  lower. This is mostly due to the worse frameId performance of *Semafor* on the new test sets, as shown in column *frameId*: frameId performance is at least 19 percentage points lower. This negatively affects roleId for the out-of-domain test sets (see column *roleId/auto*). *RoleId/auto* scores are also low on das-test, but higher than for the other sets.

When using gold frame labels, roleId and SRL performance improve for all test sets. As shown in columns *roleId/gold* and *SRL/gold*, the difference between in-domain and out-of-domain evaluation vanishes. Only MASC scores are still two points lower for full SRL than those for das-test. TW-av scores even surpass the in-domain scores.<sup>2</sup>

This shows how much FrameNet role labels are dependent on correct frame labels. Thus, it is crucial to improve the out-of-domain performance of frameId systems.

Domain dependence appears to be less of a problem for the role labeling step. The MASC dataset is the most difficult for both frameId and roleId. This is mostly a consequence of the lower training data coverage of MASC, as discussed below.

<sup>2</sup>Our TW-av results are not comparable to those from Sogaard et al. (2015) because their test setup includes predicate target identification and uses different evaluation metrics.

dataset	lemmas $\notin$		senses $\notin$	
	lexicon	das-train	das-train	monosemous $\in$ das-train
das-test	2.59	9.99	14.03	53.99
YAGS	2.79	17.33	30.36	27.07
MASC	7.45	21.72	51.25	23.51
TW <sub>1</sub>	1.01	17.51	36.06	26.73
TW <sub>2</sub>	1.27	17.91	51.25	27.07
TW <sub>3</sub>	1.25	17.24	35.65	27.17

Table 3: Training data coverage of test sets in %. Sense is a combination of predicate lemma, POS and frame; lexicon refers to the `SemaFor` lexicon.

**Analysis** In our study, it became clear that domain dependence is crucial to the frame identification step in SRL. The lower scores for the out-of-domain test sets can be a result of different domain-specific predicate-frame distributions, or a lack of coverage of the domain in the training data.

To get a better understanding of these phenomena, we compared detailed statistics of the different test sets, cf. Table 3. Das-test has the largest predicate coverage and contains a lot of monosemous predicates, which boosts the overall performance. The occurrence of fewer monosemous predicates is expected for the lexical sample dataset MASC, but might indicate a domain preference for polysemous predicates in the YAGS and TW datasets.

The percentage of unseen predicates (lemmas  $\notin$  das-train) is slightly higher for the user-generated test sets than for das-test, and much higher for MASC. This is mirrored in the lower frameId performance for MASC compared to the other test sets, and the slightly higher performance of TW-av and YAGS. Not all errors can be explained by insufficient training data coverage, which indicates that domain effects occur for the out-of-domain sets.

To support this assumption, we performed a detailed error analysis on the misclassified instances for all test sets. We compute the proportion of wrongly classified instances with unseen predicates, predicates that do not occur in the training set. For MASC, the majority of the errors, 68%, are based on unseen predicates, while the number ranges between 37% and 43% for the other test sets, i.e. 37% for TW, 39% for das-test and 43% for YAGS. This shows that training data coverage is a bigger issue for MASC than for the other test sets. The proportions of in-train errors for YAGS and TW-av are similar to das-test. Together with the fact that overall proportion of errors is still much higher for the user-generated test sets YAGS and TW-av, this further supports our hypothesis of domain effects

for YAGS and TW-av. Manual analysis furthermore shows that there are differences in frequently confused frames between the in-domain das-test and out-of-domain YAGS and TW-av.

In the next section, we study new methods to improve out-of-domain frame identification.

## 5 Frame identification with distributed word representations

Given a predicate and a set of frames associated with this predicate, a frame identification system has to choose the correct frame based on the context. In this section we introduce our frame identification method and compare it to the state of the art in both in-domain and out-of-domain settings.

**Our system SimpleFrameId** We developed a straightforward approach to frame identification based on distributed word representations, and were surprised to find that this simple model achieves results comparable to the state-of-the-art system, `Hermann-14`. Our initial attempts to replicate `Hermann-14`, which is not publicly available, revealed that the container-based input feature space is very sparse: there exist many syntactic paths that can connect a predicate to its arguments, but a predicate instance rarely has more than five arguments in the sentence. So by design the input representation bears no information in most of its path containers. Moreover, `Hermann-14` makes heavy use of automatically created dependency parses, which might decline in quality when applied to a new domain. We demonstrate that our simple system achieves competitive in-domain and out-of-domain performance.

Our system, called `SimpleFrameId`, is specified as follows: given the lexicon  $L$ , the vector space  $vsm$  and the training data, our goal is to predict the frame  $f$  given the sentence  $S$  and the predicate  $p$ . From the machine learning perspective, the lexicon and the vector space are external resources. The lexicon contains associations between predicates and frames, and we further denote the set of frames available for a predicate as  $L(p)$ . The vector space provides a pre-defined dense vector representation  $vsm(w)$  for each word  $w$ . In our case  $vsm$  is a simple word lookup function, since we do not modify our word representations during training.

From the sentence we extract the context representation,  $x_c = \frac{\sum_{w \in C} vsm(w)}{|C|}$ . We experiment with two kinds of contexts: `SENTBOW` includes all

the words in the sentence, i.e.  $C = S$ , DepBOW considers the dependency parse of the sentence and only includes direct dependents of the predicate,  $C = \text{dep}(p, S)$ . As for the predicate, the plain embedding from the source vector space model is used,  $x_p = \text{vsm}(p)$ . A simple concatenation of  $x_c$  and  $x_p$  serves as input to the disambiguation classifier  $D$ , which outputs weights  $D(x_c, x_p, f)$  for each frame known to the system  $f \in L$ . Note that the classifier itself is agnostic to the predicate’s part of speech and exact lemma and only relies on the word representations from the *vsm*. We experiment with two different classification methods: one is a two-layer neural network  $D_{NN}$ , the other one is  $D_{WSB}$ , which follows the line of Hermann-14 and learns representations for frames and predicates in the same latent space using the WSABIE algorithm.<sup>3</sup> Hyperparameters are tuned on the development sets *das-dev* and *YAGS-dev* (sampled from *YAGS*); we test on the remaining 2,093 instances in *YAGS-test*.

**Lexicon-based filtering** In the testing stage, the classifier outputs weights for all the frames available in the lexicon, and the best-scoring frame is selected,  $f \leftarrow \text{argmax}_{f \in L} D(x_c, x_p, f)$ . Since the lexicon specifies available frames for each lexical unit (i.e. lemma and POS), additional filtering can be performed, which limits the search only to the available frames,  $f \leftarrow \text{argmax}_{f \in L(p)} D(x_c, x_p, f)$ . If the predicate is *unknown* to the lexicon,  $p \notin L$ , the overall best-scoring frame is chosen. If the target has only one entry in the lexicon, it’s declared unambiguous and the frame is assigned directly.

Despite being common, this setup has several flaws that can obscure the differences between systems in the testing stage. As we showed in Section 4, the FrameNet lexicon has coverage issues when applied to new domains. Neither the predicate list nor the frame associations are guaranteed to be complete, and hence the total results are highly determined by the lexicon coverage.<sup>4</sup> To take this into account, we also perform evaluation in the *no-lexicon* setting, where frames are assigned directly by the classifier and no lexicon-based fil-

<sup>3</sup>In our implementation, we use the LightFM package (Kula, 2015) with the WARP option for hybrid matrix factorization.

<sup>4</sup>A justification for this can also be found in Hermann et al. (2014): the difference in Hermann-14 accuracy when switching from the *Semafor* lexicon to the full lexicon is comparable to the difference between *Semafor* and Hermann-14 when evaluated on the same lexicon.

system	total	ambig	no-lex
DataBaseline	79.09	70.68	2.21
LexiconBaseline	79.05	56.62	2.21
Semafor*	83.60	69.19	-

WSB+DepBOW	85.69	69.93	71.21
NN+SentBOW	87.63	<b>73.80</b>	<b>77.49</b>
NN+DepBOW	87.53	73.58	76.51

Table 4: In-domain system comparison on *das-test*, \* denotes results from Hermann et al. (2014); **ambig**: evaluation on ambiguous predicates; **no-lex**: system without lexicon filter.

tering is performed. We find that our frame identification system performs surprisingly well in this setting, and we encourage the *no-lexicon* performance to be additionally reported in the future, since it better reflects the frame identification quality and smoothens the effect of lexicon coverage.

**Baselines** We employ two majority baseline models for comparison. The *DataBaseline* assigns frames based on how often a frame is evoked by the given predicate. This corresponds to the most frequent sense baseline in word sense disambiguation (WSD). The frames available for predicates are obtained by scanning the training data. The *LexiconBaseline* calculates overall frame counts first (i.e. how often a frame appears in the training data in general), and, given the predicate, selects the overall most frequent frame among the ones available for this predicate. We expect this baseline to better handle the cases when limited data is available for a given predicate sense.

**Experiments** In our experiments, we generate the lexicon  $L$  in the same way as in Hermann-14, by scanning the “frames” folder of the FrameNet 1.5 distribution. For the external vector space model *vsm* we use dependency-based word embeddings from Levy and Goldberg (2014).

**In-domain performance** We report the performance of our system in the in-domain setting to compare to the state-of-the-art results from Hermann-14.<sup>5</sup> We train our system on *das-train* and test it on *das-test* using the full FrameNet lexicon. When available, we report the *no-lexicon* scores as well. As Table 4 shows, our system out-

Table 5: Out-of-domain frameId, total accuracy. Semafor scores calculated during our own experiments; YAGS results on YAGS-test.

performs Semafor and performs on par with the results reported for Hermann-14. One interesting observation is that our systems perform almost as well in the no-lexicon setting as the DataBaseline, which has access to the lexicon, in the total setting. To our surprise, the WSABIE-based frame identification did not yield a consistent improvement in-domain, compared to the simple NN-based approach. We also observe that in many cases the SentBOW representation performs on par with the DepBOW, while requiring significantly less data preprocessing: SentBOW only uses tokenization, whereas DepBOW relies on lemmatization, POS-tagging, and dependency parsing. We attribute this effect to the fact that SentBOW provides more context information than the sparse, dependency-filtered DepBOW.

**Out-of-domain performance** We also investigate how well the systems perform in the out-of-domain setting. Table 5 summarizes the results. Each of the systems was trained on *das-train* and tested on a variety of test sets. As we can see, our systems outperform Semafor for all datasets. The YAGS dataset is the only dataset on which we do not strongly outperform Semafor. We attribute this to the complexity of the YAGS dataset that contains a high proportion of verbs.

Overall out-of-domain performance stays behind the  $F_1$ -agreement observed for the human annotators for TW and YAGS, which shows that there is a large margin for improvement. Corresponding scores for in-domain data are not available.

**Error analysis** To further investigate the performance of our system in the out-of-domain setup we analyse statistics on the errors made by the system variant NN+SentBOW.

The system’s wrong predictions are affected by the lexicon in two ways. First, if the predicate is

not listed in the lexicon (unknown), the system has to choose among all frames. As we have shown before, the quality of predictions for unknown predicates is generally lower. The second case is when the predicate *is* listed in lexicon (so it is not unknown), but the correct frame is not associated with this predicate. We further refer to this class of errors as *unlinked*. For unlinked predicates, the system is restricted to the set of frames provided by the lexicon, and by design has no means to select the right frame for a given predicate occurrence.

The unlinked-predicate issue points to a major design flaw in the standard frameId architecture. Although choosing among frames defined in the lexicon provides a quality boost, it also renders many instances intractable for the system, if the lexicon coverage is incomplete. As Table 6 shows, unknown and unlinked predicates are almost non-present in the in-domain case, but are a major source of errors in the out-of-domain case and even might be responsible for the majority of errors occurring due to domain shift (see MASC). It is important to point out that there is still no guarantee that these would be classified correctly once the missing linking information is available in the lexicon. However, if the correct frame is not listed among the frames available for the predicate, the misclassification is inevitable.

A more detailed analysis of the errors made by the system shows that the majority of false predictions for known and linked predicates are due to the domain differences in word usage. For example, the predicate **window** was assigned the frame *Connecting\_architecture* instead of the correct frame *Time\_period\_of\_action* in the following sentence:

“No effect of anesthetic protocol on IOP during a 12 minute measurement [**window**].”

This problem is also relevant in generic WSD (Agirre et al., 2010) and benefits from the same solutions, for instance adapting embeddings to a particular domain (Taghipour and Ng, 2015) and efficient use of embeddings (Iacobacci et al., 2016).

Another major source of errors are subtle syntactic and semantic differences between frames which are hard to resolve on the sentence level (e.g. distinguishing between *Similarity* and *Identity* for the predicate **different**). This could be addressed by incorporating subcategorization information and document context into the disam-

dataset	% errors			accuracy loss	
	unk	unl	$\Sigma$	unkUnl	total
test-das	0.83	0.66	1.49	0.18	-
YAGS-test	3.76	13.05	16.81	6.40	25.60
MASC	12.15	33.70	45.85	24.03	33.90
TW-avg	10.40	9.68	20.08	6.31	18.96

biguation model, which has been proposed in recent work in FrameNet SRL, see e.g. Hermann et al. (2014) and Roth and Lapata (2015).

To further explore the impact of user-generated text, we applied word-processor spelling correction to YAGS and tested our systems on the corrected set. The results do not change significantly, which indicates that a) our distributed representations provide enough information to classify also noisy user-generated text, and b) frameId errors cannot be attributed to preprocessing problems at large scale.

## 6 Discussion and outlook

Our analysis in Section 4 shows that domain adaptation is mainly required for the frameId step of FrameNet SRL. Unlike in PropBank SRL, in FrameNet SRL there is no significant performance drop for roleId once correct frames are available. The number of available roles given the correct frame is lower, on average 10, which reduces the complexity of the roleId task.

In Section 5 we introduced a simple, yet efficient frame identification method and evaluated it on in-domain and out-of-domain data. The method achieves competitive in-domain results, and outperforms the best available open-source system in out-of-domain accuracy. We also observe that our system performs well in the newly introduced no-lexicon evaluation setting, where no lexicon-based filtering is applied.

We identified a major issue in the standard frameId architecture: shifting to a new domain might render the predicate-frame associations in the FrameNet lexicon incomplete, which leads to errors for a standard classifier trained on in-domain data. One could optimize a frameId system to work in the no-lexicon setting which does not rely on the lexicon knowledge at all. However, in this setting the classification results are currently lower. Manually or automatically increasing both predicate and predicate-frame association coverage of

the FrameNet lexicon could help, and we suggest investigating this line of research in future work.

While our method achieves state-of-the-art results on out-of-domain data, overall results are still significantly lower than the human performance observed for YAGS and TW, which shows that there is large room for improvement. Some further benefits could be gained from combining the WSABIE and NN-based classification, using advanced context representations, e.g. *context2vec* (Melamud et al., 2016) and incorporating syntactic information into the model. The out-of-domain performance could be further improved by adapting word representations to a new domain.

A direct comparison to the Hermann-14 system in the out-of-domain setup would shed some more light on the properties of the task affecting the out-of-domain performance. On the one hand, we expect Hermann-14 to perform worse due to its heavy reliance on syntactic information, which might decline in quality when moved to a new domain; on the other hand, the WSABIE-based classification might smoothen this effect. We make our dataset publicly available to enable comparison to related work.<sup>6</sup>

## 7 Conclusion

Domain dependence is a well-known issue for supervised NLP tasks such as FrameNet SRL. To the best of our knowledge, there is no recent study of the domain dependence of FrameNet SRL, also prohibited by a lack of appropriate datasets.

To address this problem, we 1) present the first comprehensive study of the domain generalization performance of the open-source SemaFor system on several diverse benchmark sets. As a prerequisite, we introduce YAGS, a new, substantially sized test set in the domain of user-generated question-and-answer text. We find that the major bottleneck for out-of-domain FrameNet SRL is the frame identification step; we 2) explore a promising way to improve out-of-domain frame identification, i.e. using distributed word representations. Our simple frame identification system based on distributed word representations achieves higher scores for out-of-domain frame identification than previous systems and approaches state-of-the-art results in-domain. To support reproducibility of our results, we publish the YAGS test set annotations and our frame identification system for research purposes.

## Abstract

Existing target-specific sentiment recognition methods consider only a single target per tweet, and have been shown to miss nearly half of the actual targets mentioned. We present a corpus of UK election tweets, with an average of 3.09 entities per tweet and more than one type of sentiment in half of the tweets. This requires a method for multi-target specific sentiment recognition, which we develop by using the context around a target as well as syntactic dependencies involving the target. We present results of our method on both a benchmark corpus of single targets and the multi-target election corpus, showing state-of-the-art performance in both corpora and outperforming previous approaches to multi-target sentiment task as well as deep learning models for single-target sentiment.

## 1 Introduction

Recent years have seen increasing interest in mining Twitter to assess public opinion on political affairs and controversial issues (Tumasjan et al., May 2010; Wang et al., 2012) as well as products and brands (Pak and Paroubek, 2010). Opinion mining from Twitter is usually achieved by determining the overall sentiment expressed in an entire tweet. However, inferring the sentiment towards specific targets (e.g. people or organisations) is severely limited by such an approach since a tweet may contain different types of sentiment expressed towards each of the targets mentioned. An early study by Jiang et al. (2011) showed that 40% of classification errors are caused by using tweet-level approaches that are independent of the target. Consider the tweet:

*“I will b voting 4 **Greens** ... 1st reason:  
2 remove 2 party alt. of **labour** or **conservative** every 5 years. 2nd: **fracking**”*

The overall sentiment is positive but there is a negative sentiment towards “labour”, “conservative” and “fracking” and a positive sentiment towards “Greens”. Examples like this are common in tweets discussing topics like politics. As has been demonstrated by the failure of election polls in both referenda and general elections (Burnap et al., 2016), it is important to understand not only the overall mood of the electorate, but also to distinguish and identify sentiment towards different key issues and entities, many of which are discussed on social media on the run up to elections.

Recent developments on target-specific Twitter sentiment classification have explored different ways of modelling the association between target entities and their contexts. Jiang et al. (2011) propose a rule-based approach that utilises dependency parsing and contextual tweets. Dong et al. (2014), Tang et al. (2016a) and Zhang et al. (2016) have studied the use of different recurrent neural network models for such a task but the gain in performance from the complex neural architectures is rather unclear<sup>1</sup>

In this work we introduce the multi-target-specific sentiment recognition task, building a corpus of tweets from the 2015 UK general election campaign suited to the task. In this dataset, target entities have been semi-automatically selected, and sentiment expressed towards multiple target entities as well as high-level topics in a tweet have been manually annotated. Unlike all existing studies on target-specific Twitter sentiment analysis, we move away from the assumption that

<sup>1</sup>They have yet to show a clear out-performance on a benchmarking dataset and our multi-target corpus, possibly because they usually require large amount of training data.

each tweet mentions a single target; we introduce a more realistic and challenging task of identifying sentiment towards multiple targets within a tweet. To tackle this task, we propose TDParse, a method that divides a tweet into different segments building on the approach introduced by Vo and Zhang (2015). TDParse exploits a syntactic dependency parser designed explicitly for tweets (Kong et al., 2014), and combines syntactic information for each target with its left-right context.

We evaluate and compare our proposed system both on our new multi-target UK election dataset, as well as on the benchmarking dataset for single-target dependent sentiment (Dong et al., 2014). We show a clear state-of-the-art performance of TDParse over existing approaches for tweets with multiple targets, which encourages further research on the multi-target-specific sentiment recognition task.<sup>2</sup>

## 2 Related Work: Target-dependent Sentiment Classification on Twitter

The 2015 Semeval challenge introduced a task on target-specific Twitter sentiment (Rosenthal et al., 2015) which most systems (Boag et al., 2015; Plotnikova et al., 2015) treated in the same way as tweet level sentiment. The best performing system in the 2016 Semeval Twitter challenge subtask B (Nakov et al., 2016), named Tweester, also performs on tweet level sentiment classification. This is unsurprising since tweets in both tasks only contain a single predefined target entity and as a result often a tweet-level approach is sufficient. An exception to tweet level approaches for this task, showing promise, is Townsend et al. (2015), who trained a SVM classifier for tweet segmentation, then used a phrase-based sentiment classifier for assigning sentiment around the target. The Semeval aspect-based sentiment analysis task (Pontiki et al., 2015; Pateria and Choubey, 2016) aims to identify sentiment towards entity-attribute pairs in customer reviews. This differs from our goal in the following way: both the entities and attributes are limited to a predefined inventory of limited size; they are aspect categories reflected in the reviews rather than specific targets, while each review only has one target entity, e.g. a laptop or a restaurant. Also sentiment classification in formal text such as product reviews

is very different from that in tweets. Recently Vargas et al. (2016) analysed the differences between the overall and target-dependent sentiment of tweets for three events containing 30 targets, showing many significant differences between the corresponding overall and target-dependent sentiment labels, thus confirming that these are distinct tasks.

Early work tackling target-dependent sentiment in tweets (Jiang et al., 2011) designed target-dependent features manually, relying on the syntactic parse tree and a set of grammar-based rules, and incorporating the sentiment labels of related tweets to improve the classification performance. Recent work (Dong et al., 2014) used recursive neural networks and adaptively chose composition functions to combine child feature vectors according to their dependency type, to reflect sentiment signal propagation to the target. Their data-driven composition selection approach relies on the dependency types as features and a small set of rules for constructing target-dependent trees. Their manually annotated dataset contains only one target per tweet and has since been used for benchmarking by several subsequent studies (Vo and Zhang, 2015; Tang et al., 2016a; Zhang et al., 2016). Vo and Zhang (2015) exploit the left and right context around a target in a tweet and combine low-dimensional embedding features from both contexts and the full tweet using a number of different pooling functions. Despite not fully capturing semantic and syntactic information given the target entity, they show a much better performance than Dong et al. (2014), indicating useful signals in relation to the target can be drawn from such context representation. Both Tang et al. (2016a) and Zhang et al. (2016) adopt and integrate left-right target-dependent context into their recurrent neural network (RNN) respectively. While Tang et al (2016a) propose two long short-term memory (LSTM) models showing competitive performance to Vo and Zhang (2015), Zhang et al (2016) design a gated neural network layer between the left and right context in a deep neural network structure but require a combination of three corpora for training and evaluation. Results show that conventional neural network models like LSTM are incapable of explicitly capturing important context information of a target (Tang et al., 2016b). Tang et al. (2016a) also experiment with adding attention layers for LSTM but

<sup>2</sup>The data and code can be found at <https://goo.gl/S2T1GO>

fail to achieve competitive results possibly due to the small training corpus.

Going beyond the existing work we study the more challenging task of classifying sentiment towards multiple target entities within a tweet. Using the syntactic information drawn from tweet-specific parsing, in conjunction with the left-right contexts, we show the state-of-the-art performance in both single and multi-target classification tasks. We also show that the tweet level approach that many sentiment systems adopted in both Semeval challenges, fail to capture all target-sentiments in a multi-target scenario (Section 5.1).

### 3 Creating a Corpus for Target Specific Sentiment in Twitter

We describe the design, collection and annotation of a corpus of tweets about the 2015 UK election.

#### 3.1 Data Harvesting and Entity Recognition

We collected a corpus of tweets about the UK elections, as we wanted to select a political event that would trigger discussions on multiple entities and topics. Collection was performed through Twitter’s streaming API and tracking 14 hashtags<sup>3</sup>. Data harvesting was performed between 7th February and 30th March 2015. This led to the collection of 712k tweets, from which a subset was sampled for manual annotation of target-specific sentiment. We also created a list of 438 topic keywords relevant to 9 popular election issues<sup>4</sup> for data sampling. The initial list of 438 seed words provided by a team of journalists was augmented by searching for similar words within a vector space on the basis of cosine similarity. Keywords are used both in order to identify thematically relevant tweets and also targets. We also consider named entities as targets.

Sampling of tweets was performed by removing retweets and making sure each tweet contained at least one topic keyword from one of the 9 election issues, leading to 52,190 highly relevant tweets. For the latter we ranked tweets based on a “similarity” relation, where “similarity” is measured as a function of content overlap (Mihalcea, 2004). Formally, given a tweet  $S_i$  being represented by

<sup>3</sup>#ukelection2015, #ge2015, #ukge2015, #ukgeneralelection2015, #bbcqt, #bbcsp, #bbcdp, #marrshow, #generalelection2015, #ge15, #generalelection, #electionuk, #ukelection and #electionuk2015

<sup>4</sup>EU and immigration, economy, NHS, education, crime, housing, defense, public spending, environment and energy

the set of  $N$  words that appear in the tweet:  $S_i = W_i^1, W_i^2, \dots, W_i^N$  and our list of curated topic keywords  $T$ , the ranking function is defined as:

$$\log(|S_i|) * |W_i \in S_i \cap W_i \in T| \quad (1)$$

where  $|S_i|$  is the total number of words in the tweet; unlike Mihalcea (2004) we prefer longer tweets. We used exact matching with flexibility on the special characters at either end. TF-IDF normalisation and cosine similarity were then applied to the dataset to remove very similar tweets (empirically we set the cosine similarity threshold to 0.6). We also collected all external URLs mentioned in our dataset and their web content throughout the data harvesting period, filtering out tweets that only contain an external link or snippets of a web page. Finally we sampled 4,500 top-ranked tweets keeping the representation of tweets mentioning each election issue proportionate to the original dataset.

For annotation we considered sentiment towards two types of targets: entities and topic keywords. Entities were processed in two ways: firstly, named entities (people, locations, and organisations) were automatically annotated by combining the output of Stanford Named Entity Recognition (NER) (Finkel et al., 2005), NLTK NER (Bird, 2006) and a Twitter-specific NER (Ritter et al., 2011). All three were combined for a more complete coverage of entities mentioned in tweets and subsequently corrected by removing wrongly marked entities through manual annotation. Secondly, to make sure we covered all key entities in the tweets, we also matched tweets against a manually curated list of 7 political-party names and added users mentioned therein as entities. The second type of targets matched the topic keywords from our curated list.

#### 3.2 Manual Annotation of Target Specific Sentiment

We developed a tool for manual annotation of sentiment towards the targets (i.e. entities and topic keywords) mentioned in each tweet. The annotation was performed by nine PhD-level journalism students, each of them annotating approximately a ninth of the dataset, i.e. 500 tweets. Additionally, they annotated a common subset of 500 tweets consist of 2,197 target entities, which was used to measure inter-annotator agreement (IAA). An-

## Annotation of Target-Specific Tweet Sentiment

The screenshot shows a web-based annotation tool. At the top, there is a tab labeled 'Entities'. Below it, the text 'Sentiment of the tweet towards the highlighted keyword(s):' is displayed. The main content area shows a tweet snippet: 'Ah so I compiled an analysis article on the lack of **defence** in #GE2015 and then **Ed Balls** drops this on me today. Cheers **Ed**'. Each highlighted keyword is followed by three sentiment icons: a smiley face (positive), a neutral face (neutral), and a sad face (negative), along with an 'X' icon for 'does not apply'. Below the tweet, there are three input fields labeled 'Additional entity #1:', 'Additional entity #2:', and 'Additional entity #3:'. Each field has a text input area and a set of the same sentiment and 'X' icons for selection.

Figure 1: Annotation tool for human annotation of target specific sentiment analysis

notators were shown detailed guidelines<sup>5</sup> before taking up the task, after which they were redirected to the annotation tool itself (see Figure 1).

Tweets were shown to annotators one by one, and they had to complete the annotation of all targets in a tweet to proceed. The tool shows a tweet with the targets highlighted in bold. Possible annotation actions consisted in: (1) marking the sentiment for a target as being positive, negative, or neutral, (2) marking a target as being mistakenly highlighted (i.e. ‘doesnotapply’) and hence removing it, and (3) highlighting new targets that our preprocessing step had missed, and associating a sentiment value with them. In this way we obtained a corrected list of targets for each tweet, each with an associated sentiment value.

We measure inter-annotator agreement in two different ways. On the one hand, annotators achieved  $\kappa = 0.345$  ( $z = 92.2, p < 0.0001$ ) (fair agreement)<sup>6</sup> when choosing targets to be added or removed. On the other hand, they achieved a similar score of  $\kappa = 0.341$  ( $z = 77.7, p < 0.0001$ ) (fair agreement) when annotating the sentiment of the resulting targets. It is worth noting that the sentiment annotation for each target also involves choosing among not only positive/negative/neutral but also a fourth category ‘doesnotapply’. The resulting dataset contains 4,077 tweets, with an average of 3.09 entity mentions (targets) per tweet. As many as 3,713 tweets have more than a single entity mention (target) per tweet, which makes the task different from 2015 Semeval 10 subtask C (Rosenthal et al., 2015) and a target-dependent benchmarking dataset of Dong et al. (2014) where each tweet has only one target annotated and thus

one sentiment label assigned. The number of targets in the 4,077 tweets to be annotated originally amounted to 12,874. However, the annotators un-highlighted 975 of them, and added 688 new ones, so that the final number of targets in the dataset is 12,587. These are distributed as follows: 1,865 are positive, 4,707 are neutral, and 6,015 are negative. This distribution shows the tendency of a theme like politics, where users tend to have more negative opinions. This is different from the Semeval dataset, which has a majority of neutral sentiment. Looking at the annotations provided for different targets within each tweet, we observe that 2,051 tweets (50.3%) have all their targets consistently annotated with a single sentiment value, 1,753 tweets (43.0%) have two different sentiments, and 273 tweets (6.7%) have three different sentiment values. These statistics suggest that providing a single sentiment for the entire tweet would not be appropriate in nearly half of the cases confirming earlier observations (Jiang et al., 2011).

We also labelled each tweet containing one or more topics from the 9 election issues, and asked the annotators to mark the author’s sentiment towards the topic. Unlike entities, topics may not be directly present in tweets. We compare topic sentiment with target/entity sentiment for 3963 tweets from our dataset adopting the approach by Vargas et al. (2016). Table 1 reports the individual  $c(s_{target})$ ,  $c(s_{topic})$  and joint  $c(s_{target}, s_{topic})$  distributions of the target/entity  $s_{target}$  and topic  $s_{topic}$  sentiment. While  $s_{target}$  and  $s_{topic}$  report how often each sentiment category occurs in the dataset, the joint distribution  $c(s_{target}, s_{topic})$  (the inner portions of the table) shows the discrepancies between target and topic sentiments. We observe marked differences between the two sentiment labels. For example it shows the topic sentiment is more neutral (1438.7 vs. 1104.1) and less negative (1930.7 vs. 2285.5) than the target sen-

<sup>5</sup>This guidelines can be found along with our released corpus: <https://goo.gl/CjuHzd>

<sup>6</sup>We report the strength of agreement using the benchmarks by Landis and Koch (1977) for interpreting Fleiss’ kappa.

timent. There is also a number of tweets expressing neutrality towards the topics mentioned but polarised sentiment towards targets (i.e. we observe  $c(s_{topic} = neu \cap s_{targets} = neg) = 258.6$  also  $c(s_{topic} = neu \cap s_{targets} = pos) = 101.4$ ), and vice versa. This emphasises the importance of distinguishing target entity sentiment not only on the basis of overall tweet sentiment but also in terms of sentiment towards a topic.

$c(s_{target}, s_{topic})$		$s_{topic}$			$c(s_{topic})$
		negative	neutral	positive	
$s_{target}$	negative	<b>1553.9</b>	258.6	118.3	1930.9
	neutral	557.6	<b>744.1</b>	137.0	1438.7
	positive	174.0	101.4	<b>318.1</b>	593.5

## 4 Developing a state-of-the-art approach for target-specific sentiment

### 4.1 Model development for single-target benchmarking data

Firstly we adopt the context-based approach by Vo and Zhang (2015), which divides each tweet into three parts (left context, target and right context), and where the sentiment towards a target entity results from the interaction between its left and right contexts. Such sentiment signal is drawn by mapping all the words in each context into low-dimensional vectors (i.e. word embeddings), using pre-trained embedding resources, and applying neural pooling functions to extract useful features. Such context set-up does not fully capture the syntactic information of the tweet and the given target entity, and by adding features from the full tweet (as done by Vo and Zhang (2015)) interactions between the left and right context are only implicitly modeled. Here we use a syntactic dependency parser designed explicitly for tweets (Kong et al., 2014) to find the syntactically connected parts of the tweet to each target. We then extract word embedding features from these syntactically dependent tokens  $[D_1, \dots, D_n]$  along its dependency path in the parsing tree to the target<sup>7</sup>, as well as from the left-target-right contexts (i.e.  $L - T - R$ ). Feature vectors generated from different contexts are concatenated into a final feature

<sup>7</sup>Empirically the proximity/location of such syntactic relations have not made much difference when used in feature weighting and is thus ignored.

vector as shown in (2), where  $P(X)$  presents a list of  $k$  different pooling functions on an embedding matrix  $X$ . Not only does this proposed framework make the learning process efficient without labor intensive manual feature engineering and heavy architecture engineering for neural models, it has also shown that complex syntactic and semantic information can be effectively drawn by simply concatenating different types of context together without the use of deep learning (other than pre-trained word embeddings).

$$F = [P(D), P(L), P(T), P(R)]; \quad (2)$$

with  $P(X) = [f_1(X), \dots, f_k(X)]$

**Data set:** We evaluate and compare our proposed system to the state-of-the-art baselines on a benchmarking corpus (Dong et al., 2014) that has been used by several previous studies (Vo and Zhang, 2015; Tang et al., 2016a; Zhang et al., 2016). This corpus contains 6248 training tweets and 692 testing tweets with a sentiment class balance of 25% negative, 50% neutral and 25% positive. Although the original corpus has only annotated one target per tweet, without specifying the location of the target, we expand this notion to consider cases where the target entity may appear more than once at different locations in the tweet, e.g.:

*“Nicki Minaj has brought back the female rapper. - really? Nicki Minaj is the biggest parody in popular music since the Lonely Island.”*

Semantically it is more appropriate and meaningful to consider both target appearances when determining the sentiment polarity of “Nicki Minaj” expressed in this tweet. While it isn’t clear if Dong et al. (2014) and Tang et al. (2016a) have considered this realistic **same-target-multi-appearance scenario**, Vo et al. (2015) and Zhang et al. (2016) do not take it into account when extracting target-dependent contexts. Contrary to these studies we extend our system to fully incorporate the situation where a target appears multiple times at different locations in the tweet. We add another pooling layer in (2) where we apply a *medium* pooling function to combine extracted feature vectors from each target appearance together into the final feature vector for the sentiment classification of such targets. Now the feature extraction function  $P(X)$  in (2) becomes:

$$P(X) = [P_{medium}([f_1(X_1), \dots, f_1(X_m)]), \dots \dots], \quad (3)$$

$$P_{medium}([f_k(X_1), \dots, f_k(X_m)])]$$

where  $m$  is the number of appearances of the target and  $P_{medium}$  represents the dimension-wise *medium* pooling function.

**Models:** To investigate different ways of modelling target-specific context and evaluate the benefit of incorporating the same-target-multi-appearance scenario, we build these models:

- **Semeval-best:** is a tweet-level model using various types of features, namely ngrams, lexica and word embeddings with extensive data pre-processing and feature engineering. We use this model as a target-independent baseline as it approximates and beats the best performing system (Boag et al., 2015) in Semeval 2015 task 10. It also outperforms the highest ranking system, Tweester, on the Semeval 2016 corpus (by +4.0% in macro-averaged recall) and therefore constitutes a state-of-the-art tweet level baseline.
- **Naive-seg models:** **Naive-seg-** slices each tweet into a sequence of sub-sentences by using punctuation (i.e. ‘,’ ‘.’ ‘?’ ‘!’). Embedding features are extracted from each sub-sentence and pooling functions are applied to combine word vectors. **Naive-seg** extends it by adding features extracted from the left-target-right contexts, while **Naive-seg+** extends Naive-seg by adding lexicon filtered sentiment features.
- **TDParse models:** as described in Section 4.1. **TDParse-** uses a dependency parser to extract a syntactic parse tree to the target and map all child nodes to low-dimensional vectors. Final feature vectors for each target are generated using neural pooling functions. While **TDParse** extends it by adding features extracted from the left-target-right contexts, **TDParse+** uses three sentiment lexica for filtering words. **TDParse+ (m)** differs from **TDParse+** by taking into account the ‘same-target-multi-appearance’ scenario. Both **TDParse+** and **TDParse+ (m)** outperform state-of-the-art target-specific models.
- **TDPWindow-N:** the same as **TDParse+** with a window to constrain the left-right context.

For example if  $N = 3$  then we only consider 3 tokens on each side of the target when extracting features from the left-right context.

## 4.2 Experimental Settings

To compare our proposed models with Vo & Zhang (2015), we have used the same pre-trained embedding resources and pooling functions (i.e. *max*, *min*, *mean*, *standard deviation* and *product*). For classification we have used LIBLINEAR (Fan et al., 2008), which approximates a linear SVM. In tuning the cost factor  $C$  we perform five-fold cross validation on the training data over the same set of parameter values for both Vo and Zhang (2015)’s implementation and our system. This makes sure our proposed models are comparable with those of Vo and Zhang (2015).

**Evaluation metrics:** We follow previous work on target-dependent Twitter sentiment classification, and report our performance in accuracy, 3-class macro-averaged (i.e. negative, neutral and positive)  $F_1$  score as well as 2-class macro-averaged (i.e. negative and positive)  $F_1$  score<sup>8</sup>, as used by the Semeval competitions (Rosenthal et al., 2015) for measuring Twitter sentiment classification performance.

## 4.3 Experimental results and comparison with other baselines

We report our experimental results in **Table 2** on the single-target benchmarking corpus (Dong et al., 2014), with three model categories: 1) tweet-level target-independent models, 2) target-dependent models without considering the ‘same-target-multi-appearance’ scenario and 3) target-dependent models incorporating the ‘same-target-multi-appearance’ scenario. We include the models presented in the previous section as well as models for target specific sentiment from the literature where possible.

Among the target-independent baseline models **Target-ind** (Vo and Zhang, 2015) and **Semeval-best** have shown strong performance compared with **SSWE** (Tang et al., 2014) and **SVM-ind** (Jiang et al., 2011) as they use more features, especially rich automatic features using the embeddings of Mikolov et al. (2013). Interestingly they also perform better than some of the target-dependent baseline systems, namely **SVM-dep**

<sup>8</sup>Note that this isn’t a binary classification task; the  $F_1$  score is still effected by the neutral tweets.

(Jiang et al., 2011), **Recursive NN** and **AdaRNN** (Dong et al., 2014), showing the difficulty of fully extracting and incorporating target information in tweets. Basic **LSTM** models (Tang et al., 2016a) completely ignore such target information and as a result do not perform as well.

Among the target-dependent systems neural network baselines have shown varying results. The adaptive recursive neural network, namely **AdaRNN** (Dong et al., 2014), adaptively selects composition functions based on the input data and thus performs better than a standard recursive neural network model (**Recursive NN** (Dong et al., 2014)). **TD-LSTM** and **TC-LSTM** from Tang et al. (2016a) model left-target-right contexts using two LSTM neural networks and by doing so incorporate target-dependent information. **TD-LSTM** uses two LSTM neural networks for modeling the left and right contexts respectively. **TC-LSTM** differs from (and outperforms) **TD-LSTM** in that it concatenates target word vectors with embedding vectors of each context word. We also test the Gated recurrent neural network models proposed by Zhang et al. (2016) on the same dataset. The gated models include: **GRNN**, that includes gates in its recurrent hidden layers, **G3** that connects left-right context using a gated NN structure, and a combination of the two - **GRNN+G3**. Results show these gated neural network models do not achieve state-of-the-art performance. When we compare our target-dependent model **TDParse+**, which incorporates target-dependent features from syntactic parses, against the target-dependent models proposed by Vo and Zhang (2015), namely **Target-dep** which combines full tweet (pooled) word embedding features with features extracted from left-target-right contexts and **Target-dep+** that adds target-dependent sentiment features on top of **Target-dep**, we see that our method beats both of these, without using full tweet features<sup>9</sup>. **TDParse+** also outperforms the state-of-the-art **TC-LSTM**.

When considering the ‘same-target-multi-appearance’ scenario, our best model - **TDParse+ (m)** in Table 2). Even though **TDParse** doesn’t use lexica, it shows competitive results to **Target-dep+** which uses lexicon filtered sen-

<sup>9</sup>Note that the results reported in Vo and Zhang (2015) (71.1 in accuracy and 69.9 in  $F_1$ ) were not possible to reproduce by running their code with very fine parameter tuning, as suggested by the authors

Model	Accuracy	3 Class $F_1$	2 Class $F_1$
SSWE	62.4	60.5

TDPWindow-12	70.5	67.9	63.8

Table 2: Performance comparison on the benchmarking data (Dong et al., 2014)

timent features. In the case of **TDParse-**, which uses exclusively features from syntactic parses, while it performs significantly worse than **Target-ind**, that uses only full tweet features, when the former is used in conjunction with features from left-target-right contexts it achieves better results than the equivalent **Target-dep** and **Target-dep+**. This indicates that syntactic target information derived from parses complements well with the left-target-right context representation. Clausal segmentation of tweets or sentences can provide a simple approximation to parse-tree based models (Li et al., 2015). In Table 2 we can see our naive tweet segmentation models **Naive-seg** and **Naive-seg+** also achieve competitive performance suggesting to some extent that such simple parse-tree approximation preserves the semantic structure of text and that useful target-specific information can be drawn from each segment or clause rather than the entire tweet.

## 5 Evaluating Baselines for target-specific sentiment in a multi-target setting

We perform multi-target-specific sentiment classification on our election dataset by extending

and applying our models described in Section 4.1. We compare the results with our other developed baseline models in Section 4.1, including a tweet-level model **Semeval-best** and clausal-segmentation models that provide simple parse-tree approximation, as well as state-of-the-art target-dependent models by Vo and Zhang (2015) and Zhang et al. (2016). The experimentation setup is the same as described in Section 4.2<sup>10</sup>.

**Data set:** Our election data has a training/testing ratio of 3.70, containing 3210 training tweets with 9912 target entities and 867 testing tweets with 2675 target entities.

**Models:** In order to limit our use of external resources we do not include **Naive-seg+** and **TD-Parse+** for evaluation as they both use lexica for feature generation. Since most of our tweets here contain  $N > 1$  targets and the target-independent classifiers produce a single output per tweet, we evaluate its result  $N$  times against the ground truth labels, to make different models comparable.

**Results:** Overall the models perform much poorer than for the single-target benchmarking corpus, especially in 2-class  $F_1$  score, indicating the challenge of the multi-target-specific sentiment recognition. As seen in Table 3 though the feature-rich tweet-level model **Semeval-best** gives a reasonably strong baseline performance (same as in Table 2), both it and **Target-ind** perform worse than the target-dependent baseline models **Target-dep/Target-dep+** (Vo and Zhang, 2015), indicating the need to capture and utilise target-dependent signals in the sentiment classification model. The Gated neural network models - **G3/GRNN/GRNN+G3** (Zhang et al., 2016) also perform worse than **Target-dep+** while the combined model - **GRNN+G3** fails to boost performance, presumably due to the small corpus size.

Our final model **TDParse** achieves the best performance especially in 3-class  $F_1$  and 2-class  $F_1$  scores in comparison with other target-dependent and target-independent models. This indicates that our proposed models can provide better and more balanced performance between precision and recall. It also shows the target-dependent syntactic information acquired from parse-trees is beneficial to determine the target’s sentiment particularly when used in conjunction with the left-

<sup>10</sup>Class weight parameter is not optimised for all experiments, though better performances can be achieved here by tuning the class weight due to the class imbalance nature of this dataset.

Model	Accuracy	3 Class $F_1$	2 Class $F_1$
Semeval-best	54.09	42.60	40.73
Target-ind	52.30	42.19	40.50

S3	Semeval-best	Target-dep+	TDParse
Macro 3-class- $F_1$	35.08	42.83	51.26
Micro 3-class- $F_1$	38.16	46.05	53.07
Macro 2-class- $F_1$	35.17	40.53	50.14

Table 4: Performance analysis in S1, S2 and S3

target-right contexts originally proposed by Vo and Zhang (2015) and in a scenario of multiple targets per tweet. Our clausal-segmentation baseline - **Naive-seg** models approximate such parse-trees by identifying segments of the tweet relevant to the target, and as a result **Naive-seg** achieves competitive performance compared to other baselines.

### 5.1 State-of-the-art tweet level sentiment vs target-specific sentiment in a multi-target setting

To fully compare our multi-target-specific models against other target-dependent and target-independent baseline methods, we conduct an additional experiment by dividing our election data test set into three disjoint subsets, on the basis of number of distinct target sentiment values per tweet: (**S1**) contains tweets having only one target sentiment, where the sentiment towards each target is the same; (**S2**) and (**S3**) contain two and three different types of targeted sentiment respec-

<sup>11</sup>Any further results will be shared on our Github page: <https://goo.gl/S2T1GO>

tively (i.e. in **S3**, positive, neutral and negative sentiment are all expressed in each tweet). As described in Section 3.2, there are 2,051, 1,753 and 273 tweets in **S1**, **S2** and **S3** respectively.

Table 4 shows results achieved by the tweet-level target-independent model - **Semeval-best**, the state-of-the-art target-dependent baseline model - **Target-dep+**, and our proposed final model - **TDParse**, in each of the three subsets. We observe **Semeval-best** performs the best in **S1** compared to the two other models but its performance gets worse when different types of target sentiment are mentioned in the tweet. It has the worst performance in **S2** and **S3**, which again emphasises the need for multi-target-specific sentiment classification. Finally, our proposed final model **TDParse** achieves better performance than **Target-dep+** consistently over all subsets indicating its effectiveness even in the most difficult scenario **S3**.

## 6 Conclusion and Future work

In this work we introduce the challenging task of multi-target-specific sentiment classification for tweets. To help the study we have generated a multi-target Twitter corpus on UK elections which will be made publicly available. We develop a state-of-the-art approach which utilises the syntactic information from parse-tree in conjunction with the left-right context of the target. Our method outperforms previous approaches on a benchmarking single-target corpus as well as our new multi-target election data. Future work could investigate sentiment connections among all targets appearing in the same tweet as a multi-target learning task, as well as a hybrid approach that applies either Semeval-best or TDParse depending on the number of targets detected in the tweet.

## Acknowledgments

We would like to thank Duy-Tin Vo, Meishan Zhang and Duyu Tang for sharing their implementation code respectively, which we have used for system performance comparison. We would also like to thank Li Dong for sharing their data, and City University London for recruiting PhD students for the annotation of our election corpus.

## Abstract

We propose a new evaluation for automatic solvers for algebra word problems, which can identify mistakes that existing evaluations overlook. Our proposal is to evaluate such solvers using *derivations*, which reflect how an equation system was constructed from the word problem. To accomplish this, we develop an algorithm for checking the equivalence between two derivations, and show how derivation annotations can be semi-automatically added to existing datasets. To make our experiments more comprehensive, we include the derivation annotation for DRAW-1K, a new dataset containing 1000 general algebra word problems. In our experiments, we found that the annotated derivations enable a more accurate evaluation of automatic solvers than previously used metrics. We release derivation annotations for over 2300 algebra word problems for future evaluations.

## 1 Introduction

Automatically solving math reasoning problems is a long-pursued goal of AI (Newell et al., 1959; Bobrow, 1964). Recent work (Kushman et al., 2014; Shi et al., 2015; Koncel-Kedziorski et al., 2015) has focused on developing solvers for *algebra word problems*, such as the one shown in Figure 1. Developing a solver for word problems can open several new avenues, especially for online education and intelligent tutoring systems (Kang et al., 2016). In addition, as solving word problems requires the ability to understand and analyze natural language, it serves as a good test-bed for evaluating progress towards goals of artificial intelligence (Clark and Etzioni, 2016).

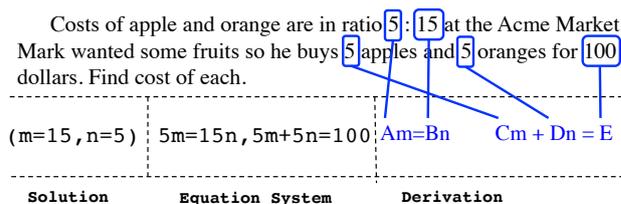

Figure 1: An algebra word problem with its *solution*, *equation system* and *derivation*. Evaluating solvers on derivation is more reliable than evaluating on solution or equation system, as it reveals errors that other metric overlook.

An automatic solver finds the solution of a given word problem by constructing a *derivation*, consisting of an un-grounded equation system<sup>1</sup> ( $\{A_m = B_n, C_m + D_n = E\}$  in Figure 1) and *alignments* of numbers in the text to its coefficients (blue edges). The derivation identifies a grounded equation system  $\{5m = 15n, 5m + 5n = 100\}$ , whose *solution* can then be generated to answer the problem. A derivation precisely describes *how* the grounded equation system was constructed from the word problem by the automatic solver. On the other hand, the grounded equation systems and the solutions are less informative, as they do not explain which span of text aligns to the coefficients in the equations.

While the derivation is clearly the most informative structure, surprisingly, no prior work evaluates automatic solvers using derivations directly. To the best of our knowledge, none of the current datasets contain human-annotated derivations, possibly due to the belief that the current evaluation metrics are sufficient and the benefit of evaluating on derivations is minor. Currently, the most popular evaluation strategy is to use *solution accuracy* (Kushman et al., 2014; Hosseini et al., 2014; Shi et al., 2015; Koncel-Kedziorski et

<sup>1</sup>Also referred to as a *template*. We use these two terms interchangeably.

al., 2015; Zhou et al., 2015; Huang et al., 2016), which computes whether the solution was correct or not, as this is an easy-to-implement metric. Another evaluation strategy was proposed in (Kushman et al., 2014), which finds an approximate derivation from the gold equation system and uses it to compare against a predicted derivation. We follow (Kushman et al., 2014) and call this evaluation strategy the *equation accuracy*.<sup>2</sup>

In this work, we argue that evaluating solvers against human labeled derivation is important. Existing evaluation metrics, like solution accuracy are often quite generous — for example, an incorrect equation system, such as,

$$\{m + 5 = n + 15, \quad m + n = 15 + 5\}, \quad (1)$$

can generate the correct solution of the word problem in Figure 1. While equation accuracy appears to be a stricter metric than solution accuracy, our experiments show that the approximation can mislead evaluation, by assigning higher scores to an inferior solver. Indeed, a correct equation system,  $(5m = 15n, 5m + 5n = 100)$ , can be generated by using a wrong template,  $Am = Bn, Am + An = C$ , and aligning numbers in the text to coefficients incorrectly. We show that without knowing the correct derivation at evaluation time, a solver can be awarded for the wrong reasons.

The lack of annotated derivations for word problems and no clear definition for comparing derivations present technical difficulties in using derivation for evaluation. In this paper, we address these difficulties and for the first time propose to evaluate the solvers using *derivation accuracy*. To summarize, the contributions of this paper are:

- We point out that evaluating using derivations is more precise compared to existing metrics. Moreover, contrary to popular belief, there is a meaningful gap between the derivation accuracy and existing metrics, as it can discover crucial errors not captured previously.
- We formally define when two derivations are equivalent, and develop an algorithm that can determine the same. The algorithm is simple

<sup>2</sup>Note that an approximation of the derivation is necessary, as there is no annotated derivation. From the brief description in their paper and the code released by Kushman et al. (2014), we found that their implementation assumes that the first derivation that matches the equations and generates the correct solution is the correct reference derivation against which predicted derivations are then evaluated.

Word Problem	$x$	We are mixing a solution of 32% sodium and another solution of 12% sodium. How many liters of 32% and 12% solution will produce 50 liters of a 20% sodium solution?

to implement, and can accurately detect the equivalence even if two derivations have very different syntactic forms.

- We annotated over 2300 word algebra problems<sup>3</sup> with detailed derivation annotations, providing high quality labeled semantic parses for evaluating word problems.

## 2 Evaluating Derivations

We describe our notation and revisit the notion of derivation introduced in (Kushman et al., 2014). We then formalize the notion of derivation equivalence and provide an algorithm to determine it.

**Structure of Derivation** The word problem in Table 1 shows our notation, where our proposed annotations are shown in **bold**. We denote a word problem by  $x$  and an *equation system* by  $y$ .

An un-grounded equation system (or *template*)  $T$  is a family of equation systems parameterized by a set of coefficients  $\mathcal{C}(T) = \{c_i\}_{i=1}^k$ , where each coefficient  $c_i$  aligns to a *textual number* (e.g., *four*) in the word problem. We also refer to the coefficients as *slots* of the template. We use  $(A, B, C, \dots)$  to represent coefficients and  $(m, n, \dots)$  to represent the unknown variables in the templates.

Let  $\mathcal{Q}(x)$  be the set of all the textual numbers in the problem  $x$ , and  $\mathcal{C}(T)$  be the coefficients to be determined in the template  $T$ . An *alignment* is a set of tuples  $A = \{(q, c) \mid q \in \mathcal{Q}(x), c \in \mathcal{C}(T) \cup \{\epsilon\}\}$  aligning textual numbers to coefficient slots,

<sup>3</sup>available at <https://aka.ms/datadraw>

where a tuple  $(q, \epsilon)$  indicates that the number  $q$  is not relevant to the final equation system.

Note that there may be multiple semantically equivalent textual numbers. e.g., in Figure 1, either of the 32 can be aligned to coefficient slot A in the template. These equivalent textual numbers are marked in the `EquivTNum` field in the annotation. If two textual numbers  $q, q' \in \text{EquivTNum}$ , then we can align a coefficient slot to either  $q$  or  $q'$ , and generate a equivalent alignment.

An alignment  $A$  and a template  $T$  together identify a *derivation*  $z = (T, A)$  of an equation system. Note that there may be multiple valid derivations, using one of the equivalent alignments. We assume there exists a routine `Solve(y)` that find the solution of an equation system. We use a Gaussian elimination solver for our `Solve` routine. We use hand-written rules and the quantity normalizer in Stanford CoreNLP (Manning et al., 2014) to identify textual numbers.

**Derivation Equivalence** We define two derivations  $(T_1, A_1)$  and  $(T_2, A_2)$  to be equivalent *iff* the corresponding templates  $T_1, T_2$  and alignments  $A_1, A_2$  are equivalent.

Intuitively, two templates  $T_1, T_2$  are equivalent if they can generate the same space of equation systems – i.e., for every assignment of values to slots of  $T_1$ , there exists an assignment of values to slots of  $T_2$  such that they generate the same equation systems. For instance, template (2) and (3) below are equivalent

$$m = A + Bn \quad m = C - n \quad (2)$$

$$m + n = A \quad m - Cn = B. \quad (3)$$

because after renaming  $(A, B, C)$  to  $(B, C, A)$  respectively in template (2), and algebraic manipulations, it is identical to template (3). We can see that any assignment of values to *corresponding* slots will result in the same equation system.

Similarly, two alignments  $A_1$  and  $A_2$  are equivalent if corresponding slots from each template align to the same textual number. For the above example, the alignment  $\{1 \rightarrow A, 3 \rightarrow B, 4 \rightarrow C\}$  in template (2), and alignment  $\{1 \rightarrow B, 3 \rightarrow C, 4 \rightarrow A\}$  in template (3) are equivalent. Note that the alignment  $\{1 \rightarrow A, 3 \rightarrow B, 4 \rightarrow C\}$  for (2) is not equivalent to  $\{1 \rightarrow A, 3 \rightarrow B, 4 \rightarrow C\}$  in (3), because it does not respect variable renaming. Our definition also allows two alignments to be

equivalent, if they use textual numbers in equivalent positions for corresponding slots (as described by `EquivTNum` field).

In the following, we carefully explain how template and alignment equivalence are determined algorithmically. Algorithm 1 shows the complete algorithm for comparing two derivations.

**Template Equivalence** We propose an approximate procedure `TEMPLEQUIV` (line 13) that detects equivalence between two templates. The procedure relies on the fact that under appropriate renaming of coefficients, two equivalent templates will generate equations which have the same solutions, for all possible coefficient assignments.

For two templates  $T_1$  and  $T_2$ , with the same number of coefficients  $|\mathcal{C}(T_1)| = |\mathcal{C}(T_2)|$ , we represent a choice of renaming coefficients by  $\gamma$ , a

1-to-1 mapping from  $\mathcal{C}(T_1)$  to  $\mathcal{C}(T_2)$ . The two templates are equivalent if there exists a  $\gamma$  such that solutions of the equations identified by  $T_1$  and  $T_2$  are same, for all possible coefficient assignments. The `TEMPLEQUIV` procedure exhaustively tries all possible renaming of coefficients (line 16), checking if the solutions of the equation systems generated from a random assignment (line 19) match exactly. It declares equivalence if for a renaming  $\gamma$ , the solutions match for  $R = 10$  such random assignments.<sup>4</sup> The procedure returns all renamings  $\Gamma$  of coefficients between two templates under which they are equivalent (line 27). We discuss its effectiveness in §3.

**Alignment Equivalence** The `TEMPLEQUIV` procedure returns every mapping  $\gamma$  in  $\Gamma$  under which the templates were equivalent (line 4). Recall that  $\gamma$  identifies corresponding slots,  $c$  and  $\gamma(c)$ , in  $T_1$  and  $T_2$  respectively. We describe alignment equivalence using these mappings.

Two alignments  $A_1$  and  $A_2$  are equivalent if corresponding slots (according to  $\gamma$ ) align to the same textual number. More formally, if we find a mapping  $\gamma$  such that for each tuple  $(q, c)$  in  $A_1$  there is  $(q, \gamma(c))$  in  $A_2$ , then the alignments are equivalent (line 33). We allow for equivalent textual numbers (as identified by `EquivTNum` field) to match when comparing tuples in alignments.

The proof of correctness of Algorithm 1 is sketched in the appendix. Using Algorithm 1, we can define *derivation accuracy*, to be 1 if the predicted derivation  $(T_p, A_p)$  and the reference derivation  $(T_g, A_g)$  are equivalent, and 0 otherwise.

**Properties of Derivation Accuracy** By comparing derivations, we can ensure that the following errors are detected by the evaluation.

Firstly, correct solutions found using incorrect equations will be penalized, as the template used will not be equivalent to reference template. Secondly, correct equation system obtained by an incorrect template will also be penalized for the same reason. Lastly, if the solver uses the correct template to get the correct equation system, but aligns the wrong number to a slot, the alignment will not be equivalent to the reference alignment, and the solver will be penalized too.

<sup>4</sup>Note that this procedure is a Monte-Carlo algorithm, and can be made more precise by increasing  $R$ . We found making  $R$  larger than 10 did not have an impact on the empirical results.

We will see some illustrative examples of above errors in §5.3. Note that the currently popular evaluation metric of solution accuracy will not detect *any* of these error types.

### 3 Annotating Derivations

As none of the existing benchmarks contain derivation annotations, we decided to augment existing datasets with these annotations. We also annotated `DRAW-1K`, a new dataset of 1000 general algebra word problems to make our study more comprehensive. Below, we describe how we reduced annotation effort by semi-automatic generated some annotations.

Annotating gold derivations from scratch for all problems is time consuming. However, not all word problems require manual annotation – sometimes all numbers appearing in the equation system can be uniquely aligned to a textual number without ambiguity. For such problems, the annotations are generated automatically.<sup>5</sup> We identify word problems which have at least one *alignment ambiguity* – multiple textual numbers with the same value, which appears in the equation system. An example of such a problem is shown in Figure 1, where there are three textual numbers with value 5, which appears in the equation system. Statistics for the number of word problems with such ambiguity is shown in Table 2.

We only ask annotators to resolve such alignment ambiguities, instead of annotating the entire derivation. If more than one alignments are genuinely correct (as in word problem of Table 1), we ask the annotators to mark both (using the `EquivTNum` field). This ensures our derivation annotations are *exhaustive* – all correct derivations are marked. With the correct alignment annotations, templates for all problems can be easily induced.

**Annotation Effort** To estimate the effort required to annotate derivations, we timed our annotators when annotating 50 word problems (all involved alignment ambiguities). As a control, we also asked annotators to annotate the entire derivation from scratch (i.e., only provided with the word problem and equations), instead of only fixing alignment ambiguities. When annotating from scratch, annotators took an average of 4 minute per word problem, while when fixing alignment ambiguities this time dropped to average of 1 minute

<sup>5</sup>Annotations for *all* problems are manually verified later.

Dataset	DRAW-1K	ALG-514	DOLPHIN-L
# problems	1000	514	832
w/ ambiguity	21%	23%	35%
vocab.	2.21k	1.83k	0.33k
Number of Templates			
before	329	30	273
after	224	24	203
% reduction	32%	20%	25%

Table 2: Statistics of the datasets. At least 20% of problems in each dataset had alignment ambiguities that required human annotations. The number of templates before and after annotation is also shown (reduction > 20%).

per word problem. We attained a inter-annotator agreement of 92% (raw percentage agreement), with most disagreements arising on EquivTNum field.<sup>6</sup>

**Reconciling Equivalent Templates** The number of templates has been used as a measure of dataset diversity (Shi et al., 2015; Huang et al., 2016), however prior work did not reconcile the equivalent templates in the dataset. Indeed, if two templates are equivalent, we can replace one with the other and still generate the correct equations. Therefore, after getting human judgements on alignments, we reconcile all the templates using TEMPLEQUIV as the final step of annotation.

TEMPLEQUIV is quite effective (despite being approximate), reducing the number of templates by at least 20% for all datasets (Table 2). We did not find any false positives generated by the TEMPLEQUIV in our manual examination. The reduction in Table 2 clearly indicates that equivalent templates are quite common in all datasets, and number of templates (and hence, dataset diversity) can be significantly overestimated without proper reconciliation.

## 4 Experimental Setup

We describe the three datasets used in our experiments. Statistics comparing the datasets is shown in Table 2. In total, our experiments involve over 2300 word problems.

**Alg-514** The dataset ALG-514 was introduced in (Kushman et al., 2014). It consists of 514 general algebra word problems ranging over a variety of narrative scenarios (distance-speed, object counting, simple interest, etc.).

<sup>6</sup>These were adjudicated on by the first author.

**Dolphin-L** DOLPHIN-L is the linear-T2 subset of the DOLPHIN dataset (Shi et al., 2015), which focuses on *number word problems* – algebra word problems which describe mathematical relationships directly in the text. All word problems in the linear-T2 subset of the DOLPHIN dataset can be solved using linear equations.

**DRAW-1K** Diverse Algebra Word (DRAW-1K), consists of 1000 word problems crawled from algebra.com. Details on the dataset creation can be found in the appendix. As ALG-514 was also crawled from algebra.com, we ensured that there is little overlap between the datasets.

We randomly split DRAW-1K into train, development and test splits with 600, 200, 200 problems respectively. We use 5-fold cross validation splits provided by the authors for DOLPHIN-L and ALG-514.

### 4.1 Evaluation

We compare derivation accuracy against the following evaluation metrics.

**Solution Accuracy** We compute solution accuracy by checking if each number in the reference solution appears in the generated solution (disregarding order), following previous work (Kushman et al., 2014; Shi et al., 2015).

**Equation Accuracy** An approximation of derivation accuracy that is similar to the one used in Kushman et al. (2014). We approximate the reference derivation  $\tilde{z}$  by randomly chosen from the (several possible) derivations which lead to the gold  $y$  from  $x$ . Derivation accuracy is computed against this (possibly incorrect) reference derivation. Note that in equation accuracy, the approximation is used instead of annotated derivation. We include the metric of equation accuracy in our evaluations to show that human annotated derivation is necessary, as approximation made by equation accuracy might be problematic.

### 4.2 Our Solver

We train a solver using a simple modeling approach inspired by Kushman et al. (2014) and Zhou et al. (2015). The solver operates as follows. Given a word problem, the solver ranks all templates seen during training,  $\Gamma_{train}$ , and selects the set of the top- $k$  (we use  $k = 10$ ) templates  $\Pi \subset \Gamma_{train}$ . Next, all possible derivations  $\mathcal{D}(\Pi)$  that use a template from  $\Pi$  are generated

Setting	Soln. Acc.	Eqn. Acc.	Deriv. Acc.
ALG-514			
TE	76.2	72.7	75.5
TD	78.4	73.9	77.8
TD - TE	2.2	1.2	<b>2.3</b>
DRAW-1K			
TE	52.0	48.0	48.0
TD	55.0	48.0	53.0
TD - TE	3.0	0	<b>5.0</b>
DOLPHIN			
TE	55.1	50.1	44.2
TD	57.5	36.8	54.9
TD - TE	2.4	-13.3	<b>10.7</b>

Table 3: TE and TD compared using different evaluation metrics. Note that while TD is clearly superior to TE due to extra supervision using the annotations, only derivation accuracy is able to correctly reflect the differences.

and scored. The equation system  $\hat{y}$  identified by highest scoring derivation  $\hat{z}$  is output as the prediction. Following (Zhou et al., 2015), we do not model the alignment of nouns phrases to variables, allowing for tractable inference when scoring the generated derivations. The solver is trained using a structured perceptron (Collins, 2002). We extract the following features for a  $(x, z)$  pair,

**Template Features.** Unigrams and bigrams of lemmas and POS tags from the word problem  $x$ , conjoined with  $|\mathcal{Q}(x)|$  and  $|\mathcal{C}(T)|$ .

**Alignment Tuple Features.** For two alignment tuples,  $(q_1, c_1), (q_2, c_2)$ , we add features indicating whether  $c_1$  and  $c_2$  belong to the same equation in the template or share the same variable. If they belong to the same sentence, we also add lemmas of the nouns and verbs between  $q_1$  and  $q_2$  in  $x$ .

**Solution Features.** Features indicating if the solution of the system identified by the derivation are integer, negative, non-negative or fractional.

## 5 Experiments

Are solution and equation accuracy equally capable as derivation accuracy at distinguishing between good and bad models? To answer this question, we train the solver under two settings such that one of the settings has clear advantage over the other, and see if the evaluation metrics reflect this advantage. The two settings are,

Setting	Soln. Acc.	Eqn. Acc.	Deriv. Acc.
DRAW-1K + Alg-514			
TE	32.5	31.5	29.5
TE*	60.5	56.0	54.0
TD	62.0	53.0	59.5
TD - TE*	1.5	-3.0	<b>5.5</b>
DRAW-1K + Dolphin			
TE	41.0	37.5	37.5
TE*	58.5	55.5	51.5
TD	60.0	53.0	58.0
TD - TE*	1.5	-2.5	<b>6.5</b>

Table 4: When combining two datasets, it is essential to reconcile templates across datasets. Here TE\* denotes training on equations after reconciling the templates, while TE simply combines datasets naively. As TE\* represents a more appropriate setting, we compare TE\* and TD in this experiment.

**TE (TRAIN ON EQUATION)** Only the  $(x, y)$  pairs are provided as supervision. Similar to (Kushman et al., 2014; Zhou et al., 2015), the solver finds a derivation which agrees with the equation system and the solution, and trains on it. Note that the derivation found by the solver may be incorrect.

**TD (TRAIN ON DERIVATION)**  $(x, z)$  pairs obtained by the derivation annotation are used as supervision. This setting trains the solver on human-labeled derivations. Clearly, the TD setting is a more informative supervision strategy than the TE setting. TD provides the correct template and correct alignment (i.e. labeled derivation) as supervision and is expected to perform better than TE, which only provides the question-equation pair.

We first present the main results comparing different evaluation metrics on solvers trained using the two settings.

### 5.1 Main Results

We compare the evaluation metrics in Table 3. We want to determine to what degree each evaluation metric reflects the superiority of TD over TE.

We note that solution accuracy always exceeds derivation accuracy, as a solver can sometimes get the right solutions even with the wrong derivation. Also, solution accuracy is not as sensitive as derivation accuracy to improvements in the solver. For instance, solution accuracy only changes by 2.4 on Dolphin-L when comparing TE and TD, whereas derivation accuracy changes

by 10.7 points. We found that the large gap on Dolphin-L was due to several alignment errors in the predicted derivations, which were detected by derivation accuracy. Recall that over 35% of the problems in Dolphin-L have alignment ambiguities (Table 2). In the TD setting, many of these errors made by our solver were corrected as the gold alignment was part of supervision.

Equation accuracy too has several limitations. For DRAW-1K, it cannot determine which solver is better and assigns them the same score. Furthermore, it often (incorrectly) considers TD to be a worse setting than TE, as evident from decrease in the scores (for instance, on DOLPHIN-L). Recall that equation accuracy attempts to approximate derivation accuracy by choosing a random derivation agreeing with the equations, which might be incorrect.

**Study with Combining Datasets** With several ongoing annotation efforts, it is a natural question to ask is whether we can leverage multiple datasets in training to generalize better. In Table 4, we combine DRAW-1K’s train split with other datasets, and test on DRAW-1K’s test split. DRAW-1K’s test split was chosen as it is the largest test split with general algebra problems (recall Dolphin-L contains only number word problems).

We found that in this setting, it was important to reconcile the templates *across* datasets. Indeed, when we simply combine the two datasets in the TE setting, we notice a sharp drop in performance (compared to Table 3). However, if we reconciled all templates and then used the new equations for training (called TE\* setting in Table 4), we were able to see improvements from training on more data. We suspect difference in annotation style led to several equivalent templates in the combined dataset, which got resolved in TE\*. Therefore, in Table 4, we compare TE\* and TD settings.<sup>7</sup>

In Table 4, a trend similar to Table 3 can be observed – solution accuracy assigns a small improvement to TD over TE\*. Derivation accuracy clearly reflects the fact that TD is superior to TE\*, with a larger improvement compared to solution accuracy (eg., 5.5 vs 1.5). Equation accuracy, as before, considers TD to be worse than TE\*.

Note that this experiment also shows that differences in annotation styles across different algebra problem datasets can lead to poor performance

<sup>7</sup>In TE\*, the model still trains only using equations, without access to derivations. So TD is still better than TE\*.

Dataset	Ours	KAZB	Best Result
ALG-514	76.2	68.7	<b>79.7</b> (ZDC)
DOLPHIN-L	55.1	37.5	46.3 <sup>‡</sup> (SWLLR)
DRAW-1K	52.0	43.2	–

Table 5: Comparison of our solver and other state-of-the-art systems, when trained under TE setting. All numbers are solution accuracy. See footnote for details on the comparison to SWLLR.

when combining these datasets naively. Our findings suggest that derivation annotation and template reconciliation are crucial for such multi-data supervision scenarios.

## 5.2 Comparing Solvers

To ensure that the results in the previous section were not an artifact of any limitations of our solver, we show here that our solver is competitive to other state-of-the-art solvers, and therefore it is reasonable to assume that similar results can be obtained with other automatic solvers.

In Table 5, we compare our solver to KAZB, the system of Kushman et al. (2014), when trained under the existing supervision paradigm, TE (i.e., training on equations) and evaluated using solution accuracy. We also report the best scores on each dataset, using ZDC and SWLLR to denote the systems of Zhou et al. (2015) and Shi et al. (2015) respectively. Note that our system and KAZB are the only systems that can process all three datasets without significant modification, with our solver being clearly superior to KAZB.

## 5.3 Case Study

We discuss some interesting examples from the datasets, to show the limitations of existing metrics, which derivation accuracy overcomes.

**Correct Solution, Incorrect Equation** In the following example from the DOLPHIN-L dataset, by choosing the correct template and the wrong alignments, the solver arrived at the correct solutions, and gets rewarded by solution accuracy.

The sum of  $2(q_1)$  numbers is  $25(q_2)$ .  $12(q_3)$   
less than  $4(q_4)$  times one( $q_5$ ) of the numbers is  
 $16(q_6)$  more than twice( $q_7$ ) the other number.  
Find the numbers.

<sup>‡</sup>SWLLR also had a solver which achieves 68.0, using over 9000 semi-automatically generated rules tailored to number word problems. We compare to their similarity based solver instead, which does not use any such rules, given that the rule-based system cannot be applied to general word problems.

Note that there are seven textual numbers ( $q_1, \dots, q_7$ ) in the word problem. We can arrive at the correct equations ( $\{m + n = 25, 4m - 2n = 16 + 12\}$ ), by the correct derivation,

$$m + n = q_2 \quad q_4m - q_7n = q_6 + q_3.$$

However, the solver found the following derivation, which produces the incorrect equations ( $\{m + n = 25, 2m - n = 2 + 12\}$ ),

$$m + n = q_2 \quad \mathbf{q_1}m - \mathbf{q_5}n = \mathbf{q_7} + q_3.$$

Both the equations have the same solutions ( $m = 13, n = 12$ ), but the second derivation is clearly using incorrect reasoning.

**Correct Equation, Incorrect Alignment** In such cases, the solver gets the right equation system, but derived it using wrong alignment. Solution accuracy still rewards the solver. Consider the problem from the DOLPHIN-L dataset,

The larger of two( $q_1$ ) numbers is  $2(q_2)$  more than  $4(q_3)$  times the smaller. Their sum is  $67(q_4)$ . Find the numbers.

The correct derivation for this problem is,

$$m - q_3n = q_2 \quad m + n = q_4.$$

However, our system generated the following derivation, which although results in the exact same equation system (and thus same solutions), is clearly incorrect due incorrect choice of "two",

$$m - q_3n = \mathbf{q_1} \quad m + n = q_4.$$

Note that derivation accuracy will penalize the solver, as the alignment is not equivalent to the reference alignment ( $q_1$  and  $q_2$  are not semantically equivalent textual numbers).

**Bad Approx. in Equation Accuracy** The following word problem is from the ALG-514 dataset:

Mrs. Martin bought  $3(q_1)$  cups of coffee and  $2(q_2)$  bagels and spent  $12.75(q_3)$  dollars. Mr. Martin bought  $2(q_4)$  cups of coffee and  $5(q_5)$  bagels and spent  $14.00(q_6)$  dollars. Find the cost of one( $q_7$ ) cup of coffee and that of one( $q_8$ ) bagel.

The correct derivation is,

$$q_1m + q_2n = q_3 \quad q_4m + q_5n = q_6.$$

However, we found that equation accuracy used the following incorrect derivation for evaluation,

$$q_1m + \mathbf{q_2}n = q_3 \quad \mathbf{q_2}m + q_5n = q_6.$$

Note while this derivation does generate the correct equation system and solutions, the derivation utilizes the wrong numbers and misunderstood the word problem. This example demonstrates the needs to evaluate the quality of the word problem solvers using the annotated derivations.

## 6 Related Work

We discuss several aspects of previous work in the literature, and how it relates to our study.

**Existing Solvers** Current solvers for this task can be divided into two broad categories based on their inference approach – *template-first* and *bottom-up*. Template-first approaches like (Kushman et al., 2014; Zhou et al., 2015) infer the derivation  $z = (T, A)$  *sequentially*. They first predict the template  $T$  and then predict alignments  $A$  from textual numbers to coefficients. In contrast, bottom-up approaches (Hosseini et al., 2014; Shi et al., 2015; Koncel-Kedziorski et al., 2015) *jointly* infer the derivation  $z = (T, A)$ . Inference proceeds by identifying parts of the template (eg.  $Am + Bn$ ) and aligning numbers to it ( $\{2 \rightarrow A, 3 \rightarrow B\}$ ). At any intermediate state during inference, we have a partial derivation, describing a fragment of the final equation system ( $2m + 3n$ ). While our experiments used a solver employing the template-first approach, it is evident that performing inference in all such solvers requires constructing a derivation  $z = (T, A)$ . Therefore, annotated derivations will be useful for evaluating *all* such solvers, and may also aid in debugging errors.

Other reconciliation procedures are also discussed (though briefly) in earlier work. Kushman et al. (2014) reconciled templates by using a symbolic solver and removing pairs with the same canonicalized form. Zhou et al. (2015) also reconciled templates, but do not describe how it was performed. We showed that reconciliation is important for correct evaluation, for reporting dataset complexity, and also when combining multiple datasets.

**Labeling Semantic Parses** Similar to our work, efforts have been made to annotate semantic parses for other tasks, although primarily for providing supervision. Prior to the works of Liang et al. (2009) and Clarke et al. (2010), semantic parsers were trained using annotated logical forms (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Wong and Mooney, 2007, *inter alia*), which were expensive to annotate. Recently, Yih et al. (2016) showed that labeled semantic parses for the knowledge based question answering task can be obtained at a cost comparable to obtaining answers. They showed significant improvements in performance of a question-answering system using the labeled parses instead of answers for training. More recently, by treating word problems as a semantic parsing task, Upadhyay et al. (2016) found that joint learning using both explicit (derivation as labeled semantic parses) and implicit supervision signals (solution as responses) can significantly outperform models trained using only one type of supervision signal.

**Other Semantic Parsing Tasks** We demonstrated that response-based evaluation, which is quite popular for most semantic parsing problems (Zelle and Mooney, 1996; Berant et al., 2013; Liang et al., 2011, *inter alia*) can overlook reasoning errors for algebra problems. A reason for this is that in algebra word problems there can be several semantic parses (i.e., derivations, both correct and incorrect) that can lead to the correct solution using the input (i.e., textual number in word problem). This is not the case for semantic parsing problems like knowledge based question answering, as correct semantic parse can often be identified given the question and the answer. For instance, paths in the knowledge base (KB), that connect the answer and the entities in the question can be interpreted as legitimate semantic parses. The KB therefore acts as a constraint which helps prune out possible semantic parses, given only the problem and the answer. However, such KB-based constraints are unavailable for algebra word problems.

## 7 Conclusion and Discussion

We proposed an algorithm for evaluating derivations for word problems. We also showed how derivation annotations can be easily obtained by only involving annotators for ambiguous cases. We augmented several existing benchmarks with

derivation annotations to facilitate future comparisons. Our experiments with multiple datasets also provided insights into the right approach to combine datasets – a natural step in future work. Our main finding indicates that derivation accuracy leads to a more accurate assessment of algebra word problem solvers, finding errors which other metrics overlook. While we should strive to build such solvers using as little supervision as possible for training, having high quality annotated data is essential for correct evaluation.

The value of such annotations for evaluation becomes more immediate for online education scenarios, where such word solvers are likely to be used. Indeed, in these cases, merely arriving at the correct solution, by using incorrect reasoning may prove detrimental for teaching purposes. We believe derivation based evaluation closely mirrors how humans are evaluated in schools (by forcing solvers to show “their work”).

Our datasets with the derivation annotations have applications beyond accurate evaluation. For instance, certain solvers, like the one in (Roy and Roth, 2015), train a *relevance classifier* to identify which textual numbers are relevant to solving the word problem. As we only annotate relevant numbers in our annotations, our datasets can provide high quality supervision for such classifiers. The datasets can also be used in evaluation test-beds, like the one proposed in (Koncel-Kedziorski et al., 2016).

We hope our datasets will open new possibilities for the community to simulate new ideas and applications for automatic problem solvers.

## A Creating DRAW-1K

We crawl over 100k problems from <http://algebra.com>. The 100k word problems include some problems which require solving non-linear equations (e.g. finding roots of quadratic equations). We filter out these problems using keyword matching. We also filter problems whose explanation do not contain a variable named “x”. This leaves us with 12k word problems.

**Extracting Equations** A word problem on [algebra.com](http://algebra.com) is accompanied by a detailed explanation provided by instructors. In our crawler, we use simple pattern matching rules to extract all the equations in the explanation. The problems often have sentences which are irrelevant to solving the word problem (e.g. “Please help me, I am stuck.”). During cleaning, the annotator removes such sentences from the final word problem and performs some minor editing if necessary.<sup>8</sup>

1000 problems were randomly chosen from these pool of 12k problems, which were then shown to annotators as described earlier to get the derivation annotations.

## B Proof of Correctness (Sketch)

For simplicity, we will assume that `EquivTNum` is empty. The proof can easily be extended to handle the more general situation.

<sup>8</sup>In some cases, some of the numbers in the text are rephrased (“10ml” to “10 ml”) in order to allow NLP pipeline work properly.

**Lemma 1.** The procedure `TEMPLEQUIV` returns  $\Gamma \neq \emptyset$  iff templates  $T_1, T_2$  are equivalent (w.h.p.).

**Proof** First we prove that with high probability we are correct in claiming that a  $\gamma$  found by the algorithm leads to equivalence. Let probability of getting the same solution even when the template are not equivalent be  $\epsilon(T_1, T_2, \gamma) < 1$ . The probability that solution is same for  $R$  rounds for  $T_1, T_2$  which are not equivalent is  $\leq \epsilon^R$ , which can be made arbitrarily small by choosing large  $R$ . Therefore, with a large enough  $R$ , obtaining  $\Gamma \neq \emptyset$  from `TEMPLEQUIV` implies there is a  $\gamma$  under which templates generate equations with the same solution, and by definition, are equivalent.

Conversely, if templates are equivalent, it implies  $\exists \gamma^*$  such that under that mapping for any assignment, the generated equations have the same solution. As we iterate over all possible 1-1 mappings  $\gamma$  between the two templates, we will find  $\gamma^*$  eventually.

**Proposition** Algorithm 1 returning 1 implies derivations  $(T_p, A_p)$  and  $(T_g, A_g)$  are equivalent.

**Proof** Algorithm returns 1 only if `TEMPLEQUIV` found a  $\Gamma \neq \emptyset$ , and  $\exists \gamma \in \Gamma$ , following holds

$$(q, c) \in A_g \iff (q, \gamma(c)) \in A_p$$

i.e., the corresponding slots aligned to the same textual number. `TEMPLEQUIV` found a  $\Gamma \neq \emptyset$  implies templates are equivalent (w.h.p). Therefore,  $\exists \gamma \in \Gamma$  such that the corresponding slots aligned to the same textual number implies the alignments are equivalent under mapping  $\gamma$ . Together they imply that the derivation was equivalent (w.h.p.).

# An Extensive Empirical Evaluation of Character-Based Morphological Tagging for 14 Languages

## Abstract

This paper investigates neural character-based morphological tagging for languages with complex morphology and large tag sets. Character-based approaches are attractive as they can handle rarely and unseen words gracefully. We evaluate on 14 languages and observe consistent gains over a state-of-the-art morphological tagger across all languages except for English and French, where we match the state-of-the-art. We compare two architectures for computing character-based word vectors using recurrent (RNN) and convolutional (CNN) nets. We show that the CNN based approach performs slightly worse and less consistently than the RNN based approach. Small but systematic gains are observed when combining the two architectures by ensembling.

## 1 Introduction

Character-based approaches have been studied for many applications in natural language processing, including part-of-speech (POS) tagging (dos Santos and Zadrozny, 2014; Ling et al., 2015; Gillick et al., 2016; Plank et al., 2016; Ma and Hovy, 2016), morphological tagging (Labeau et al., 2015), parsing (Ballesteros et al., 2015), named entity recognition (Gillick et al., 2016), language modeling (Ling et al., 2015; Kim et al., 2016), and neural machine translation (Costajussà and Fonollosa, 2016). Character-based representations have the advantage of gracefully handling rare or unseen words and tend to produce more compact models as the number of atomic units, i.e., characters, is smaller compared to the number of words in word-level approaches. The issue of rare or unseen words is particularly pro-

nounced when working on morphologically-rich languages, small amounts of training data or noisy user input.

Morphological tagging is the task of assigning a morphological analysis to a token in context. The morphological analysis for a word consists of a sequence of feature:value pairs describing, for example, case, gender, person and tense. A particular concatenation of such feature:value pairs is referred to as a single tag (Oflazer and İlker Kuroz, 1994; Hajic and Hladka, 1998; Mueller et al., 2013).

Following (Müller and Schuetze, 2015), we also add the part-of-speech to this morphological tag and refer to it as POS-MORPH:

```
I see four words
                |
                POS=noun:CASE=acc:...
                ...:NUMBER=plural
```

Given a word in context, we predict a POS-MORPH tag as a complete unit, rather than as the individual component parts. This approach allows us to share large parts of the model but can only produce POS-MORPH analyses attested in the training data (cf. Table 2). This is still the standard approach to morphological tagging and disambiguation as, given sufficient amounts of training data, the number of POS-MORPH descriptions that cannot be produced usually is small.

Character-based POS tagging (rather than full POS-MORPH tagging) has been extensively evaluated in the literature (dos Santos and Zadrozny, 2014; Ling et al., 2015; Gillick et al., 2016; Plank et al., 2016). The results are competitive but do not systematically outperform the state of the art. Only Plank et al. (2016) report consistent gains by using shallow neural network architectures in combination with multitask learning, multilingual

learning, and pre-trained word embeddings.

State-of-the-art results for morphological tagging (full POS-MORPH tagging) can be found in (Mueller et al., 2013; Müller and Schuetze, 2015). To the best of our knowledge, there has not been much research on character-based morphological tagging so far. Labeau et al. (2015) is an exception but report results for German only. Their best results are on a par with state-of-the-art results. Heigold et al. (2016) show clear gains of character-based over state-of-the-art morphological taggers. However, the evaluation is limited to German and Czech.

Research on character-based approaches in general NLP clearly divides into papers that use CNN-based architectures (dos Santos and Zadrozny, 2014; Kim et al., 2016; Costa-jussà and Fonollosa, 2016) and papers that use LSTM-based architectures (Labeau et al., 2015; Ling et al., 2015; Gillick et al., 2016; Ballesteros et al., 2015; Plank et al., 2016; Ma and Hovy, 2016). There are a number of examples where an LSTM paper reports results of a CNN paper for comparison, such as (Ling et al., 2015) (POS tagging for English) and (Gillick et al., 2016) (named entity recognition for English). However, there is no direct comparison between CNN and LSTM based architectures in morphological tagging.

In this paper, we investigate character-based morphological tagging in more depth. More specifically, the contributions of this paper include:

- the evaluation of character-based morphological tagging on 14 different languages of different morphological complexity;
- the empirical comparison of long-short term memory (LSTM) and convolutional neural network (CNN) based architectures;
- the demonstration of systematic gains of our character-based, language-agnostic morphological tagger over a state-of-the-art morphological tagger across morphologically rich languages; moreover, and perhaps as expected, we show that the relative gains are clearly correlated with the amount of the training data;
- the evaluation of the complementarity of LSTM- and CNN-based architectures by ensemble experiments.

The remainder of the paper is organized as follows. Section 2 summarizes the character-based neural network approaches used in this paper. The data sets and model configurations are described in Section 3 and in Section 4, respectively. The empirical evaluation is presented in Section 5. Section 6 concludes the paper. The Appendix contains a listing of all experimental results obtained in this paper.

## 2 Character-based Tagging

We assume an input sentence  $w_1^N$  with (complex POS-MORPH morphological) output tags  $t_1^N$  and a zeroth-order Markov model

$$p(t_1^N | w_1^N) = \prod_{n=1}^N p(t_n | w_1^N) \quad (1)$$

whose factors are modeled by a suitable neural network. For character-based tagging, we use the character representation of the word,  $w = c_1^M$ . This assumes that the segmentation of the sentence into words is known, which is straightforward for the languages under consideration.

At the top level, each input word maps to one complex POS-MORPH morphological output tag. Hence, we can model the position-wise probabilities  $p(t | w_1^N)$  with recurrent neural networks, such as long short-term memory recurrent neural networks (LSTMs) (Graves, 2012). Fig. 1 (a) shows such a network architecture where the inputs are the word vectors  $v_1^N$ . At the lower level, we use a CNN-based (Fig. 1 (b)) or an LSTM-based (Fig. 1 (c)) architecture to compute the character-based word vectors. As we are using bidirectional LSTMs (BLSTMs) at the top level, we shall refer to the complete architectures as CNNHighway-BLSTM and LSTM-BLSTM. The two architectures are fairly similar. In our opinion, however, there is an important difference between the two. CNNHighway is more constructive in the sense that it explicitly specifies the possible character context widths with a hard upper bound and defines an embedding size for each context width. LSTMs are more generic as they are claimed to implicitly learn these details (Schmidhuber, 1992).

The weights of the network,  $\theta$ , are jointly estimated using conditional log-likelihood

$$F(\theta) = - \sum_{n=1}^N \log p_{\theta}(t_n | w_1^N). \quad (2)$$

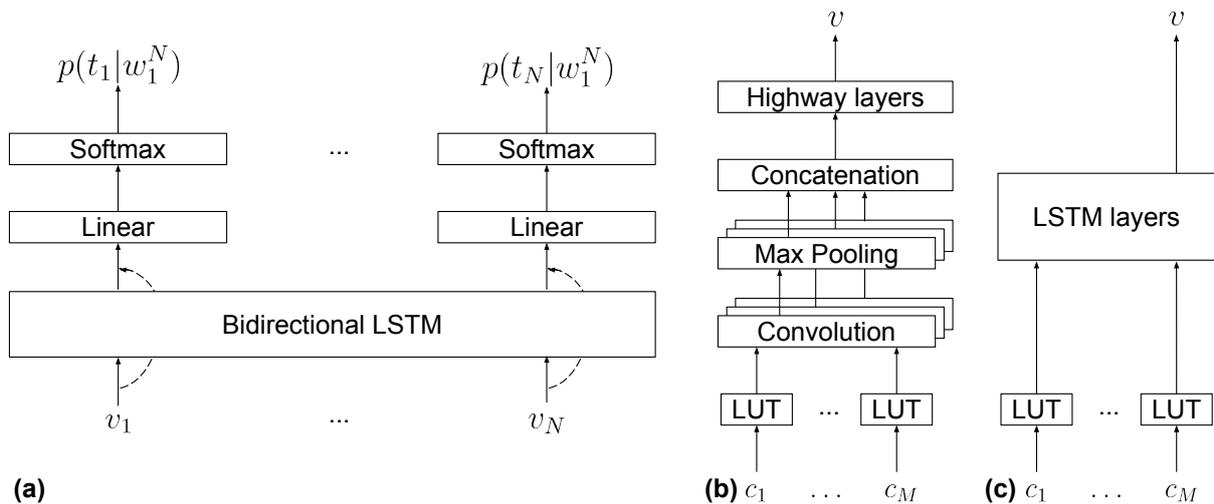

Figure 1: Character-based neural tagging architecture: (a) sub-network mapping word vectors  $v_1^N$  to tags  $t_1^N$ , dashed arrows indicate optional skip connections, (b) CNNs with different filter widths followed by fully-connected layers with highway connections (CNNHighway), and (c) deep LSTM using the last output to map the character string to a word vector. The networks in (b) and (c) are cloned to produce the input word vectors  $v_1^N$  in (a). LUT stands for lookup table.

Learning in recurrent or very deep neural networks is non-trivial and skip/shortcut connections have been proposed to improve the learning of such networks (Pascanu et al., 2014; He et al., 2016). We use such connections (dashed arrows in Fig. 1) for LSTM-BLSTM to alleviate potential learning issues.

At test time, the predicted tag sequence is the tag sequence that maximizes the conditional probability  $p(t_1^N|w_1^N)$ . For the factorization in Eq. (1), the search can be done position-wise. This significantly reduces the computational and implementation complexity compared to first-order Markov models as used in (Collobert et al., 2011; dos Santos and Zdrozny, 2014; Labeau et al., 2015).

### 3 Data

Most of the data sets are taken from the UD treebanks<sup>1</sup>. We also use a number of older data sets in order to compare our results with existing results in the literature, including Czech/PDT<sup>2</sup>, German/TIGER<sup>3</sup>, and Korean/SPMRL<sup>4</sup>. The corpus statistics for the different languages can be found in Table 1. The chosen languages are from different language families: Balto-Slavic (Bulgar-

ian, Czech, Russian), Finnic (Estonian, Finnish), Finno-Ugric (Hungarian), Germanic (German), Indo-Iranian (Hindi), Koreanic (Korean), Romance (Romanian, Semitic (Arabic), and Turkic (Turkish). They include several examples for both agglutinative and fusional languages. The amount of training data ranges from 33k training tokens (Hungarian/UD) to 1,174k training tokens (Czech/UD).

Table 2 summarizes the tag statistics for the different languages. The number of tags is the number of POS-MORPH tags occurring in the training data. We give the test entropy based on a unigram tag model estimated on the training data as a simple measure for the difficulty of the associated sequence classification problem. The type/token ratio (TTR), also known as vocabulary size divided by text length, is computed on 1M words from randomly selected sentences from a different data set<sup>5</sup> and is a simple measure to quantify the morphological complexity of a language (Bane, 2008). A higher TTR value indicates higher morphological complexity.

Russian/UD	434	54.6	16
Turkish/UD	987	73.0	10

## 4 Setups

We use the same model setups for LSTM-BLSTM and CNNHighway-BLSTM as in (Heigold et al., 2016). The hyper-parameters are set to

- CNNHighway: the large setup from (Kim et al., 2016), i.e., character vector size = 15, filter widths ranging from one to seven, number of filters as a function of the filter width  $\min\{200, 50 \cdot \text{filter width}\}$ , two highway layers
- LSTM: character vector size = 128, two layers with 1024 and 256 nodes

The BLSTM modeling the context of words in a sentence (Fig. 1 (a)) consists of two hidden layers, each with 256 hidden nodes.

These hyper-parameters were tuned on the German TIGER development data and are optimal on a "best effort basis." German is good for the hyper-parameter tuning as it is a relatively hard task (see Table 2) and shows morphological effects both within and across words. Furthermore, the TIGER corpus is relatively large, which reduces statistical fluctuations in training and testing. Apart from these considerations, the choice was random. Furthermore, we tested language-specific tuning for a few languages, but it does not seem to give further gains. Moreover, the network hyper-parameters were tuned to give best accuracy rather than most compact models or even comparable numbers of

parameters as our application is not constrained by memory or runtime. The hyper-parameters were then used for all languages. We ran the external tools MarMoT<sup>6</sup> and JNN<sup>7</sup> (see Appendix) with the suggested default values.

The networks are optimized as described in (Heigold et al., 2016). In particular, the optimization is done with RMSProp (Tieleman and Hinton, 2012), with a fixed initial learning rate and a learning rate decay of two every tenth epoch for German, TIGER, and is adjusted for the other languages according to the amount of training data. The batch size is always 16. Furthermore, we use dropout. The dropout probability is empirically set to 0.4 for Hungarian and Turkish, which only have a very limited amount of training data (Table 1), and to 0.2 for all other languages.

## 5 Empirical Evaluation

We empirically evaluate an LSTM-based and a CNN-based architecture for character-based morphological tagging (Section 2) and compare them against MarMoT, a state-of-the-art morphological tagger (Mueller et al., 2013). For the evaluation we use twelve different morphologically-rich languages with different characteristics, plus two morphologically-poor languages for contrastive results (Section 3). The configurations are described in Section 4.

Fig. 2 plots the relative gain over MarMoT (see Appendix A for more details) against the amount of training data. The horizontal dotted line at 0% indicates the MarMoT baseline. The blue squares are for LSTM-BLSTM results. Connecting them for the morphologically-rich languages shows a clear, nearly-linear dependency of the relative gain on the amount of training data. Only the data point for Turkish at 40% is an outlier (should be around 20%). This result suggests that compared to MarMoT, LSTM-BLSTM is very data efficient. Even for very small amounts of training data (e.g., 33k tokens for Hungarian), the relative gain is still 15%. On the other hand, more data helps. In case of Czech, increasing the amount of training data from 691k (Czech/PDT) to 1174k (Czech/UD) tokens leads to some additional gain and yields almost a 50% relative gain. It should be noted, however, that the two data sets use different tag sets, with the Czech/UD one being more complex than

the Czech/PDT (Table 2).

We use an LSTM-BLSTM of the same size for all languages, although the amount of training data varies by roughly two orders of magnitude. Therefore, it is a valid question if a larger model specifically designed for Czech/UD or a smaller model for Turkish/UD would improve the results. We have developed locally tuned and tested larger and smaller models in terms of number of nodes or layers but with similar or worse performance: -0.1% with more nodes (Czech) or approx. -1% with fewer nodes or fewer layers (Turkish). This observation suggests that the configuration optimized for German is fairly robust across many different languages, which is an attractive property from a practical perspective.

In contrast, we do not observe a gain of LSTM-BLSTM over MarMoT for English and French. Both languages are considered to be morphologically poor, as supported by the tag statistics in Table 2. This may be because of the low morphological complexity, i.e., a character representation does not add much information to a word representation. Another explanation might be that the linguistic experts have focused on English and French in the last decades and found a good set of features, which however does not well generalize to other, morphologically more complex languages.

It is tempting to analyze these results in more detail by splitting languages into sub-categories. Here, we refrain from doing so as it is delicate to draw conclusions from very small sample sizes (3-4 languages, say).

The green circles (in Fig. 2) are for CNNHighway-BLSTM results, a neural network architecture that has been developed for character-based language modeling (Kim et al., 2016). Overall, LSTM-BLSTM and CNNHighway-BLSTM perform similarly, see Fig. 2. Looking at the details, however, CNNHighway-BLSTM tends to perform slightly worse and less consistently than LSTM-BLSTM.

While LSTM-BLSTM and CNNHighway-BLSTM perform similarly they may capture complementary effects. To measure the complementarity of the two architectures, we build an ensemble consisting of the LSTM-BLSTM and the CNNHighway-BLSTM by taking the geometric mean of the scores. The accuracies are shown in Fig. 2 as LSTM+CNNHighway-BLSTM. Ex-

<sup>6</sup><http://cistern.cis.lmu.de/marmot/>

<sup>7</sup><https://github.com/wlin12/JNN>

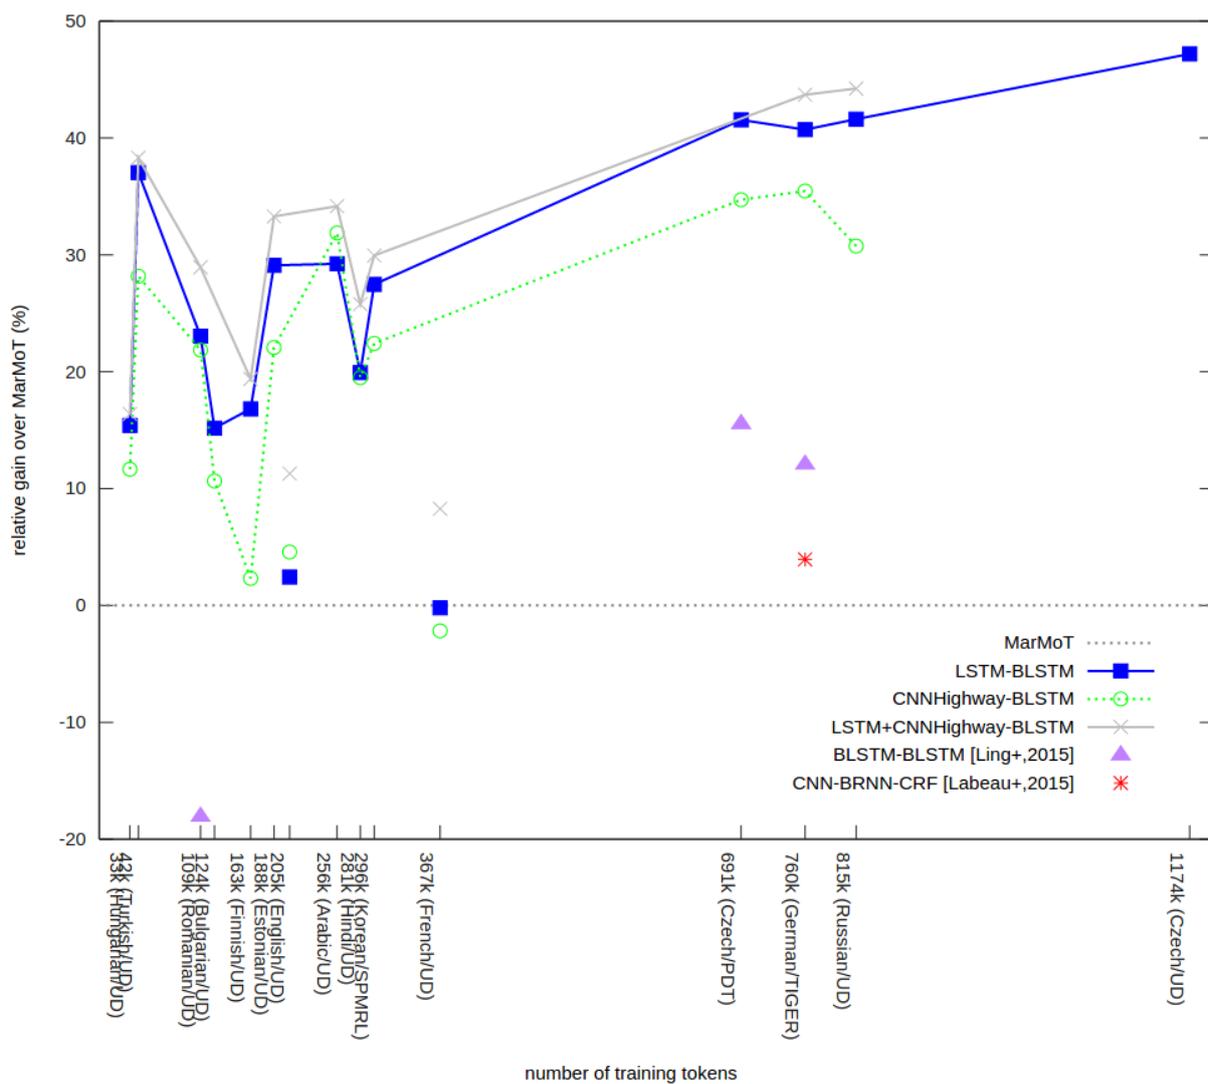

Figure 2: Relative gains (%) over MarMoT

cept maybe for English and French, we observe marginal but consistent gains over LSTM-BLSTM or CNNHighway-BLSTM.

For additional comparison, we add a few additional points in the plot. The red cross indicates the result from (Labeau et al., 2015), which is a combination of a CNN, a bidirectional RNN, and a Markov model. The purple triangles are generated with the external tool JNN<sup>8</sup>, which implements a shallow BLSTM-BLSTM (i.e., only one bidirectional LSTM layer in each BLSTM). One might expect that this model performs better on smaller data sets. But actually, it is clearly worse both for large (Czech/PDT and German/TIGER) and small data sets (Romanian/UD).

## 6 Summary & Future Work

In this paper, we demonstrated that a character-based neural approach can achieve consistent improvements over a state-of-the-art morphological tagger (MarMoT). The evaluation included a dozen of languages of different morphological complexity and with different characteristics. The relative gains for the morphologically-rich languages range from 15% to almost 50%, with a clear dependency on the amount of training data. Several aspects are remarkable about this result.

First, these results use the same model architecture with the same number of layers and nodes, without any language-specific modifications. Further local language and training data setting specific tuning does not seem to help much.

Second, the neural approach seems to be more data efficient than the baseline tagger with manually designed features, also when only 30k training tokens are available.

Third, a fairly generic deep and hierarchical recurrent neural network architecture seems to perform as well or better than a more specialized convolutional neural network based architecture.

Fourth, to keep the setup as simple as possible, we have not used advanced techniques which are reported to lead to improvements, including a non-trivial structured prediction model (e.g., a first-order Markov model) (Collobert et al., 2011; dos Santos and Zadrozny, 2014; Labeau et al., 2015; Ma and Hovy, 2016), additional unsupervised data (e.g., via word2vec) (Müller and Schuetze, 2015; Ling et al., 2015; Plank et al., 2016; Ma and Hovy, 2016), combination of dif-

ferent word representations (Labeau et al., 2015; Ma and Hovy, 2016; Plank et al., 2016), multilingual learning (Gillick et al., 2016; Plank et al., 2016), and auxiliary tasks (Plank et al., 2016). Future work will include the investigation of these more advanced techniques. From this perspective, our paper provides a baseline for future research in multilingual character-based neural morphological tagging.

Last but not least, we do not observe any gains for English and French (except when using ensembles). This may be due to the low morphological complexity of these languages or because manual feature engineering has focused on these languages over the last decades with good results.

## A Raw Results

This appendix contains Table 3 with the raw results used in this paper. When available, the best comparable error rates from the literature are used. Otherwise, we produced the error rates with the publicly available tools and the suggested default values. More specifically, we used the state-of-the-art tagger MarMoT<sup>9</sup> for the baselines and the LSTM-based POS tagger JNN<sup>10</sup> for some contrastive results.

## Abstract

We explore the task of multi-source morphological reinflection, which generalizes the standard, single-source version. The input consists of (i) a target tag and (ii) multiple pairs of source form and source tag for a lemma. The motivation is that it is beneficial to have access to more than one source form since different source forms can provide complementary information, e.g., different stems. We further present a novel extension to the encoder-decoder recurrent neural architecture, consisting of multiple encoders, to better solve the task. We show that our new architecture outperforms single-source reinflection models and publish our dataset for multi-source morphological reinflection to facilitate future research.

## 1 Introduction

Morphologically rich languages still constitute a challenge for natural language processing (NLP). The increased data sparsity caused by highly inflected word forms in certain languages causes otherwise state-of-the-art systems to perform worse in standard tasks, e.g., parsing (Ballesteros et al., 2015) and machine translation (Bojar et al., 2016). To create systems whose performance is not deterred by complex morphology, the development of NLP tools for the generation and analysis of morphological forms is crucial. Indeed, these considerations have motivated a great deal of recent work on the topic (Ahlberg et al., 2015; Dreyer, 2011; Nicolai et al., 2015).

In the area of generation, the most natural task is morphological inflection—finding an inflected form for a given target tag and lemma. An example for English is as follows: ( $\text{trg}:3\text{rdSgPres}$ , *bring*)

	Present Ind		Past Ind		Past Sbj	
	Sg	Pl	Sg	Pl	Sg	Pl
1	<b>treffe</b>	<b>treffen</b>	<b>traf</b>	<b>trafen</b>	<b>träfe</b>	<b>träfen</b>
2	<b>triffst</b>	<b>trefft</b>	<b>trafst</b>	<b>traft</b>	<b>träfest</b>	<b>träfet</b>
3	<b>trifft</b>	<b>treffen</b>	<b>traf</b>	<b>trafen</b>	<b>träfe</b>	<b>träfen</b>

Table 1: The paradigm of the strong German verb **TREFFEN**, which exhibits an irregular ablaut pattern. Different parts of the paradigm make use of one of four bolded theme vowels: **e**, **i**, **a** or **ä**. In a sense, the verbal paradigm is partitioned into subparadigms. To see why multi-source models could help in this case, starting only from the infinitive **treffen** makes it difficult to predict subjunctive form **träfest**, but the additional information of the fellow subjunctive form **träfe** makes the task easier.

$\mapsto$  *brings*. In this case, the 3rd person singular present tense of *bring* is generated. One generalization of inflection is morphological reinflection (MRI) (Cotterell et al., 2016a), where we must produce an inflected form from a triple of target tag, source form and source tag. The inflection task is the special case where the source form is the lemma. As an example, we may again consider generating the English past tense form from the 3rd person singular present: ( $\text{trg}:3\text{rdSgPres}$ , *brought*,  $\text{src}:\text{Past}$ )  $\mapsto$  *brings* (where  $\text{trg}$  = “target tag” and  $\text{src}$  = “source tag”). As the starting point varies, MRI is more difficult than morphological inflection and exhibits more data sparsity. However, it is also more widely applicable since lexical resources are not always complete and, thus, the lemma is not always available. A more complex German example is given in Table 1.

In this work, we generalize the MRI task to a multi-source setup. Instead of using a single source form-tag pair, we use *multiple* source form-tag pairs. Our motivation is that (i) it is often beneficial to have access to more than one source form since different source forms can provide complementary information, e.g., different stems; and (ii)

in many application scenarios, we will have encountered more than one form of a paradigm at the point when we want to generate a new form.

We will make the intuition that multiple source forms provide complementary information precise in the next section, but first return to the English verb *bring*. Generating the form *brings* from *brought* may be tricky—there is an irregular vowel shift. However, if we had a second form with the same theme vowel, e.g., *bringing*, the task would be much easier, i.e., (`trg:3rdSgPres, form1:brought, src1:Past, form2:bringing, src2:Gerund`). A multi-source approach clearly is advantageous for this case since mapping *bringing* to *brings* is regular even though the verb itself is irregular.

The contributions of the paper are as follows. (i) We define the task of multi-source MRI, a generalization of single-source MRI. (ii) We show that a multi-source MRI system, implemented as a novel encoder-decoder, outperforms the top-performing system in the SIGMORPHON 2016 Shared Task on Morphological Reinflection on seven out of eight languages, when given additional source forms. (iii) We release our data to support the development of new systems for MRI.

## 2 The Task: Multi-Source Reinflection

Previous work on morphological reinflection has assumed a single source form, i.e., an input consisting of exactly one inflected source form (potentially the lemma) and the corresponding morphological tag. The output is generated from this input. In contrast, multi-source morphological reinflection, the task we introduce, is a generalization in which the model receives multiple form-tag pairs. In effect, this gives the model a partially annotated paradigm from which it predicts the rest.

The multi-source variant is a more natural problem than single-source morphological reinflection since we often have access to more than just one form.<sup>1</sup> For example, corpora such as the universal dependency corpus (McDonald et al., 2013) that are annotated on the token level with inflectional features often contain several different inflected forms of a lemma. Such corpora would provide an ideal source of data for the multi-source MRI task.

<sup>1</sup>Scenarios where a single form is available and that form is the lemma are perhaps not infrequent. In high-resource languages, an electronic dictionary may have near-complete coverage of the lemmata of the language. However, paradigm completion is especially crucial for neologisms and low-resource languages.

Formally, we can think of a morphological paradigm as follows. Let  $\Sigma$  be a discrete alphabet for a given language and  $\mathcal{T}$  be the set of morphological tags in the language. The inflectional table or morphological paradigm  $\pi$  of a lemma  $w$  can be formalized as a set of pairs:

$$\pi(w) = \{(f_1, t_1), (f_2, t_2), \dots, (f_N, t_N)\}, \quad (1)$$

where  $f_i \in \Sigma^+$  is an inflected form of  $w$ , and  $t_i \in \mathcal{T}$  is the morphological tag of the form  $f_i$ . The integer  $N$  is the number of slots in the paradigm that have the syntactic category (POS) of  $w$ .

Using this notation, single-source morphological reinflection (MRI) can be described as follows. Given a target tag and a pair of source form and source tag ( $t_{\text{trg}}, (f_{\text{src}}, t_{\text{src}})$ ) as input, predict the target form  $f_{\text{trg}}$ . There has been a substantial amount of prior work on this task, including systems that participated in Task 2 of the SIGMORPHON 2016 shared task (Cotterell et al., 2016a). Thus, we may define the task of *multi-source morphological reinflection* as follows: Given a target tag and a set of  $k$  form-tag source pairs ( $t_{\text{trg}}, \{(f_{\text{src}}^1, t_{\text{src}}^1), \dots, (f_{\text{src}}^k, t_{\text{src}}^k)\}$ ) as input, predict the target form  $f_{\text{trg}}$ . Note that single-source MRI is a special case of multi-source MRI for  $k = 1$ .

### 2.1 Motivating Examples

Figure 1 gives examples for four different configurations that can occur in multi-source MRI.<sup>2</sup> We have colored the source forms green and drawn a dotted line to the target if they contain sufficient information for correct generation. If two source forms together are needed, the dotted line encloses both of them. Source forms that provide no information in the configuration are colored red (no arrow); note these forms could provide (and in most cases will provide) useful information for other combinations of source and target forms.

<sup>2</sup>Figure 1 is not intended as a complete taxonomy of possible MRI configurations, e.g., there are hybrids of ANYFORM and NOFORM (some forms are informative, others are suppletive) and fuzzy variants (a single form gives pretty good evidence for how to generate the target form, but another single form gives better evidence). All of our examples make additional assumptions, e.g., that we have not seen other similar forms in training either of the same lemma (e.g., *poner*) or of a similar lemma (e.g., *reponer*). Hopefully, the examples are illustrative of the main conceptual distinction: several single forms each are sufficient by themselves (ANYFORM), a single, but carefully selected form is sufficient (SINGLEFORM), multiple forms are needed to generate the target (MULTIFORM) and the target form cannot be predicted (irregular) from the source forms (NOFORM).

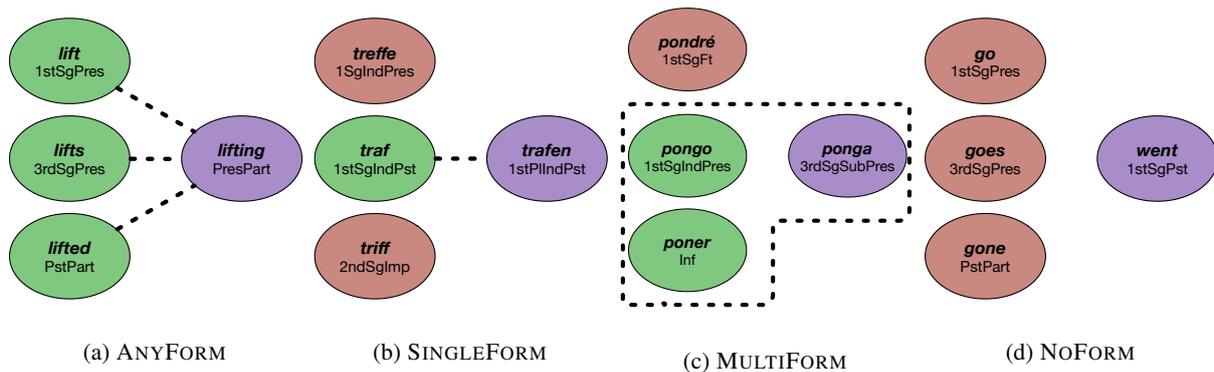

Figure 1: Four possible input configurations in multi-source morphological reinfection (MRI). In each subfigure, the target form on the right is **purple**. The source forms are on the left and are **green** if they can be used to predict the target form (also connected with a dotted line) and **red** if they cannot. There are four possible configurations: (i) ANYFORM is the case where one can predict the target form from any of the source forms. (ii) SINGLEFORM is the case where only one form can be used to regularly predict the target form. (iii) MULTIFORM is the case where multiple forms are *necessary* to predict the target form. (iv) NOFORM is the case where the target form cannot be regularly derived from any of the source forms. Multi-source MRI is expected to perform better than single-source MRI for the configurations SINGLEFORM and MULTIFORM, but not for the configurations ANYFORM and NOFORM.

The first type of configuration is ANYFORM: each of the available source forms in the subset of the English paradigm (*lift*, *lifts*, *lifted*) contains enough information for a correct generation of the target form *lifting*. The second configuration is SINGLEFORM: there is a single form that contains enough information for correct generation, but it has to be carefully selected. Inflected forms of the German verb *treffen* ‘to meet’ have different stem vowels (see Table 1). In single-source reinfection, producing a target form with one stem vowel (*a* in *trafe* in the figure) from a source form with another stem vowel (e.g., *e* in *treffe*) is difficult.<sup>3</sup>

In contrast, the learning problem for the SINGLEFORM configuration is much easier in multi-source MRI. The multi-source model does not have to learn the possible vowel changes of this irregular verb; instead, it just needs to pick the correct vowel change from the alternatives offered in the input. This is a relatively easy task since the theme vowel is identical. So we only need to learn one general fact about German morphology (which suffix to add) and will then be able to produce the correct form with high accuracy. This type of regularity is typical of complex morphology: there are groups of forms in a paradigm that are similar and it is highly predictable which of these groups a particular target form for a new word will be a member of. As long as one representative of each group is part of the multi-source input, we can select it to generate the correct form.

<sup>3</sup>It is not impossible to learn, but *treffen* is an irregular verb, so we cannot easily leverage the morphology we have learned about other verbs.

In the MULTISOURCE configuration, we are able to use information from multiple forms if no single form is sufficient by itself. For example, to generate *ponga*, 3rdSgSubPres of *poner* ‘to put’ in Spanish, we need to know what the stem is (*ponga*, not *pona*) and which conjugation class (*-ir*, *-er* or *-ar*) it is part of (*ponga*, not *pongue*). The single-source input *pongo*, 1stSgIndPres, does not reveal the conjugation class: it is compatible with both *ponga* and *pongue*. The single-source input *poner*, Inf, does not reveal the stem for the subjunctive: it is compatible with both *ponga* and *pona*—we need both source forms to generate the correct form *ponga*.

Again, such configurations are frequent cross-linguistically, either in this “discrete” variant or in more fuzzy variants where taking several forms together increases our chances of producing the correct target form. Finally, we call configurations NOFORM if the target form is completely irregular and not related to any of the source forms. The suppletive form *went* is our example for this case.

## 2.2 Principle Parts

The intuition behind the MRI task draws inspiration from the theoretical linguistic notion of **principle parts** (Finkel and Stump, 2007; Stump and Finkel, 2013). The notion is that a paradigm has a subset that allows for maximum predictability. In terms of language pedagogy, the principle parts would be a minimal set of forms a student has to learn in order to be able to generate any form in the paradigm. For instance for the partial German paradigm in Table 1, the forms *treffen*, *triffi*, *trafen*, and *träfen*

could form *one* potential set of principle parts.

From a computational learning point of view, maximizing predictability is always a boon—we want to make it as easy as possible for the system to learn the morphological regularities and subregularities of the language. Giving the system the principle parts as input is one way to achieve this.

### 3 Model Description

Our model is a multi-source extension of MED, Kann and Schütze (2016b)’s encoder-decoder network for MRI. In MED, a single bidirectional recurrent neural network (RNN) encodes the input. In contrast, we use multiple encoders to be able to handle multiple source form-tag pairs. In MED, a decoder RNN produces the output from the hidden representation. We do not change this part of the architecture, so there is still a single decoder.<sup>4</sup>

#### 3.1 Input and Output Format

For  $k$  source forms, our model takes  $k$  different inputs of parallel structure. Each of the  $1 \leq i \leq k$  inputs consists of the target tag  $t_{trg}$  and the source form  $f_i$  and its corresponding source tag  $t_i$ . The output is the target form. Each source form is represented as a sequence of characters; each character is represented as an embedding. Each tag—both the target tag and the source tags—is represented as a sequence of subtags; each subtag is represented as an embedding.

More formally, we define the alphabet  $\Sigma_{\text{lang}}$  as the set of characters in the language and  $\Sigma_{\text{subtag}}$  as the set of subtags that occur as part of the set of morphological tags  $\mathcal{T}$  of the language, e.g., if  $1\text{st-SgPres} \in \mathcal{T}$ , then  $1\text{st}$ ,  $\text{Sg}$  and  $\text{Pres} \in \Sigma_{\text{subtag}}$ . Each of the  $k$  inputs to our system is of the following format:  $S_{\text{start}} \Sigma_{\text{subtag}}^+ \Sigma_{\text{lang}}^+ \Sigma_{\text{subtag}}^+ S_{\text{end}}$  where the first subtag sequence is the source tag  $t_i$  and the second subtag sequence is the target tag. The output format is:  $S_{\text{start}} \Sigma_{\text{lang}}^+ S_{\text{end}}$ , where the symbols  $S_{\text{start}}$  and  $S_{\text{end}}$  are predefined start and end symbols.

#### 3.2 Multi-Source Encoder-Decoder

The encoder-decoder is based on the machine translation model of Bahdanau et al. (2015) and all specifics of our model are identical to the original presentation unless stated otherwise.<sup>5</sup> Whereas

<sup>4</sup>The edit tree (Chrupała, 2008; Müller et al., 2015) augmentation discussed in Kann and Schütze (2016b) was not employed here.

<sup>5</sup>We modify the implementation of the model freely available at <https://github.com/mila-udem>.

Bahdanau et al. (2015)’s model has only one encoder, our model consists of  $k \geq 1$  encoders and processes  $k$  sources simultaneously. The  $k$  sources have the form  $X_m = (t_{trg}, f_{src}^m, t_{src}^m)$ , represented as  $S_{\text{start}} \Sigma_{\text{subtag}}^+ \Sigma_{\text{lang}}^+ \Sigma_{\text{subtag}}^+ S_{\text{end}}$  as described above. Characters and subtags are embedded.

The input to encoder  $m$  is  $X_m$ . Each encoder consists of a bidirectional RNN that computes a hidden state  $h_{mi}$  for each position, the concatenation of forward and backward hidden states. Decoding proceeds as follows:

$$p(y | X_1, \dots, X_k) = \prod_{t=1}^{|Y|} p(y_t | \{y_1, \dots, y_{t-1}\}, c_t) \\ = \prod_{t=1}^{|Y|} g(y_{t-1}, s_t, c_t), \quad (2)$$

where  $y = (y_1, \dots, y_{|Y|})$  is the output sequence (a sequence of  $|Y|$  characters),  $g$  is a nonlinear function,  $s_t$  is the hidden state of the decoder and  $c_t$  is the sum of the encoder states  $h_{mi}$ , weighted by attention weights  $\alpha_{mi}(s_{t-1})$  that depend on the decoder state:

$$c_t = \sum_{m=1}^k \sum_{i=1}^{|X_m|} \alpha_{mi}(s_{t-1}) h_{mi}. \quad (3)$$

A visual depiction of this model may be found in Figure 2. A more complex hierarchical attention structure would be an alternative, but this simple model in which all hidden states contribute on the same level in a single attention layer (i.e.,  $\sum_{m=1}^k \sum_{i=1}^{|X_m|} \alpha_{mi} = 1$ ) works well as our experiments show. The  $k$  encoders share their weights.

### 4 Multi-Source Reinflection Experiment

We evaluate the performance of our model in an experiment based on Task 2 of the SIGMORPHON Shared Task on Morphological Reinflection (Cotterell et al., 2016a). This is a single-source MRI task as outlined in Section 1.

#### 4.1 Experimental Settings

**Datasets.** Our datasets are based on the data from the SIGMORPHON 2016 Shared Task on Morphological Reinflection (Cotterell et al., 2016a). Our experiments cover eight languages: Arabic, Finnish, Georgian, German, Hungarian, Russian, Spanish and Turkish. The languages were chosen to represent different types of morphology. Finnish,

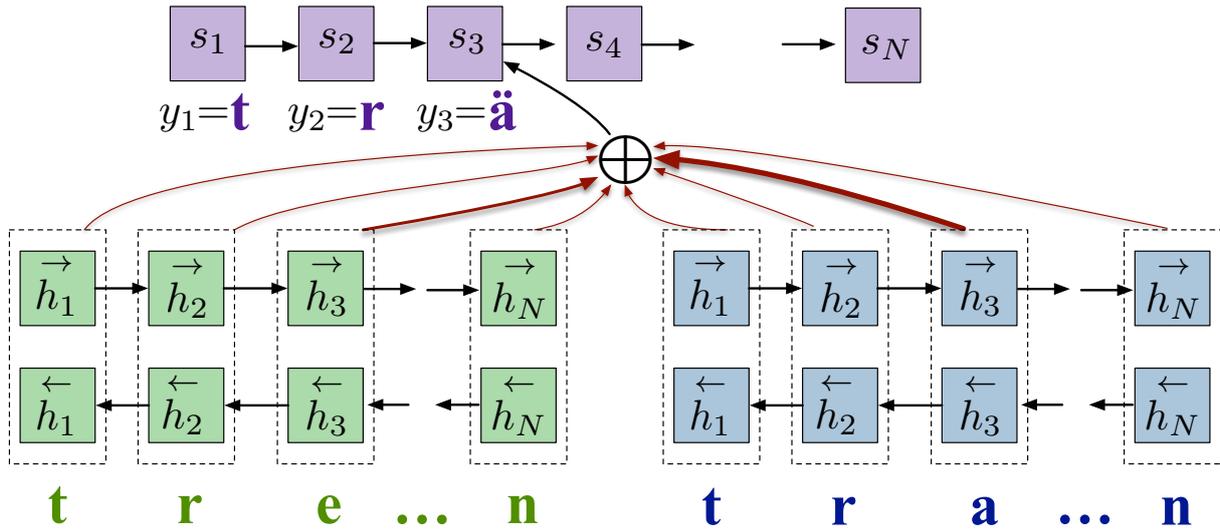

Figure 2: Visual depiction of our multi-source encoder-decoder RNN. We sketch a two encoder model, where the left encoder reads in the present form **treffen** and the right encoder reads in the past tense form **trafen**. They work together to predict the subjunctive form **träfen**. The shadowed red arcs indicate the strength of the attention weights—we see the network is focusing more on **a** because it helps the decoder better predict **ä** than **e**. We omit the source and target tags as input for conciseness.

German, Hungarian, Russian, Turkish and Spanish are all suffixing. In addition to being suffixing, three of these languages employ vocalic (German, Spanish) and consonantal (Russian) stem changes for many inflections. The members of the remaining sub-group are agglutinative. Georgian makes use of prefixation as well as suffixation. Arabic morphology contains both concatenative and templatic elements. We build multi-source versions of the dataset for Task 2 of the SIGMORPHON shared task in the following way. We use data from the UNIMORPH project,<sup>6</sup> containing complete paradigms for all languages of the shared task. The shared task data was sampled from the same set of paradigms; our new dataset is a superset of the SIGMORPHON data.

We create our new dataset by uniformly sampling three additional word forms from the paradigm of each source form in the original data. In combination with the source and target forms of the original dataset, this means that our dataset is a set of 5-tuples consisting each of four source forms and one target form.<sup>7</sup> Ideally, we would like to keep the experimental variable  $k$ , the number of sources we use in multi-source MRI, con-

<sup>6</sup><http://unimorph.org>

<sup>7</sup>One thing to note is that the original shared task data was sampled depending on word frequency in unlabeled corpora. We do not impose a similar condition, so the frequency distributions of our data and the shared task data are different. Also, we excluded Maltese and Navajo due to a lack of data to create the additional multi-source datasets.

stant for a particular experiment or vary it systematically across other experimental conditions. Table 2 gives an overview of the number of different source forms per language in our dataset. Our dataset is available for download at <http://cistern.cis.lmu.de>.

**Hyperparameters.** We use embeddings of size 300. Our encoder and decoder GRUs have 100 hidden units each. Following Le et al. (2015), we initialize all encoder and decoder weights as well as the embeddings with an identity matrix. All biases are initialized with zero. We use stochastic gradient descent, Adadelata (Zeiler, 2012) and a minibatch size of 20 for training. Training is done for a maximum number of 90 epochs. If no improvement occurs for 20 epochs, we stop training early. The final model we run on test is the model

Table 3: Accuracy on MRI for single-source (1, 2, 3, 4) and multi-source (1–2, 1–4) models. Best result in bold.

that performs best on the development data.

**Baselines.** For the single-source case, we apply MED, the top-scoring system in the SIGMORPHON 2016 Shared Task on Morphological Reinflexion (Cotterell et al., 2016a; Kann and Schütze, 2016b). At the time of writing, MED constitutes the state of the art on the dataset. For Arabic, German and Turkish, we run an additional set of experiments to test two additional architectural configurations of multi-source encoder-decoders: (i) In addition to the default configuration in which all encoders share parameters, we also test the option of each encoder learning its own set of parameters (shared par’s: yes vs. no in Table 4). (ii) Another way of realizing a multi-source system is to concatenate all sources and give this to an encoder-decoder with a single encoder as one input (encoders:  $k = 1$  vs.  $k > 1$  in Table 4).

**Evaluation Metric.** We evaluate on 1-best accuracy (exact match) against the gold form. We deviate from the shared task, which also evaluates under mean reciprocal rank and edit distance. We omit the later two since all these metrics were highly correlated (Cotterell et al., 2016a).

## 4.2 Results

Table 3 shows the results of the MRI experiment on test data. We compare using a single source, the first two sources and all four sources. The first source (in column “1”) is the original source from the SIGMORPHON shared task. Recall that we used uniform sampling to identify additional forms whereas the sampling procedure of the shared task took into account frequency. We suspect that this is the reason for the worse performance of the new sources compared to the original source; e.g., in German there are rarely used subjunctive forms like

encoders: par’s shared:	$k = 1$		$k = 4$

Table 4: Accuracy of different architectures for the dataset with 4 source forms being available for prediction. The best result for each row is in bold.

*befähle* that are unlikely to help generate related forms that are more frequent.

The main result of the experiment is that multi-source MRI performs better than single-source MRI for all languages except for Hungarian and that, clearly, the more sources the better: using four sources is always better than using two sources. This result confirms our hypothesis, illustrated in Figure 1, that for most languages, different source forms provide complementary information when generating a target form and thus performance of the multi-source model is better than of the single-source model. Table 3 demonstrates that the two configurations we identified as promising for multi-source MRI, SINGLEFORM and MULTIFORM, occur frequently enough to boost the performance for seven of the eight languages, with the largest gains observed for Arabic (7.3%) and Russian (3.5%) and the smallest for Spanish (0.9%) and Georgian (1.3%) (comparing using source form 1 with using source forms 1–4).

Hungarian is the only language for which performance decreases, by a small amount (0.3%). We attribute this to overfitting: the multi-source model has a larger number of parameters, so it is more prone to overfitting. We would expect the performance to be the same in a comparison of two models that have the same size.

**Error Analysis.** We compare errors of single-source and multi-source models for German on development data. Most mistakes of the multi-source model are stem-related: *versterbst* for *verstirbst*, *erwerben* for *erwürben*, *Apfelsinenbaume* for *Apfelsinenbäume*, *lungenkränkes* for *lungenkrankes* and *übernehmte* for *übernahme*. In most of these cases, the stem of the lemma was used, which is correct for some forms, but not for the form that had to be generated. In one case, the multi-source model did not use the correct inflection rule: *braucht* for *gebraucht*—the inflectional rule that the past participle is formed by *ge-* was not applied.

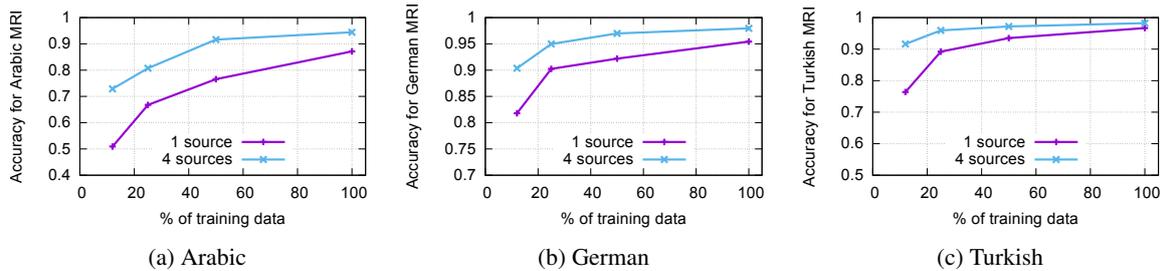

Figure 3: Learning curves for single-source and multi-source models for Arabic, German and Turkish. We observe that the multi-source model generalizes faster than the single source case—this is to be expected since the multi-source model often faces an easier transduction problem.

Errors of the single-source model that were “corrected” by the multi-source model include *emp-fahlt* for *empfehl*, *Throne* for *Thron* and *befielen* for *befallen*. These are all SINGLEFORM cases: the multi-source model will generate the correct form if it succeeds in selecting the most predictive source form. The single-source model is at a disadvantage if this most predictive source form is not part of its input.

### 4.3 Comparison of Different Architectures

Table 4 compares different architectural configurations. All experiments use 4 sources. We see that sharing parameters is superior as expected. Using a single encoder on 4 sources performs as well as 4 encoders (and very slightly better on Turkish). Apparently, it has no difficulty learning to understand an unstructured (or rather lightly structured) concatenation of form-tag pairs; on the other hand, this parsing task, i.e., learning to parse the sequence of form-tag pairs, is easy, so this is not a surprising result.

### 4.4 Learning Curves

Figure 3 shows learning curves for Arabic, German and Turkish. We iteratively halve the training set and train models for each subset. In this analysis, we train all models for 90 epochs, but use the numbers from the main experiment for the full training set. For the single-source model, we use the SIGMORPHON source. The figure shows that the single-source model needs more individual paradigms in the training data to achieve the same performance as the multi-source model. The largest difference between single-source and multi-source is  $> 20\%$  for Arabic when only 1/8 of the training set is used. This suggests that multi-source MRI is an attractive option for low-resource languages since it exploits available data better than single-source.

### 4.5 Attention Visualization

Figure 4 shows for one example, the generation of the German form *wögen*, 3rdPISubPst, the attention weights of the multi-source model at each time step of the decoder, i.e., for each character as it is being produced by the decoder. For characters that simply need to be copied, the main attention lies on the corresponding characters of the input sources. For example, the character *g* is produced when attention is on the characters *g* in *wögest*, *wöge* and *wogen*. This aspect of the multi-source model is not different from the single-source model, offering no advantage.

However, even for *g*, the source form that is least relevant for generating *wögen* receives almost no weight: *wägst* is an indicative singular form that does not provide helpful information for generating a plural form in the subjunctive; the model seems to have learned that this is the case. In contrast, *wogen* does receive some weight; this makes sense as it is a past indicative form and the past subjunctive is systematically related to the past indicative for many German verbs. These observations suggest that the network has learned to correctly predict (at least in this case) which forms provide potentially useful information. For the last two time steps (i.e., characters to be generated), attention is mainly focused on the tags. Again, this indicates that the model has learned the regularity in generating this part of the word form: the suffix, consisting of *en*, is predictable from the tag.

## 5 Related Work

Recently, variants of the RNN encoder-decoder have seen widespread adoption in many areas of NLP due to their strong performance. Encoder-decoders with and without attention have been applied to tasks such as machine translation (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et

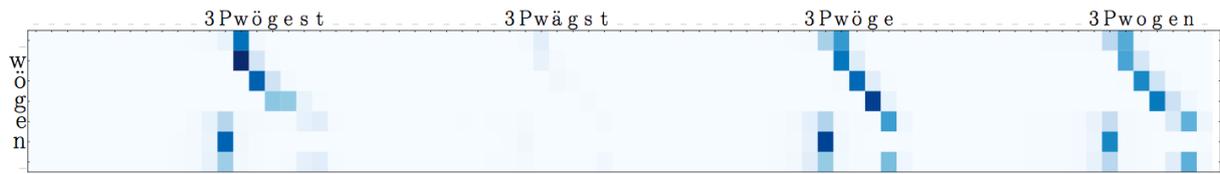

Figure 4: Attention heatmap for the multi-source model. The example is for the German verb *wiegen* ‘to weigh’. The model learns to focus most of its attention on forms that share the irregular subjunctive stem *wög* in addition to the target subtags *3* and *P* that encode that the target form is 3rd person plural. We omit the tags from the diagram to which the model hardly attends.

al., 2015), parsing (Vinyals et al., 2014) and automatic speech recognition (Graves and Schmidhuber, 2005; Graves et al., 2013).

The first work on multi-source models was presented for machine translation. Zoph and Knight (2016) made simultaneous use of source sentences in multiple languages in order to find the best match possible in the target language. Unlike our model, they apply transformations to the hidden states of the encoders that are input to the decoder. Firat et al. (2016)’s neural architecture for MT translates from any of  $N$  source languages to any of  $M$  target languages, using language specific encoders and decoders, but sharing one single attention-mechanism. In contrast to our work, they obtain a single output for each input.

Much ink has been spilled on morphological reinflection over recent years. Dreyer et al. (2008) develop a high-performing weighted finite-state transducer for the task, which was later hybridized with an LSTM (Rastogi et al., 2016). Durrett and DeNero (2013) apply a semi-CRF to heuristically extracted rules to generate inflected forms from lemmata using data scraped from Wiktionary. Improved systems for the Wiktionary data were subsequently developed by Hulden et al. (2014), who used a semi-supervised approach, and Faruqui et al. (2016), who used a character-level LSTM. All of the above work has focused on the single input case. Two important exceptions, however, have considered the multi-input case. Both Dreyer and Eisner (2009) and Cotterell et al. (2015b) define a string-valued graphical model over the paradigm and apply the missing values.

The SIGMORPHON 2016 Shared Task on Morphological Reinflection (Cotterell et al., 2016a), based on the UNIMORPH (Sylak-Glassman et al., 2015) data, resulted in the development of numerous methods. RNN encoder-decoder models (Aharoni et al., 2016; Kann and Schütze, 2016a; Östling, 2016) obtained the strongest performance and are the current state of the art on the task. The best-

performing model made use of an attention mechanism (Kann and Schütze, 2016a), first popularized in machine translation (Bahdanau et al., 2015). We generalize this architecture to the multi-source case in this paper for the reinflection task.

Besides generation, computational work on morphology has also focused on analysis. In this area, a common task—morphological segmentation—is to break up a word into its sequence of constituent morphs. The unsupervised MORFESSOR model (Creutz and Lagus, 2002) has achieved widespread adoption. Bayesian methods have also proven themselves successful in unsupervised morphological segmentation (Johnson et al., 2006; Goldwater et al., 2009). When labeled training data for segmentation is available, supervised methods significantly outperform the unsupervised techniques (Ruokolainen et al., 2013; Cotterell et al., 2015a; Cotterell et al., 2016b).

As we pointed out in Section 2, morphologically annotated corpora provide an ideal source of data for the multi-source MRI task: they are annotated on the token level with inflectional features and often contain several different inflected forms of a lemma. Eskander et al. (2013) develop an algorithm for automatic learning of inflectional classes and associated lemmas from morphologically annotated corpora, an approach that could be usefully combined with our multi-source MRI framework.

## 6 Conclusion

Generation of unknown inflections in morphologically rich languages is an important task that remains unsolved. We provide a new angle on the problem by considering systems that are allowed to have multiple inflected forms as input. To this end, we define the task of multi-source morphological reinflection as a generalization of single-source MRI (Cotterell et al., 2016a) and present a model that solves the task. We extend an attention-based RNN encoder-decoder architecture from the single-source case to the multi-source case. Our

new model consists of multiple encoders, each receiving one of the inputs. Our model improves over the state of the art for seven out of eight languages, demonstrating the promise of multi-source MRI. Additionally, we publically release our implementation.<sup>8</sup>

## 7 Future Work

The new dataset for multi-source morphological reinflection that we release is a superset of the dataset of the SIGMORPHON 2016 Shared Task on Morphological Reinflection to facilitate research on morphological generation. One focus of future work should be the construction of more complex datasets, e.g., datasets that have better coverage of irregular words and datasets in which there is no overlap in lemmata between training and test sets. Further, for difficult inflections, it might be interesting to find an effective way to include unsupervised data into the setup. For example, we could define one of our  $k$  inputs to be a form mined from a corpus that is not guaranteed to have been correctly tagged morphologically, but likely to be helpful.

We show in this paper that multi-source MRI outperforms single-source MRI. This is an important contribution because—as we discussed in Section 2.1—multi-source MRI is only promising for paradigms with specific properties, which we referred to as SINGLEFORM and MULTIFORM configurations. Whether such configurations occur and whether these configurations have a strong effect on MRI performance was an open empirical question. Indeed, we found that for one of the languages we investigated, for Hungarian, single-source MRI works at least as well as multi-source MRI—presumably because its paradigms almost exclusively contain SINGLEFORM configurations. Thus, single-source MRI is probably preferable for Hungarian since single-source is simpler than multi-source.

There is another important question that we have not answered in this paper: in an experimental setting in which the amount of training information available is exactly the same for single-source and multi-source, does multi-source still outperform single-source and by how much? For example, the numbers we compare in Table 3 are matched with respect to the number of target forms, but not with respect to the number of source forms: multi-

source has more source forms available for training than single-source. We leave investigation of this important issue for future work.

## Acknowledgments

We gratefully acknowledge the financial support of Siemens and of DFG (SCHUE 2246/10-1) for this research. The second author was supported by a DAAD Long-Term Research Grant and an NDSEG fellowship.

## Abstract

Automatic post-editing (APE) for machine translation (MT) aims to fix recurrent errors made by the MT decoder by learning from correction examples. In controlled evaluation scenarios, the representativeness of the training set with respect to the test data is a key factor to achieve good performance. Real-life scenarios, however, do not guarantee such favorable learning conditions. Ideally, to be integrated in a real professional translation workflow (e.g. to play a role in computer-assisted translation framework), APE tools should be flexible enough to cope with continuous streams of diverse data coming from different domains/genres. To cope with this problem, we propose an online APE framework that is: *i*) robust to data diversity (i.e. capable to learn and apply correction rules in the right contexts) and *ii*) able to evolve over time (by continuously extending and refining its knowledge). In a comparative evaluation, with English-German test data coming in random order from two different domains, we show the effectiveness of our approach, which outperforms a strong batch system and the state of the art in online APE.

## 1 Introduction

Automatic post-editing (APE) systems for machine translation (MT) aim to correct the errors present in a machine-translated text before showing it to the user, thereby reducing human workload and eventually increase translation productivity. The choice of having such post-processing systems is well motivated in (Bojar et al., 2015) and becomes a must when the MT engine used

to translate is not directly accessible for retraining or for more radical internal modifications (e.g. when working with a third party MT system). As pointed out by (Parton et al., 2012; Chatterjee et al., 2015b), from the application point of view an APE system can help to: *i*) Improve MT output by exploiting information unavailable to the decoder, or by performing deeper text analysis that is too expensive at the decoding stage; *ii*) Provide professional translators with improved MT output quality to reduce (human) post-editing effort and *iii*) Adapt the output of a general-purpose MT system to the lexicon/style requested in a specific application domain. Similar to what is usually done in MT, APE components learn post-editing rules from “parallel” corpora consisting of machine-translated text (*mt*, optionally with its corresponding source text – *src*) and its post-edits (*pe*) provided by human post-editors. The effectiveness of learning from relatively small amounts of post-edited data is evident from the impressive outcomes of the recently held APE shared task at WMT 2016 (Bojar et al., 2016). Different APE paradigms, like neural (Junczys-Dowmunt and Grundkiewicz, 2016), hybrid (Chatterjee et al., 2016), and phrase-based (Pal et al., 2016) were all able to significantly improve MT output quality in the IT domain, with gains ranging from 2.0 to 5.5 BLEU points. Nevertheless, this success and the positive outcomes of previous work on automatic MT error correction build on a problem formulation that assumes to operate in a controlled lab environment, where the systems are trained and evaluated across a coherent/homogeneous data set. Moving from this controlled scenario to real-world translation workflows, where training and test data can be produced by different MT systems, post-edited by various translators and belong to several text genres, makes the task inherently more challenging, because the APE systems have to adapt to

all these diversities in real-time. In addition to the problem that training data provide a fraction of the possible error correction examples (a normal issue when learning from finite, often small training data), the additional complexity derives from two concurrent factors. First, not all the learned error correction rules are universally applicable: applying them in the wrong context can damage the MT output instead of improving it. Second, once in production, the APE system should be able to process streams of diverse input data presented in random order: promptly reacting to such variability is hence crucial. We define this more complex and realistic scenario as a *multi-domain* translation environment (MDTE), where a domain is made of segments belonging to the same text genre and the MT outputs are generated by the same MT system.

To our knowledge, the evaluation of APE systems on MDTE data in real-time/online translation scenarios is still unexplored. This paper represents a first step along this direction: although a full-fledged evaluation centered on human translation in a computer-assisted translation (CAT) framework is out of our reach, we provide a proof of concept in which we simulate the MDTE scenario by running different APE solutions on a stream of data coming from two different domains. By analysing alternative solutions, we discuss the limitations not only of batch APE methods (insensitive to domain shifts), but also of state-of-the-art online translation systems evaluated in the APE task in MDTE conditions. Thot (Ortiz-Martinez and Casacuberta, 2014), the online system used as term of comparison, shows in fact the inability to discern which of the learned correction rules is suitable for a specific context. In practice, all rules are created equal, for any given domain.

To overcome this limitation, we proceed incrementally. First, we propose an approach based on an instance selection strategy, which learns local, sentence-specific APE models from small amounts of relevant data for each translation to be post-edited. Then, on top of it, we add an improved way to estimate the parameters of the sentence-specific APE models. To this aim, we exploit a dynamic knowledge base that keeps track of global statistics computed over all the previously seen data (i.e. it does not rely only on those computed from the selected instances). Finally, the dynamic knowledge base gives us the possibility to experiment with new features in addition to those

used by current APE systems based on the phrase-based MT paradigm. Such features incorporate in the translation models also the negative feedback collected from human post-editors. Instead of continuously expanding our knowledge base of correction rules (i.e. only considering the positive feedback about how to correct a given error), we also stepwise refine it by weighing the acquired correction rules according to their reliability (e.g. demoting those that led to corrections eventually modified by the human). Positive evaluation results reflect this incremental approach. To summarize, our contribution is a fully automated online APE system that does not rely on pre-trained models or tuned weights (unlike Thot that needs to be pre-trained and tuned) and incorporates for the first time both positive and negative post-editors' feedback to set the state-of-the-art in the difficult task of APE in the MDTE scenario.

## 2 Related work

Most of the previous works on APE cast the problem as a phrase-based statistical MT task<sup>1</sup> and operate in a batch framework where systems are evaluated on static test sets that are homogeneous with the training data (Simard et al., 2007; Dugast et al., 2007; Terumasa, 2007; Pilevar, 2011; Béchara et al., 2011; Chatterjee et al., 2016). These systems, however, are not able to leverage the feedback of the post-editors in an online translation scenario. The capability to evolve by learning from human feedback has been addressed by several online translation systems but mainly focusing on the MT task (Hardt and Elming, 2010; Bertoldi et al., 2013; Mathur et al., 2013; Simard and Foster, 2013; Ortiz-Martinez and Casacuberta, 2014; Denkowski et al., 2014; Wuebker et al., 2015). From these several online MT systems, we discuss the two that have been used also for the APE task.

**PEPr: Post-Edit Propagation.** (Simard and Foster, 2013) proposed a method for post-edit propagation (PEPr), which learns post-editors' corrections and applies them on-the-fly to an MT output sequence. To perform post-edit propagation, the system is trained incrementally us-

---

<sup>1</sup>Only recently, the wave of neural models has also reached the APE task (Junczys-Dowmunt and Grundkiewicz, 2016), setting the new state of the art at WMT (Bojar et al., 2016). The problem addressed in this paper (dealing with MDTE data), as well as the proposed online solution are still too computationally intensive to experiment with neural models. We hence leave this aspect as a future work direction.

ing pairs of machine-translated (*mt*) and human post-edited (*pe*) segments as they were produced. When receiving a new (*mt*, *pe*) pair, word alignments are obtained using Damerau-Levenshtein distance. In the next step, the phrase pairs are extracted and appended to the existing phrase table. The whole process is assumed to take place within the context of a single document and, for every new document, the APE system is initialised with an “empty” model. This represents a possible limitation of the approach: although document-specific correction rules show a relatively high precision, some of them might in fact be useful also in other contexts and should be retained. Our approach avoids this limitation by maintaining a global knowledge base to store all the processed documents, still being able to retrieve post-editing rules specific to a document to be translated.<sup>2</sup>

**Thot.** The Thot toolkit (Ortiz-Martinez and Casacuberta, 2014) is developed to support automatic and interactive statistical machine translation.<sup>3</sup> It was also successfully used by Lagarda et al. (2015) to experiment in an online APE setting with several data sets for multiple language pairs, with base MT systems built using different technologies (rule-based MT, statistical MT). In order to incorporate user feedback in the underlying translation and language models, the systems maintains and incrementally updates all the required statistics. For the language model, it simply updates n-gram counts. In the case of the translation model, the process exploits an incremental version of expectation maximization algorithm to obtain word alignments and extract the phrase pairs whose counts are continuously updated. Other features, like source/target phrase-length models or the distortion model, are extracted considering geometric distributions with fixed parameters. The feature weights of the log-linear model are static throughout the online learning process, as opposed to our method that updates the weights on-the-fly. This makes our online APE approach independent from any pre-trained model or pre-tuned feature weights. Moreover, while in Thot the correction rules are learned in real-time from all the data processed, our system only learns from the most relevant data samples. Neverthe-

less, considering Thot as the state-of-the-art in online APE, we will use it as a term of comparison in our experiments.

### 3 Online APE system

The backbone of our online APE system is similar to the state-of-the-art statistical batch APE approach proposed in (Chatterjee et al., 2015b). The system is trained on (*src*, *mt*, *pe*) triplets, and learns correction rules in the form of (*mt*#*src*, *pe*) pairs. The first element of each pair consists of MT phrases (single or multiple words) that are associated to their corresponding source words by using a word alignment model. This “joint representation” helps to restrict the applicability of each rule to the appropriate context, and was shown to perform better than using only the *mt* words as the left-hand side of the rules (Béchara et al., 2011). Our migration to the online scenario builds on incrementally extending this backbone with an instance selection mechanism (§3.1), a dynamic knowledge base (§3.2) and new features (§3.3).

#### 3.1 Instance selection

Current batch and online APE methods estimate parameters of the models over all the available training data. This strategy may not be effective in the MDTE scenario, since the model will tend to become more and more generic by incorporating knowledge from several domains. In the long-run, this can complicate the selection of domain-specific correction rules suitable for a particular MT segment. One of the possible solutions is to constrain the system to work at document level as proposed by Simard and Foster (2013). In their approach, however, the models are reset back to their original state once the entire document is processed, due to which knowledge gained from the current document is lost. Our instance selection technique aims to overcome this issue, allowing the system to preserve all the knowledge acquired during the online learning process, still being able to apply specific post-editing rules when needed.

The instance selection mechanism consists in retrieving *ad-hoc* training sentence pairs for each MT output to be post-edited. In practice, the creation of the APE model and the estimation of its parameters are performed on-the-fly by processing relevant instances retrieved from the previously processed data. In the MDTE scenario, this will come from heterogeneous domains. The rele-

<sup>2</sup>In our experiments we do not compare against PEP since, being designed for document-level translation it is unable to operate in the MDTE scenario.

<sup>3</sup><https://github.com/daormar/thot>

vance of a training sample is measured in terms of a similarity score based on term frequency-inverse document frequency (tf-idf<sup>4</sup>) computed using the Lucene software library.<sup>5</sup> Indexing and retrieving training triplets (*src*, *mt*, and *pe*) in this mechanism is fast, which makes it perfectly suitable to use in an online learning scenario. The cut-off similarity score is empirically estimated over a held-out development set. Input segments not having training samples above the threshold are left untouched to avoid any possible damage resulting from the application of unreliable correction rules learned from unrelated contexts. This is in contrast with the strategy adopted by current APE systems, which tend to always “translate” the given input segment, independently from the reliability of the applicable correction rules.

Once the training samples are selected for an input segment, several models are built on-the-fly. A tri-gram local language model (LM) is built over the target side of the training corpus with the IRSTLM toolkit (Federico et al., 2008). Along with the local LM a tri-gram global LM is also used, which is updated whenever a human post-edition (*pe*) is received. Local translation and reordering models are built with the Moses toolkit (Koehn et al., 2007), computing word alignment for each sentence pair using the incremental GIZA++ software.<sup>6</sup>

The feature weights of the log-linear model are optimized over a subset of the selected instances. The size of this development set is critical: if it is too large, then parameter optimization will be expensive. On the other hand, if it is too small, the tuned weights might not be reliable. To achieve fast optimization with reliably-tuned weights, multiple instances of MIRA (Crammer and Singer, 2003) are run in parallel on multiple development sets (Tange, 2011). For this purpose, the retrieved samples are randomly split three times into training and development. The tuned weights resulting from the three development runs are then averaged and used to decode the input MT segment.

To summarize, our training/tuning scheme requires a minimum number of retrieved sentence

<sup>4</sup>In MT, tf-idf was previously used by Hildebrand et al. (2005) to create a pseudo in-domain corpus from a large out-of-domain corpus. Our work is the first to investigate it for the APE task in an online learning scenario.

<sup>5</sup><https://lucene.apache.org/>

<sup>6</sup><https://code.google.com/archive/p/inc-giza-pp/>

pairs. Following an 80%-20% distribution over training and development data, and setting to 5 the minimum number of samples needed for tuning, the complete process requires the retrieval of at least 25 samples. If this number is not reached, all the retrieved samples are used for training, the optimization step is skipped and the previously computed weights are used. If no sample is selected, then the MT output will be left untouched.

### 3.2 Dynamic knowledge base

The APE system described so far is built by considering only the most similar retrieved sentences, which we hypothesize to be the most useful to learn reliable corrections for a given MT output. On one hand, this strategy avoids to end up with correction options that are not appropriate to post-edit the MT output. On the other hand, it computes the statistics of the models (i.e. translation and lexicalized reordering probabilities) using only few parallel sentences, resulting in potentially unreliable values that can penalise the work of the decoder. To address this issue, we complement instance selection with a dynamic knowledge base able to keep track of all the previous observations relevant for post-editing. Such a component provides the decoder with all the translation options extracted from the retrieved sentences but, instead of computing the probabilities only on these segments, it takes advantage of all the occurrences of a translation option in the previously processed sentences. This allows our online APE system to use only the most useful translation options, associated with more reliable statistics.

The dynamic knowledge base is implemented by a distributed, scalable and real-time inverted index that, after insertion, makes all data immediately available for search and update. The ElasticSearch<sup>7</sup> engine is used for this purpose. Once the post-edit is made available to our system, the word alignment between the *mt* and the *pe* is computed, the sentence pair is split in phrases and then added to the dynamic model. If a translation option is already present, then the phrase translation and the orientation counts are updated, otherwise it is inserted for the first time. This is run in multi-threading, by also managing possible conflicts (i.e. the access to the same translation option by different threads). Word lexical information and phrase

<sup>7</sup><http://www.elastic.co/products/elasticsearch>

counts are stored apart. At decoding time, the IDs of the samples retrieved by instance selection and the *mt* sentences are used to query the dynamic knowledge base. The translation options that satisfy the query are retrieved and supplied to the decoder in the form of translation and reordering model information. All the feature scores (four for the translation model and six for the reordering model) are computed on-the-fly.

Compared to the suffix arrays used to implement MT dynamic models (Germann, 2014; Denkowski et al., 2014), in which the whole sentence pairs are stored, our technique needs to save more information (all the translation options) but: *i*) the amount of data in APE is much less than in MT so it can be easily managed by *ad hoc* solutions, and *ii*) it allows us to collect global information at translation option level that can result in useful additional features for the model. This last aspect is explored in the next section, in which the reliability of the translation options is measured by looking at the behavior of the post-editors.

### 3.3 Negative feedback in-the-loop

Similar to the APE systems mentioned in Section 2, the one described so far stores only post-editors’ positive feedback. Its knowledge base of correction rules and the statistics to estimate the model parameters are in fact continuously updated only based on alignment information between (*mt*, *pe*) pairs. Post-edits, however, can also be used to infer negative feedback and use it to penalize unreliable correction options (i.e. those resulting in post-edits eventually modified by the human). The dynamic knowledge base allows us to easily integrate this kind of information, in the form of two additional “negative feedback” features:

- F1. This feature penalizes the correction rules that are selected by the decoder but eventually modified by the post-editor. This can be due to the application of a rule in the wrong context (e.g. in case of domain changes in the input stream of data) but, most likely, to the fact that the learned rule is wrong (e.g. as the result of ambiguous/wrong word alignment). It is computed as the ratio of the number of times the post-editors modified a correction made by the APE decoder to the total number of times the decoder has made the correction. The information about which correction rules have been

applied by the APE system is obtained from the Moses decoder `trace` option. The information about which of them has been modified is derived by string matching the target side of the rule in the final human post-edit.

- F2. This rule penalizes the correction rules that, even if not used, were available to the decoder (i.e. translation options discarded during decoding). Assuming that the application of these options would have been eventually corrected by the post-editor, all the rules in the phrase table are scanned to check if their target side (i.e. the correction) is present in the final human post-edit (again by string matching). If not, then the corresponding rule is penalised. This feature is computed as the ratio of the number of times the correction in the phrase table is (assumed to be) modified by the post-editor to the total number of time the correction rule has been seen in the local phrase table for all the segments processed so far. Since the decoder operates with a segment-specific local phrase table containing only the options relevant to the segment to be post-edited, computing this feature is not expensive.

We also evaluate system performance by using the two features together. As we will see in Section 5, although our use of negative feedback is still at a preliminary stage, its integration in our online APE framework yields some improvements.

## 4 Evaluation setting

**Data.** We experiment with two English-German data sets: *i*) the data released for the APE shared task organised within the first Conference on Machine Translation (WMT16) (Bojar et al., 2016), and *ii*) the data used in (Chatterjee et al., 2015b), which is a subset of the Autodesk Post-Editing Data corpus.<sup>8</sup> Although they come from the same category (IT), they feature variability in terms of vocabulary, MT engines used for translation, MT errors and post-editing style. According to our broad notion of “domain”, these variations contribute to make the two data sets different enough to emulate an MDTE scenario for testing online APE capabilities. The data are pre-processed to obtain a joint representation that

<sup>8</sup><https://autodesk.app.box.com/v/autodesk-postediting>

	Tokens		Types		Avg. segment length		RR ( <i>mt#src</i> )	TER
	<i>mt#src</i>	<i>pe</i>	<i>mt#src</i>	<i>pe</i>	<i>mt#src</i>	<i>pe</i>		
Autodesk	153,943	160,801	31,939	15,023	12.57	13.13	4.938	45.35
WMT16	210,573	214,720	32211	16,388	17.54	17.89	4.907	26.22

Table 1: Data statistics

links each MT word with its corresponding source word/s (*mt#src*). This representation, proposed by Béchara et al. (2011), leverages the source information to disambiguate post-editing rules and foster their application only in appropriate contexts (the matching condition is defined both on the source and on the target language). The joint representation is used as a source corpus to train all the APE systems compared in this paper and it is obtained by concatenating words in the source (*src*) and in the MT (*mt*) segments after aligning them with MGIZA++ (Gao and Vogel, 2008).

The Autodesk training and development sets consist of 12,238, and 1,948 segments respectively, while the WMT16 data contains 12,000, and 1,000 segments. Table 1 provides additional statistics of the source (*mt#src*) and target (*pe*) training sets, the repetition rate (RR) to measure the repetitiveness inside a text (Bertoldi et al., 2013), and the average TER score for both the data sets (computed between MT and PE), as an indicator of the original translation quality. Looking at these statistics, there are several indicators that suggest that the WMT16 corpus provides a more difficult scenario for APE than the Autodesk one. First, the WMT16 corpus has on average longer sentences, which generally increases the complexity of the rule extraction and decoding processes. Second, although the two data sets have a similar repetition rate, the WMT16 has more tokens indicating the higher sparsity of the data. Finally, the lower TER of WMT16 suggests that there are less corrections to perform and, in turn, a higher chance to deteriorate the original MT output if the learned rules are applied in the wrong context.

To conclude, we measure the diversity of the two data sets by computing the vocabulary overlap between the two joint representations. This is performed internally to each data set (splitting the training data in two halves) and across them. As expected, in the first case the vocabulary overlap is much larger ( $> 40\%$ ) than in the second case ( $\sim 15\%$ ) indicating that the information to share between the two data sets is minimal.

In our MDTE experiments, the training data is first merged, then shuffled and then split in two halves of 12,119 segments. The same procedure is applied to the development sets.

**Evaluation metrics.** The performance of the different systems is evaluated in terms of Translation Error rate (TER) (Snover et al., 2006), BLEU (Papineni et al., 2002), and precision (Chatterjee et al., 2015a). TER and BLEU measure the similarity between the MT output and the corresponding references (in this case human post-edits) by looking at the word/n-gram overlaps. Precision is the ratio of the number of sentences an APE system improves (with respect to the MT output) over all the sentences it modifies.<sup>9</sup> Higher precision indicates that the APE system is able to improve the quality of most of the sentences it changed. The statistical significance of BLEU results is computed using paired bootstrap resampling (Koehn, 2004). For TER, we use stratified approximate randomization (Clark et al., 2011).

**Terms of comparison.** We evaluate our online learning approach against: *i*) the MT baseline (i.e. the MT output left untouched), *ii*) the batch APE system described in Section 3, on top of which we incrementally add our online learning extensions, and *iii*) the Thot toolkit.

## 5 Experiments and results

The batch APE system is trained on the first half of the shuffled training set, tuned with the development set (2,948 segments), and evaluated over the second half of the training data. Since the batch APE only learns from the training set, we expect its performance to give us a lower bound estimate, which should be outperformed by the online APE systems that can learn from the test data too. To run the online experiments with Thot, the system first needs to estimate the feature weights of the log-linear model on a develop-

<sup>9</sup>For each sentence in the test set, if the TER score of the APE system is different from the baseline then it is considered as a modified sentence.

ment set. For this purpose, it is trained and tuned off-line like a batch APE system. Three online extensions of the batch backbone architecture described in Section 3 are evaluated. These are: *i*) the instance selection system (IS); *ii*) the dynamic knowledge base system (IS+DynKB) and *iii*) the dynamic knowledge base system enhanced with the negative feedback features, both alone and in combination (IS+DynKB+F1, IS+DynKB+F2 and IS+DynKB+F1+F2). For all of them, the cut-off similarity score is obtained by grid search and is set to 0.8. The results achieved by each system are reported in Table 2.

	BLEU $\uparrow$	TER $\downarrow$	Prec. (%)
MT	52.31	34.52	N/A
Batch APE	52.52	34.45	42.67
Thot	52.51	34.37	42.22
IS	53.35 $\dagger$	33.36 $\dagger$	58.47
IS+DynKB	53.60 $\dagger$	33.23 $\dagger$	59.69
IS+DynKB+F1	53.56 $\dagger$	33.29 $\dagger$	58.97
IS+DynKB+F2	53.21 $\dagger$	33.48 $\dagger$	54.64
IS+DynKB+F1+F2	<b>53.77<math>\dagger</math></b>	<b>33.20<math>\dagger</math></b>	<b>60.93</b>

Table 2: Results on the mixed data. (“ $\dagger$ ” indicates statistically significant difference wrt. the MT baseline with  $p < 0.05$ ).

As can be seen from the table, the batch APE system is able to slightly improve over the baseline even if it damages most of the translations it changes (its precision is in fact lower than 45%). Although it learns also from the test data, Thot achieves similar results. This is probably due to its inability to identify domain-specific correction rules needed to improve the translations, thus ending up with damaging the majority of the modified MT segments. A significant gain in performance (+1.04 BLEU, -1.16 TER points) is obtained by our online IS system that, by using the instance selection technique, is able to isolate only the most useful training samples. This mechanism also improves precision up to 58.4% ( $\sim 16\%$  above Thot), indicating that the applied post-editing rules are correct in the majority of the cases. The analysis of the performance of the two online systems reveals that our approach modifies less segments compared to Thot, due to the fact that it builds sentence-specific models only if it finds relevant data, leaving the MT segment untouched otherwise. In several cases, when modified by the Thot system, these untouched segments result in deterio-

rated sentences.

Further performance improvements are yielded by the dynamic knowledge base (IS+DynKB), which provides the decoder with a better estimation of the APE model parameters. Although the BLEU and TER gains are minimal, the dynamic knowledge base helps to significantly increase the precision of the APE system avoiding unnecessary changes, thus confirming the effectiveness of keeping track of the whole past history of each translation option. Our implementation of the dynamic knowledge base also allows us to add the two “negative feedback” features that model the reliability of the translation options by looking at the changes made by the post-editors. When used in combination, the two negative feedback features (IS+DynKB+F1+F2) yield visible gains in performance over (IS+DynKB) with small but statistically significant improvement in BLEU score, along with a precision gain of 1.24%. This suggests their possible complementarity with the translation and reordering features and the need of further investigation in future work. Overall our full-fledged system achieves state-of-the-art results with significant improvement over Thot by 1.26 BLEU, 1.17 TER, and 18.71% Precision.

## 6 Analysis

To understand and compare the behavior of the batch APE, Thot and our best online system in the long-run, the plot in Figure 1 shows the TER moving average (window of 750 data points) at each segment of the test set (second half of the shuffled training data). As can be seen, our approach successfully maintains the best performance across the entire test set. Moreover, looking at the first

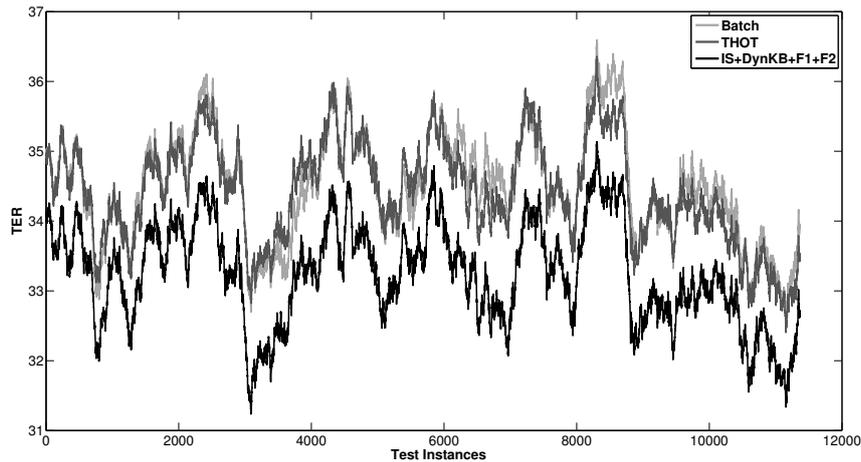

Figure 1: Performance comparison of different online APE systems (TER moving average).

Table 4: Sample outputs where our approach outperform THOT (erroneous words are in bold)

and the last 250 points in the test set, we notice that the performance gap between our best system and Thot increases on average from 0.8 to 1.6 TER points. This shows that, during processing, our approach is able to self-adapt in real-time towards the domain-shifts in the input stream of data. To better understand their behavior with respect to data coming from the two domains, systems' output has been separately evaluated per domain. The results of this evaluation are reported in Table 3.

For the Autodesk and the APE shared task domain there are 6,166 and 5,953 segments respectively. It is interesting to see that all the APE systems improve the translations belonging to the Autodesk domain by a large margin, with our approach being the best. The same does not hold for the other domain, which, as discussed in Sec-

tion 5, is more challenging due to several factors like longer sentence length, higher data sparsity and, most of all, lower translation quality. For this challenging domain, however, our approach has the least degradation compared to the other APE methods that severely damage the translations. Overall, compared to other APE approaches, our best system has the best performance in both the domains when evaluated in isolation.

To evaluate the efficiency of our approach, we computed the average time in seconds to perform a full online cycle over the test set (*i.e.* the time needed for post-editing the MT output and updating the models) for Thot, IS and IS+DynKB+F1+F2. Thot spends on average 4.75 seconds per cycle. The IS system, which builds its models on-the-fly by leveraging only the selected

Table 5: Sample output where our approach performs poor than THOT (erroneous words are in bold)

data and optimises the weights before post-editing, is faster than Thot, with a gain of 1.03 seconds (3.62" on average). The use of the dynamic model, that is faster in updating and dumping the tables, allows our best system to perform a full online cycle in 3.05", showing that our approach is not only better in terms of performance but also in computation time.

Tables 4 and 5 respectively show examples where our approach performs better/worse than Thot. Both tables report the source sentence (SRC), the MT output to be post-edited (MT), the MT and the PE segment of the top training samples retrieved based on cosine similarity (MT-TopX/PE-TopX, where X is the rank of the training sample), the output of Thot, the output of our best system (IS+DynKB+F1+F2) and the reference (REF). Table 4 seems to confirm our intuition that learning from the most similar examples yields better translation quality. An interesting counter example is shown in Table 5, where despite having access to a training sample (MT-Top1 and PE-Top1) that is exactly the same as the MT segment to be post-edited, our system deteriorates the translation by selecting a translation option ("zu platzieren" → "zum Platzieren") learned from a lower ranked training sample (MT-Top4 and PE-Top4), which probably received a higher weight from the local models. In future work, we will try to extend our system to address this issue by prioritizing the translation rules according to the rank of the training samples.

## 7 Conclusion

In recent years, APE systems achieved impressive results in fixing recurrent errors in machine-translated texts. Such gains, however, were mostly

observed in controlled lab environments, where systems are trained, tuned, and evaluated with repetitive and homogeneous training/test data. These favorable learning conditions may not hold in real-world professional translation workflow, in which streams of data to be processed in real-time may feature a high diversity in terms of domain, post-editing style and MT systems that generated the translations. In this paper, we investigated for the first time the challenges posed to APE technology by such multi-domain translation environments. Our study revealed that the existing online and batch solutions are not robust enough for this scenario due to their inability to discern which of the learned rules is suitable for a specific context (in fact, a correction rule learned from one domain may not be valid for other domains). We addressed this problem incrementally, first by proposing an instance selection technique that learns rules from contexts that are similar to the MT segment to be post-edited. The gains achieved by this solution over the existing batch APE methods were further increased by the addition of a dynamic knowledge base that stores more reliable statistics about the learned translation options, also improving the computation time. The adoption of this dynamic knowledge base allowed us to further extend our online approach by including features that capture negative human feedback, giving to the system the capability to learn from the mistakes it made in the past. Our evaluation results indicate that our approach improves state of the art performance on an English-German MDTE data set.

## Abstract

Abstract Meaning Representation (AMR) is a semantic representation for natural language that embeds annotations related to traditional tasks such as named entity recognition, semantic role labeling, word sense disambiguation and co-reference resolution. We describe a transition-based parser for AMR that parses sentences left-to-right, in linear time. We further propose a test-suite that assesses specific sub-tasks that are helpful in comparing AMR parsers, and show that our parser is competitive with the state of the art on the LDC2015E86 dataset and that it outperforms state-of-the-art parsers for recovering named entities and handling polarity.

## 1 Introduction

Semantic parsing aims to solve the problem of canonicalizing language and representing its meaning: given an input sentence, it aims to extract a semantic representation of that sentence. Abstract meaning representation (Banarescu et al., 2013), or AMR for short, allows us to do that with the inclusion of most of the shallow-semantic natural language processing (NLP) tasks that are usually addressed separately, such as named entity recognition, semantic role labeling and co-reference resolution. AMR is partially motivated by the need to provide the NLP community with a single dataset that includes basic disambiguation information, instead of having to rely on different datasets for each disambiguation problem. The annotation process is straightforward, enabling the development of large datasets. Alternative semantic representations have been developed and stud-

ied, such as CCG (Steedman, 1996; Steedman, 2000) and UCCA (Abend and Rappoport, 2013).

Several parsers for AMR have been recently developed (Flanigan et al., 2014; Wang et al., 2015a; Peng et al., 2015; Pust et al., 2015; Goodman et al., 2016; Rao et al., 2015; Vanderwende et al., 2015; Artzi et al., 2015; Zhou et al., 2016). This line of research is new and current results suggest a large room for improvement. Greedy transition-based methods (Nivre, 2008) are one of the most popular choices for dependency parsing, because of their good balance between efficiency and accuracy. These methods seem promising also for AMR, due to the similarity between dependency trees and AMR structures, i.e., both representations use graphs with nodes that have lexical content and edges that represent linguistic relations.

A transition system is an abstract machine characterized by a set of configurations and transitions between them. The basic components of a configuration are a stack of partially processed words and a buffer of unseen input words. Starting from an initial configuration, the system applies transitions until a terminal configuration is reached. The sentence is scanned left to right, with linear time complexity for dependency parsing. This is made possible by the use of a greedy classifier that chooses the transition to be applied at each step.

In this paper we introduce a parser for AMR that is inspired by the ARCEAGER dependency transition system of Nivre (2004). The main difference between our system and ARCEAGER is that we need to account for the mapping from word tokens to AMR nodes, non-projectivity of AMR structures and reentrant nodes (multiple incoming edges). Our AMR parser brings closer dependency parsing and AMR parsing by showing that dependency parsing algorithms, with some mod-

ifications, can be used for AMR. Key properties such as working left-to-right, incrementality<sup>1</sup> and linear complexity further strengthen its relevance.

The AMR parser of Wang et al. (2015a), called CAMR, also defines a transition system. It differs from ours because we process the sentence left-to-right while they first acquire the entire dependency tree and then process it bottom-up. More recently Zhou et al. (2016) presented a non-greedy transition system for AMR parsing, based on ARC-STANDARD (Nivre, 2004). Our transition system is also related to an adaptation of ARCEAGER for directed acyclic graphs (DAGs), introduced by Sagae and Tsujii (2008). This is also the basis for Ribeyre et al. (2015), a transition system used to parse dependency graphs. Similarly, Du et al. (2014) also address dependency graph parsing by means of transition systems. Analogously to dependency trees, dependency graphs have the property that their nodes consist of the word tokens, which is not true for AMR. As such, these transition systems are more closely related to traditional transition systems for dependency parsing.

Our contributions in this paper are as follows:

- In §3 we develop a left-to-right, linear-time transition system for AMR parsing, inspired by the ARCEAGER transition system for dependency tree parsing;
- In §5 we claim that the Smatch score (Cai and Knight, 2013) is not sufficient to evaluate AMR parsers and propose a set of metrics to alleviate this problem and better compare alternative parsers;
- In §6 we show that our algorithm is competitive with publicly available state-of-the-art parsers on several metrics.

## 2 Background and Notation

**AMR Structures** AMRs are rooted and directed graphs with node and edge labels. An annotation example for the sentence *I beg you to excuse me* is shown in Figure 1, with the AMR graph reported in Figure 2.

Concepts are represented as labeled nodes in the graph and can be either English words (e.g. *I* and *you*) or Propbank framesets (e.g. *beg-01* and

<sup>1</sup>Strictly speaking, transition-based parsing cannot achieve full incrementality, which requires to have a single connected component at all times (Nivre, 2004).

```
(b / beg-01
  :ARG0 (i / i
        :ARG1 (y / you
              :ARG2 (e / excuse-01
                    :ARG0 y
                    :ARG1 i)))
```

Figure 1: Annotation for the sentence “*I beg you to excuse me.*” Variables are in boldface and concepts and edge labels are in italics.

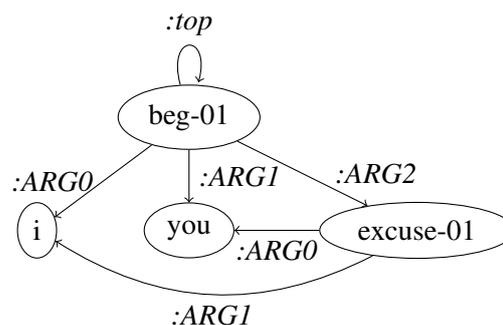

Figure 2: AMR graph representation for Figure 1.

*excuse-01*). Each node in the graph is assigned to a variable in the AMR annotation so that a variable re-used in the annotation corresponds to reentrancies (multiple incoming edges) in the graph. Relations are represented as labeled and directed edges in the graph.

**Notation** For most sentences in our dataset, the AMR graph is a directed acyclic graph (DAG), with a few specific cases where cycles are permitted. These cases are rare, and for the purpose of this paper, we consider AMR as DAGs.

We denote by  $[n]$  the set  $\{1, \dots, n\}$ . We define an AMR structure as a tuple  $(G, x, \pi)$ , where  $x = x_1 \dots x_n$  is a sentence, with each  $x_i, i \in [n]$ , a word token, and  $G$  is a directed graph  $G = (V, E)$  with  $V$  and  $E$  the set of nodes and edges, respectively.<sup>2</sup> We assume  $G$  comes along with a node labeling function and an edge labeling function. Finally,  $\pi: V \rightarrow [n]$  is a total alignment function that maps every node of the graph to an index  $i$  for the sentence  $x$ , with the meaning that node  $v$  represents (part of) the concept expressed by the word  $x_{\pi(v)}$ .<sup>3</sup>

We note that the function  $\pi$  is not invertible,

<sup>2</sup>We collapse all multi-word named entities in a single token (e.g., *United Kingdom* becomes *United\_Kingdom*) both in training and parsing.

<sup>3</sup> $\pi$  is a function because we do not consider co-references,

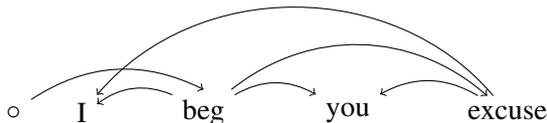

Figure 3: AMR’s edges for the sentence “I beg you to excuse me.” mapped back to the sentence, according to the alignment.  $\circ$  is a special token representing the root.

since it is neither injective nor surjective. For each  $i \in [n]$ , we let

$$\pi^{-1}(i) = \{v \mid v \in V, \pi(v) = i\}$$

be the pre-image of  $i$  under  $\pi$  (this set can be empty for some  $i$ ), which means that we map a token in the sentence to a set of nodes in the AMR. In this way we can align each index  $i$  for  $x$  to the induced subgraph of  $G$ . More formally, we define

$$\overleftarrow{\pi}(i) = (\pi^{-1}(i), E \cap (\pi^{-1}(i) \times \pi^{-1}(i))), \quad (1)$$

with the node and edge labeling functions of  $\overleftarrow{\pi}(i)$  inherited from  $G$ . Hence,  $\overleftarrow{\pi}(i)$  returns the AMR subgraph aligned with a particular token in the sentence.

## 2.1 Transition-Based AMR Parsing

Similarly to dependency parsing, AMR parsing is partially based on the identification of predicate-argument structures. Much of the dependency parsing literature focuses on *transition-based* dependency parsing—an approach to parsing that scans the sentence from left to right in linear time and updates an intermediate structure that eventually ends up being a dependency tree.

Because of the similarity of AMR structures to dependency structures, transition systems are also helpful for AMR parsing. Starting from the ARCEAGER system, we develop here a novel transition system, called AMREAGER that parses sentences into AMR structures. There are three key differences between AMRs and dependency trees that require further adjustments for dependency parsers to be used with AMRs.

**Non-Projectivity** A key difference between English dependency trees and AMR structures is projectivity. Dependency trees in English are usually projective, roughly meaning that there are no

which would otherwise cause a node to map to multiple indices. This is in line with current work on AMR parsing.

Non-projective edges	6%
Non-projective AMRs	51%
Reentrant edges	41%
AMRs with at least one reentrancy	93%

Table 1: Statistics for non-projectivity and reentrancies in 200 AMR manually aligned with the associated sentences.<sup>5</sup>

crossing arcs if the edges are drawn in the semi-plane above the words. While this restriction is empirically motivated in syntactic theories for English, it is no longer motivated for AMR structures.

The notion of projectivity can be generalized to AMR graphs as follows. The intuition is that we can use the alignment  $\pi$  to map AMR edges back to the sentence  $x$ , and test whether there exist pairs of crossing edges. Figure 3 shows this mapping for the AMR of Figure 2, where the edge connecting *excuse* to *I* crosses another edge. More formally, consider an AMR edge  $e = (u, \ell, v)$ . Let  $\pi(u) = i$  and  $\pi(v) = j$ , so that  $u$  is aligned with  $x_i$  and  $v$  is aligned with  $x_j$ . The spanning set for  $e$ , written  $\mathcal{S}(e)$ , is the set of all nodes  $w$  such that  $\pi(w) = k$  and  $i < k < j$  if  $i < j$  or  $j < k < i$  if  $j < i$ . We say that  $e$  is **projective** if, for every node  $w \in \mathcal{S}(e)$ , all of its parent and child nodes are in  $\mathcal{S}(e) \cup \{u, v\}$ ; otherwise, we say that  $e$  is **non-projective**. An AMR is projective if all of its edges are projective, and is non-projective otherwise. This corresponds to the intuitive definition of projectivity for DAGs introduced in Sagae and Tsujii (2008) and is closely related to the definition of non-crossing graphs of Kuhlmann and Jonsson (2015).

Table 1 demonstrates that a relatively small percentage of all AMR edges are non-projective. Yet, a large fraction of the sentences contain at least one non-projective edge. Our parser is able to construct non-projective edges, as described in §3.

**Reentrancy** AMRs are graphs rather than trees because they can have nodes with multiple parents, called reentrant nodes, as in the node *you* for the AMR of Figure 2. There are two phenomena that cause reentrancies in AMR: control, where a reentrant edge appears between siblings of a control verb, and co-reference, where multiple men-

<sup>5</sup>[https://github.com/jflanigan/jamr/blob/master/docs/Hand\\_Alignments.md](https://github.com/jflanigan/jamr/blob/master/docs/Hand_Alignments.md)

tions correspond to the same concept.<sup>6</sup>

In contrast, dependency trees do not have nodes with multiple parents. Therefore, when creating a new arc, transition systems for dependency parsing check that the dependent does not already have a head node, preventing the node from having additional parents. To handle reentrancy, which is not uncommon in AMR structures as shown in Table 1, we drop this constraint.

**Alignment** Another main difference with dependency parsing is that in AMR there is no straightforward mapping between a word in the sentence and a node in the graph: words may generate no nodes, one node or multiple nodes. In addition, the labels at the nodes are often not easily determined by the word in the sentence. For instance *expectation* translates to *expect-01* and *teacher* translates to the two nodes *teach-01* and *person*, connected through an *:ARG0* edge, expressing that a teacher is a person who teaches. A mechanism of concept identification is therefore required to map each token  $x_i$  to a subgraph with the correct labels at its nodes and edges: if  $\pi$  is the gold alignment, this should be the subgraph  $\overleftarrow{\pi}(i)$  defined in Equation (1). To obtain alignments between the tokens in the sentence and the nodes in the AMR graph of our training data, we run the JAMR aligner.<sup>7</sup>

### 3 Transition system for AMR Parsing

A **stack**  $\sigma = \sigma_n | \dots | \sigma_1 | \sigma_0$  is a list of nodes of the partially constructed AMR graph, with the top element  $\sigma_0$  at the right. We use the symbol ‘|’ as the concatenation operator. A **buffer**  $\beta = \beta_0 | \beta_1 | \dots | \beta_n$  is a list of indices from  $x$ , with the first element  $\beta_0$  at the left, representing the word tokens from the input still to be processed. A **configuration** of our parser is a triple  $(\sigma, \beta, A)$ , where  $A$  is the set of AMR edges that have been constructed up to this point.

In order to introduce the transition actions of our parser we need some additional notation. We use a function  $a$  that maps indices from  $x$  to AMR graph fragments. For each  $i \in [n]$ ,  $a(i)$  is a graph  $G_a = (V_a, E_a)$ , with single root  $\text{root}(G_a)$ , representing the semantic contribution of word  $x_i$  to the

<sup>6</sup>A valid criticism of AMR is that these two reentrancies are of a completely different type, and should not be collapsed together. Co-reference is a discourse feature, working by extra-semantic mechanisms and able to cross sentence boundaries, which are not crossed in AMR annotation.

<sup>7</sup><https://github.com/jflanigan/jamr>

AMR for  $x$ . As already mentioned,  $G_a$  can have a single node representing the concept associated with  $x_i$ , or it can have several nodes in case  $x_i$  denotes a complex concept, or it can be empty.

The transition **Shift** is used to decide if and what to push on the stack after consuming a token from the buffer. Intuitively, the graph fragment  $a(\beta_0)$  obtained from the token  $\beta_0$ , if not empty, is “merged” with the graph we have constructed so far. We then push onto the stack the node  $\text{root}(a(\beta_0))$  for further processing. **L**Arc( $\ell$ ) creates an edge with label  $\ell$  between the top-most node and the second top-most node in the stack, and pops the latter. **R**Arc( $\ell$ ) is the symmetric operation, but does not pop any node from the stack.

Finally, **R**educe pops the top-most node from the stack, and it also recovers reentrant edges between its sibling nodes, capturing for instance several control verb patterns. To accomplish this, **R**educe decides whether to create an additional edge between the node being removed and the previously created sibling in the partial graph. With this operation the transition system is able to capture non-projective patterns,<sup>8</sup> according to the definition given in §2.1, when formed by arcs between nodes that share the same parent. This way of handling control verbs is similar to the *REEN-TRANCE* transition of Wang et al. (2015a).

The choice of popping the dependent in the **L**Arc transition is inspired by ARCEAGER, where left-arcs are constructed bottom-up to increase the incrementality of the transition system (Nivre, 2004). This affects our ability to recover some reentrant edges: consider a node  $u$  with two parents  $v$  and  $v'$ , where the arc  $v \rightarrow u$  is a left-arc and  $v' \rightarrow u$  is any arc. If the first arc to be processed is  $v \rightarrow u$ , we use **L**Arc that pops  $u$ , hence making it impossible to create the second arc  $v' \rightarrow u$ . Nevertheless, we discovered that this approach works better than a completely unrestricted allowance of reentrancy. The reason is that if we do not remove dependents at all when first attached to a node, the stack becomes larger, and nodes which should be connected end up being distant from each other, and as such, are never connected.

The initial configuration of the system has a  $\circ$  node (representing the root) in the stack and the entire sentence in the buffer. The terminal configuration consists of an empty buffer and a stack

<sup>8</sup>In an earlier version of this paper this mechanism was not used, yielding a strictly projective parser.

with only the  $\circ$  node. The transitions required to parse the sentence *The boy and the girl* are shown in Table 2, where the first line shows the initial configuration and the last line shows the terminal configuration.

Similarly to the transitions of the ARCEAGER, the above transitions construct edges as soon as the head and the dependent are available in the stack, with the aim of maximizing the parser incrementality. We now show that our greedy transition-based AMR parser is linear-time in  $n$ , the length of the input sentence  $x$ . We first claim that the output graph has size  $\mathcal{O}(n)$ . Each token in  $x$  is mapped to a constant number of nodes in the graph by **Shift**. Thus the number of nodes is  $\mathcal{O}(n)$ . Furthermore, each node can have at most three parent nodes, created by transitions **RArc**, **LArc** and **Reduce**, respectively. Thus the number of edges is also  $\mathcal{O}(n)$ . It is possible to bound the maximum number of transitions required to parse  $x$ : the number of **Shift** is bounded by  $n$ , and the number of **Reduce**, **LArc** and **RArc** is bounded by the size of the graph, which is  $\mathcal{O}(n)$ . Since each transition can be carried out in constant time, we conclude that our parser runs in linear time.

## 4 Training the System

Several components have to be learned: (1) a transition classifier that predicts the next transition given the current configuration, (2) a binary classifier that decides whether or not to create a reentrancy after a **Reduce**, (3) a concept identification step for each **Shift** to compute  $a(\beta_0)$ , and (4) another classifier to label edges after each **LArc** or **RArc**.

### 4.1 Oracle

Training our system from data requires an oracle—an algorithm that given a gold-standard AMR graph and a sentence returns transition sequences that maximize the overlap between the gold-standard graph and the graph dictated by the sequence of transitions.

We adopt a shortest stack, static oracle similar to Chen and Manning (2014). Informally, static means that if the actual configuration of the parser has no mistakes, the oracle provides a transition that does not introduce any mistake. Shortest stack means that the oracle prefers transitions where the number of items in the stack is minimized. Given the current configuration  $(\sigma, \beta, A)$  and the gold-

standard graph  $G = (V_g, A_g)$ , the oracle is defined as follows, where we test the conditions in the given order and apply the action associated with the first match:

1. if  $\exists \ell[(\sigma_0, \ell, \sigma_1) \in A_g]$  then **LArc**( $\ell$ );
2. if  $\exists \ell[(\sigma_1, \ell, \sigma_0) \in A_g]$  then **RArc**( $\ell$ );
3. if  $\neg \exists i, \ell[(\sigma_0, \ell, \beta_i) \in A_g \vee (\beta_i, \ell, \sigma_0) \in A_g]$  then **Reduce**;
4. **Shift** otherwise.

The oracle first checks whether some gold-standard edge can be constructed from the two elements at the top of the stack (conditions 1 and 2). If **LArc** or **RArc** are not possible, the oracle checks whether all possible edges in the gold graph involving  $\sigma_0$  have already been processed, in which case it chooses **Reduce** (conditions 3). To this end, it suffices to check the buffer, since **LArc** and **RArc** have already been excluded and elements in the stack deeper than position two can no longer be accessed by the parser. If **Reduce** is not possible, **Shift** is chosen.

Besides deciding on the next transition, the oracle also needs the alignments, which we generate with JAMR, in order to know how to map the next token in the sentence to its AMR subgraph  $\overleftarrow{\pi}(i)$  defined in (1).

### 4.2 Transition Classifier

Like all other transition systems of this kind, our transition system has a “controller” that predicts a transition given the current configuration (among **Shift**, **LArc**, **RArc** and **Reduce**). The examples from which we learn this controller are based on features extracted from the oracle transition sequences, where the oracle is applied on the training data.

As a classifier, we use a feed-forward neural network with two hidden layers of 200 tanh units and learning rate set to 0.1, with linear decay-ing. The input to the network consists of the concatenation of embeddings for words, POS tags and Stanford parser dependencies, one-hot vectors for named entities and additional sparse features, extracted from the current configuration of the transition system; this is reported in more details in Table 3. The embeddings for words and POS tags were pre-trained on a large unannotated corpus consisting of the first 1 billion char-

action	stack	buffer	edges
-	[o]	[the,boy,and,the,girl]	{}
Shift	[o]	[boy,and,the,girl]	{}
Shift	[o, boy]	[and,the,girl]	{}
Shift	[o, boy, and ]	[the,girl]	{}
LArc	[o, and ]	[the,girl]	$\{\langle and, :op1, boy \rangle\} = A_1$
RArc	[o, and ]	[the,girl]	$A_1 \cup \{\langle o, :top, and \rangle\} = A_2$
Shift	[o, and ]	[girl]	$A_2$
Shift	[o, and, girl ]	[]	$A_2$
RArc	[o, and, girl ]	[]	$A_2 \cup \{\langle and, :op2, girl \rangle\} = A_3$
Reduce	[o, and ]	[]	$A_3$
Reduce	[o]	[]	$A_3$

Table 2: Parsing steps for the sentence “The boy and the girl.”

acters from Wikipedia.<sup>9</sup> For lexical information, we also extract the leftmost (in the order of the aligned words) child ( $c$ ), leftmost parent ( $p$ ) and leftmost grandchild ( $cc$ ). Leftmost and rightmost items are common features for transition-based parsers (Zhang and Nivre, 2011; Chen and Manning, 2014) but we found only leftmost to be helpful in our case. All POS tags, dependencies and named entities are generated using Stanford CoreNLP (Manning et al., 2014). The accuracy of this classifier on the development set is 84%.

Similarly, we train a binary classifier for deciding whether or not to create a reentrant edge after a **Reduce**: in this case we use word and POS embeddings for the two nodes being connected and their parent as well as dependency label embeddings for the arcs between them.

### 4.3 Concept Identification

This routine is called every time the transition classifier decides to do a **Shift**; it is denoted by  $a(\cdot)$  in §3. This component could be learned in a supervised manner, but we were not able to improve on a simple heuristic, which works as follows: during training, for each **Shift** decided by the oracle, we store the pair  $(\beta_0, \overleftarrow{\pi}(i))$  in a phrase-table. During parsing, the most frequent graph  $H$  for the given token is then chosen. In other words,  $a(i)$  approximates  $\overleftarrow{\pi}(i)$  by means of the graph most frequently seen among all occurrences of token  $x_i$  in the training set.

An obvious problem with the phrase-table approach is that it does not generalize to unseen words. In addition, our heuristic relies on the fact that the mappings observed in the data are correct,

<sup>9</sup><http://matmahoney.net/dc/enwik9.zip>

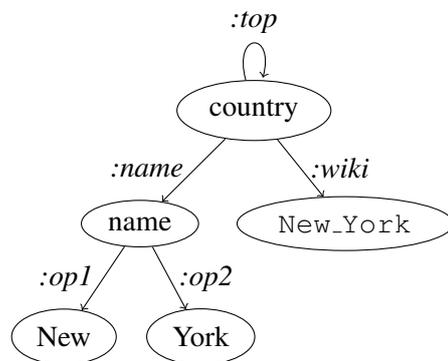

Figure 4: Subgraph for “New York.”

which is not the case when the JAMR-generated alignments contain a mistake. In order to alleviate this problem we observe that there are classes of words such as named entities and numeric quantities that can be disambiguated in a deterministic manner. We therefore implement a set of “hooks” that are triggered by the named entity tag of the next token in the sentence. These hooks override the normal **Shift** mechanism and apply a fixed rule instead. For instance, when we see the token *New York* (the two tokens are collapsed in a single one at preprocessing) we generate the subgraph of Figure 4 and push its root onto the stack. Similar subgraphs are generated for all states, cities, countries and people. We also use hooks for ordinal numbers, percentages, money and dates.

### 4.4 Edge Labeling

Edge labeling determines the labels for the edges being created. Every time the transition classifier decides to take an **LARC** or **RArc** operation, the edge labeler needs to decide on a label for it. There are more than 100 possible labels such as *:ARG0*,

depth	$d(\sigma_0), d(\sigma_1)$
children	$\#c(\sigma_0), \#c(\sigma_1)$
parents	$\#p(\sigma_0), \#p(\sigma_1)$
lexical	$w(\sigma_0), w(\sigma_1), w(\beta_0), w(\beta_1),$ $w(p(\sigma_0)), w(c(\sigma_0)), w(cc(\sigma_0)),$ $w(p(\sigma_1)), w(c(\sigma_1)), w(cc(\sigma_1))$
POS	$s(\sigma_0), s(\sigma_1), s(\beta_0), s(\beta_1)$
entities	$e(\sigma_0), e(\sigma_1), e(\beta_0), e(\beta_1)$
dependency	$\ell(\sigma_0, \sigma_1), \ell(\sigma_1, \sigma_0),$ $\forall i \in \{0, 1\}: \ell(\sigma_i, \beta_0), \ell(\beta_0, \sigma_i)$ $\forall i \in \{1, 2, 3\}: \ell(\beta_0, \beta_i), \ell(\beta_i, \beta_0)$ $\forall i \in \{1, 2, 3\}: \ell(\sigma_0, \beta_i), \ell(\beta_i, \sigma_0)$

Table 3: Features used in transition classifier. The function  $d$  maps a stack element to the depth of the associated graph fragment. The functions  $\#c$  and  $\#p$  count the number of children and parents, respectively, of a stack element. The function  $w$  maps a stack/buffer element to the word embedding for the associated word in the sentence. The function  $p$  gives the leftmost (according to the alignment) parent of a stack element, the function  $c$  the leftmost child and the function  $cc$  the leftmost grandchild. The function  $s$  maps a stack/buffer element to the part-of-speech embedding for the associated word. The function  $e$  maps a stack/buffer element to its entity. Finally, the function  $\ell$  maps a pair of symbols to the dependency label embedding, according to the edge (or lack of) in the dependency tree for the two words these symbols are mapped to.

*:ARG0-of, :ARG1, :location, :time* and *:polarity*. We use a feed-forward neural network similar to the one we trained for the transition classifier, with features shown in Table 4. The accuracy of this classifier on the development set is 77%.

We constrain the labels predicted by the neural network in order to satisfy requirements of AMR. For instance, the label *:top* can only be applied when the node from which the edge starts is the special  $\circ$  node. Other constraints are used for the *:polarity* label and for edges attaching to numeric quantities.

## 5 Fine-grained Evaluation

Until now, AMR parsers were evaluated using the Smatch score.<sup>10</sup> Given the candidate graphs and

<sup>10</sup>Since Smatch is an approximate randomized algorithm, decimal points in the results vary between different runs and are not reported. This approach was also taken by Wang et al.

name	feature template
depth	$d(\sigma_0), d(\sigma_1)$
children	$\#c(\sigma_0), \#c(\sigma_1)$
parents	$\#p(\sigma_0), \#p(\sigma_1)$
lexical	$w(\sigma_0), w(\sigma_1),$ $w(p(\sigma_0)), w(c(\sigma_0)), w(cc(\sigma_0)),$ $w(p(\sigma_1)), w(c(\sigma_1)), w(cc(\sigma_1))$
POS	$s(\sigma_0), s(\sigma_1)$
entities	$e(\sigma_0), e(\sigma_1)$
dependency	$\ell(\sigma_0, \beta_0), \ell(\beta_0, \sigma_0)$

Table 4: Features used in edge labeling. See Table 3 for a legend of symbols.

the gold graphs in the form of AMR annotations, Smatch first tries to find the best alignments between the variable names for each pair of graphs and it then computes precision, recall and F1 of the concepts and relations. We note that the Smatch score has two flaws: (1) while AMR parsing involves a large number of subtasks, the Smatch score consists of a single number that does not assess the quality of each subtasks separately; (2) the Smatch score weighs different types of errors in a way which is not necessarily useful for solving a specific NLP problem. For example, for a specific problem concept detection might be deemed more important than edge detection, or guessing the wrong sense for a concept might be considered less severe than guessing the wrong verb altogether.

Consider the two parses for the sentence *Silvio Berlusconi gave Lucio Stanca his current role of modernizing Italy’s bureaucracy* in Figure 5. At the top, we show the output of a parser (*Parse 1*) that is not able to deal with named entities. At the bottom, we show the output of a parser (*Parse 2*) which, except for *:name, :op* and *:wiki*, always uses the edge label *:ARG0*. The Smatch scores for the two parses are 56 and 78 respectively. Both parses make obvious mistakes but the three named entity errors in *Parse 1* are considered more important than the six wrong labels in *Parse 2*. However, without further analysis, it is not advisable to conclude that *Parse 2* is better than *Parse 1*. In order to better understand the limitations of the different parsers, find their strengths and gain insight in which downstream tasks they may be helpful, we compute a set of metrics on the test set.

**Unlabeled** is the Smatch score computed on (2015b) and others.

<pre>(g / give-01 :ARG0 (p3 / silvio :mod (n4 / berlusconi)) :ARG1 (r / role :time (c2 / current) :mod (m / modernize-01 :ARG0 p4 :ARG1 (b / bureaucracy :part-of (c3 / italy))) :poss p4) :ARG2 (p4 / person lucio :mod stanca))</pre>
<pre>(g / give-01 :ARG0 (p3 / person :wiki "Silvio_Berlusconi" :name (n4 / name :op1 "Silvio" :op2 "Berlusconi")) :ARG0 (r / role :ARG0 (c2 / current) :ARG0 (m / modernize-01 :ARG0 p4 :ARG0 (b / bureaucracy :ARG0 (c3 / country :wiki "Italy" :name (n6 / name :op1 "Italy")))) :ARG0 p4) :ARG0 (p4 / person :wiki - :name (n5 / name :op1 "Lucio" :op2 "Stanca"))</pre>

Figure 5: Two parses for the sentence “*Silvio Berlusconi gave Lucio Stanca his current role of modernizing Italy’s bureaucracy.*”

the predicted graphs after removing all edge labels. In this way, we only assess the node labels and the graph topology, which may be enough to benefit several NLP tasks because it identifies basic predicate-argument structure. For instance, we may be interested in knowing whether two events or entities are related to each other, while not being concerned with the precise type of relation holding between them.

**No WSD** gives a score that does not take into account word sense disambiguation errors. By ignoring the sense specified by the Propbank frame used (e.g., *duck-01* vs *duck-02*) we have a score that does not take into account this additional complexity in the parsing procedure. To compute this score, we simply strip off the suffixes from all Propbank frames and calculate the Smatch score.

Following Sawai et al. (2015), we also evaluate the parsers using the Smatch score on noun phrases only (**NP-only**), by extracting from the AMR dataset all noun phrases that do not include further NPs.

As we previously discussed, reentrancy is a very important characteristic of AMR graphs and it is not trivial to handle. We therefore implement a test for it (**Reentrancy**), where we compute the Smatch score only on reentrant edges.

Concept identification is another critical component of the parsing process and we therefore compute the F-score on the list of predicted concepts (**Concepts**) too. Identifying the correct concepts is fundamental: if a concept is not identified, it will not be possible to retrieve any edge

Metric	First parse	Second parse
Smatch	56	78
Unlabeled	65	100
No WSD	56	78
NP-only	39	86
Reentrancy	69	46
Concepts	56	100
Named Ent.	0	100
Wikification	0	100
Negations	0	0
SRL	69	54

Table 5: Evaluation of the two parses in Figure 5 with the proposed evaluation suite.

involving that concept, with likely significant consequences on accuracy. This metric is therefore quite important to score highly on.

Similarly to our score for concepts, we further compute an F-score on the named entities (**Named Ent.**) and wiki roles for named entities (**Wikification**) that consider edges labeled with *:name* and *:wiki* respectively. These two metrics are strictly related to the concept score. However, since named entity recognition is the focus of dedicated research, we believe it is important to define a metric that specifically assesses this problem. Negation detection is another task which has received some attention. An F-score for this (**Negations**) is also defined, where we find all negated concepts by looking for the *:polarity* role. The reason we can compute a simple F-score instead of using Smatch for these metrics is that there are no variable names involved.

Finally we compute the Smatch score on *:ARG* edges only, in order to have a score for semantic role labeling (**SRL**), which is another extremely important subtask of AMR, as it is based on the identification of predicate-argument structures.

Using this evaluation suite we can evaluate AMRs on a wide range of metrics that can help us find strengths and weakness of each parser, hence speeding up the research in this area. Table 5 reports the scores for the two parses of Figure 5, where we see that *Parse 1* gets a good score for semantic role labeling while *Parse 2* is optimal for named entity recognition. Moreover, we can make additional observations such as that *Parse 2* is optimal with respect to unlabeled score and that *Parse 1* recovers more reentrancies.

Metric	J'14	C'15	J'16	Ours
Smatch	58	63	<b>67</b>	64
Unlabeled	61	<b>69</b>	<b>69</b>	<b>69</b>
No WSD	58	64	<b>68</b>	65
NP-only	47	54	<b>58</b>	55
Reentrancy	38	41	<b>42</b>	41
Concepts	79	80	<b>83</b>	<b>83</b>
Named Ent.	75	75	79	<b>83</b>
Wikification	0	0	<b>75</b>	64
Negations	16	18	45	<b>48</b>
SRL	55	<b>60</b>	<b>60</b>	56

Table 6: Results on test split of LDC2015E86 for JAMR, CAMR and our AMREAGER. J stands for JAMR and C for CAMR (followed by the year of publication). Best systems are in bold.

## 6 Experiments

We compare our parser<sup>11</sup> against two available parsers: JAMR (Flanigan et al., 2014) and CAMR (Wang et al., 2015b; Wang et al., 2015a), using the LDC2015E86 dataset for evaluation. Both parsers are available online<sup>12</sup> and were recently updated for SemEval-2016 Task 8 (Flanigan et al., 2016; Wang et al., 2016). However, CAMR’s SemEval system, which reports a Smatch score of 67, is not publicly available. CAMR has a quadratic worst-case complexity (although linear in practice). In JAMR, the concept identification step is quadratic and the relation identification step is  $O(|V|^2 \log |V|)$ , with  $|V|$  being the set of nodes in the AMR graph.

Table 6 shows the results obtained by the parsers on all metrics previously introduced. On Smatch, our system does not give state-of-the-art results. However, we do obtain the best results for *Unlabeled* and *Concept* and outperform the other parses for *Named Ent.* and *Negations*. Our score of *Reentrancy* is also close the best scoring system, which is particularly relevant given the importance of reentrancies in AMR. The use of the **Reduce** transition, which targets reentrancies caused by control verbs, is critical in order to achieve this result.

The relatively high results we obtain for the un-

<sup>11</sup>Our parser is available at <https://github.com/mdtux89/amr-eager>, the evaluation suite at <https://github.com/mdtux89/amr-evaluation> and a demo at <http://cohort.inf.ed.ac.uk/amreager.html>

<sup>12</sup>JAMR: <https://github.com/jflanigan/jamr>, CAMR: <https://github.com/c-amr/camr>.

labeled case suggests that our parser has difficulty in labeling the arcs. Our score for concept identification, which is on par with the best result from the other parsers, demonstrates that there is a relatively low level of token ambiguity. State-of-the-art results for this problem can be obtained by choosing the most frequent subgraph for a given token based on a phrase-table constructed from JAMR alignments on the training data. The scores for named entities and wikification are heavily dependent on the hooks mentioned in §4.3, which in turn relies on the named entity recognizer to make the correct predictions. In order to alleviate the problem of wrong automatic alignments with respect to polarity and better detect negation, we performed a post-processing step on the aligner output where we align the AMR constant - (minus) with words bearing negative polarity such as *not*, *illegitimate* and *asymmetry*.

Our experiments demonstrate that there is no parser for AMR yet that conclusively does better than all other parsers on all metrics. Advantages of our parser are the worst-case linear complexity and the fact that is possible to perform incremental AMR parsing, which is both helpful for real-time applications and to investigate how meaning of English sentences can be built incrementally left-to-right.

## 7 Conclusion

We presented a transition system that builds AMR graphs in linear time by processing the sentences left-to-right. The system is trained with feed-forward neural networks. The parser demonstrates that it is possible to perform AMR parsing using techniques inspired by techniques from dependency parsing.

We also noted that it is less informative to evaluate the entire parsing process with Smatch than to use a collection of metrics aimed at evaluating the various subproblems in the parsing process. We further showed that our left-to-right transition system is competitive with publicly available state-of-the-art parsers. Although we do not outperform the best baseline in terms of Smatch score, we show on par or better results for several of the metrics proposed. We hope that moving away from a single-metric evaluation will further speed up progress in AMR parsing.

# Integrated Learning of Dialog Strategies and Semantic Parsing

Aishwarya Padmakumar

Jesse Thomason

Raymond J. Mooney

Department of Computer Science, University of Texas at Austin

{aish, jesse, mooney}@cs.utexas.edu

## Abstract

Natural language understanding and dialog management are two integral components of interactive dialog systems. Previous research has used machine learning techniques to individually optimize these components, with different forms of direct and indirect supervision. We present an approach to integrate the learning of *both* a dialog strategy using reinforcement learning, and a semantic parser for robust natural language understanding, using only natural dialog interaction for supervision. Experimental results on a simulated task of robot instruction demonstrate that joint learning of both components improves dialog performance over learning either of these components alone.

## 1 Introduction

Natural language understanding and dialog management are two integral components of a dialog system. Current research typically deals with optimizing only one of these components. We present an approach to integrate the learning of *both* a dialog strategy using reinforcement learning, and a semantic parser for robust natural language understanding, using only natural dialog interaction for supervision.

Research in dialog systems has primarily been focused on the problems of accurate dialog state tracking and learning a policy for the dialog system to respond appropriately in various scenarios. Dialogs are typically modeled using Partially Observable Markov Decision Processes (POMDPs), and various reinforcement learning algorithms have been proposed and evaluated for the task of learning optimal policies over these representations to accomplish user goals using as short and

natural a dialog as possible (Gašić and Young, 2014; Pietquin et al., 2011; Young et al., 2013). However, such systems typically assume a fixed language understanding component that is available a priori.

Semantic parsing is the task of mapping natural language to a formal meaning representation. It has the potential to allow for more robust mapping of free-form natural language to a representation that can be used to interpret user intentions and track dialog state. This is done by leveraging the compositionality of meaning inherent in language. Prior work has shown that a semantic parser, incrementally updated from conversations, is helpful in dialogs for communicating commands to a mobile robot (Thomason et al., 2015). We show that incremental learning of a POMDP-based dialog policy allows for further improvement in dialog success.

A major challenge with combining the above parser and dialog policy learning techniques is that reinforcement learning (RL) algorithms assume that the dialog agent is operating in a *stationary* environment. This assumption is violated when the parser is updated between conversations. For example, the improved semantic parser may be able to extract more information from a response to a question, which the old parser could not parse. So the RL algorithm may have earlier assumed that asking such a question is not useful, but this is not the case with the updated parser. Our results show that this effect can be mitigated if we break the allowed budget of training dialogs into batches, updating both parser and policy after each batch. As the next training batch gets collected using the updated parser, the policy can be updated using this experience to adapt better to it. We demonstrate, using crowd-sourced results with a simulated robot, that by integrating learning of *both* a dialog manager *and* a semantic parser in

this manner, task success is improved over cases where the components are trained individually.

## 2 Related Work

Prior work has used dialog to facilitate robot task learning, e.g. She et al. (2014), but does not account for uncertainty or dynamic changes to the language understanding module when developing a system policy. Some works use a POMDP model and common-sense knowledge (Zhang and Stone, 2015) or generate clarification questions in a probabilistic manner (Tellex et al., 2014), but these too assume that a fixed and well-trained natural language understanding component is available a-priori. Kollar et al. (2013) use a probabilistic parsing and grounding model to understand natural language instructions and extend their knowledge base by asking questions. However, unlike this work, they do not use semantic parsing to leverage the compositionality of language, and also use a fixed hand-coded policy for dialog.

There has been considerable work in semantic parsing using both direct supervision in the form of annotated meaning representations (Wong and Mooney, 2007; Kwiatkowski et al., 2013; Berant et al., 2013) and indirect signals from downstream tasks (Artzi and Zettlemoyer, 2011; Artzi and Zettlemoyer, 2013; Thomason et al., 2015). Artzi and Zettlemoyer (2011) use clarification dialogs to train semantic parsers for an airline reservation system without explicit annotation of meaning representations. More related to our work is that of Thomason et al. (2015), who incorporated this general approach into a system for instructing a mobile robot; however, they use a simple model of dialog state and a fixed, hand-coded dialog policy. We show that learning a dialog policy in addition to this, is more beneficial than only parser learning. We also use a richer state representation that incorporates multiple hypotheses from the semantic parser.

There has also been considerable work in goal-directed dialog systems in domains such as information provision (Young et al., 2013). These systems model dialog as a POMDP and focus on either the problem of tracking belief state accurately over large state spaces (Young et al., 2010; Thomson and Young, 2010; Mrkšić et al., 2015; El Asri et al., 2016) or efficiently learning a dialog policy over this state space (Gašić and Young, 2014; Pietquin et al., 2011; Png et al., 2012). However,

these systems typically assume a fixed natural language understanding component. In this work, we combine language learning with principled dialog strategy learning.

More recently, there has been work on modeling various components of a dialog system using neural networks (Mrkšić et al., 2015; Wen et al., 2015). There have also been some end-to-end neural network systems that simultaneously learn dialog policy and language comprehension for goal directed dialog (Wen et al., 2016; Williams and Zweig, 2016; Bordes and Weston, 2016), but they do not use a fully compositional semantic parser. Williams and Zweig (2016) use a very simple keyword-spotting based technique for processing input user utterances, which is unlikely to be able to handle out-of-vocabulary expressions for entities. Bordes and Weston (2016) explicitly attempt to handle out-of-vocabulary utterances in a neural dialog system but do not demonstrate much success. We expect that in a domain such as ours where out-of-vocabulary utterances are fairly likely, for example, in different forms of address for a person, a semantic parser that can be incrementally updated from a small number of interactions is likely to perform better. However, an empirical comparison of the two in domains where compositional language understanding is expected to be beneficial, is an interesting direction of future work.

## 3 Background - Partially Observable Markov Decision Process (POMDP)

A Partially Observable Markov Decision Process (POMDP) is a tuple  $(\mathbb{S}, \mathbb{A}, \mathbb{T}, \mathbb{R}, \mathbb{O}, \mathbb{Z}, \gamma, b_0)$ , where  $\mathbb{S}$  is a set of states,  $\mathbb{A}$  is a set of actions,  $\mathbb{T}$  is a transition function,  $\mathbb{R}$  is a reward function,  $\mathbb{O}$  is a set of observations,  $\mathbb{Z}$  is an observation function,  $\gamma$  is a discount factor and  $b_0$  is an initial belief state (Kaelbling et al., 1998). These are defined as follows.

At any instant of time  $t$ , the agent is in a state  $s_t \in \mathbb{S}$ . This state is hidden from the agent and only a noisy observation  $o_t \in \mathbb{O}$  of  $s_t$  is provided to it. The agent maintains a belief state  $b_t$  which is a distribution over all possible states it could be in at time  $t$ , where  $b_t(s_i)$  gives the probability of being in state  $s_i$  at time  $t$ . Based on  $b_t$ , the agent chooses to take an action  $a_t \in \mathbb{A}$  according to a policy  $\pi$ , commonly represented as a probability distribution over actions where  $\pi(a_t|b_t)$  is the

probability of taking action  $a_t$  when the agent is in belief state  $b_t$ . On taking action  $a_t$ , the agent is given a real-valued reward  $r_t$ , transitions to a state  $s_{t+1}$ , and receives a noisy observation  $o_{t+1}$  of  $s_{t+1}$ .

State transitions occur according to the probability distribution  $P(s_{t+1}|s_t, a_t) = \mathbb{T}(s_t, a_t, s_{t+1})$ , observations are related to the states by the probability distribution  $P(o_t|s_t, a_{t-1}) = \mathbb{Z}(o_t, s_t, a_{t-1})$  and rewards obtained follow the distribution  $P(r_t|s_t, a_t) = \mathbb{R}(s_t, a_t, s_{t+1})$ .

The objective is to identify a policy  $\pi$  that is optimal in the sense that it maximizes the expected long term discounted reward, called return, given by

$$g = \mathbb{E}_\pi \left[ \sum_{t=1}^{\infty} \gamma^t r_t \right]$$

While there exist both exact and approximate methods for solving POMDPs, these do not usually scale well to the state spaces commonly used in dialog domains. This has led to the development of approximate representations that exploit domain-specific properties of dialog tasks to allow tractable estimation of the belief state and policy optimization (Young et al., 2013).

#### 4 Background - Q-Learning using Kalman Temporal Differences

The quality of a policy  $\pi$  can be estimated using the action value function

$$Q^\pi(s, a) = \mathbb{E}_\pi \left[ \sum_{t=1}^{\infty} \gamma^t r_t \mid s_0 = s, a_0 = a \right]$$

The optimal policy satisfies the Bellman equation,

$$Q^*(s, a) = \mathbb{E}_{s'} \left[ \mathbb{R}(s, a, s') + \gamma \max_{a' \in \mathbb{A}} Q^*(s', a') \right]$$

When the state space is very large or continuous,  $Q^\pi$  cannot be computed for each state (or belief state) individually and is hence assumed to be a function with parameters  $\theta$  over some features that represent the state. When the transition or reward dynamics are not constant (*non-stationary* problem), a suitable approximation is the Kalman Temporal Differences framework (Geist and Pietquin, 2010). This casts the function approximation as a filtering problem and solves it using Kalman filtering. The specialization for learning the optimal action value function is called the KTD-Q algorithm.

Filtering problems estimate hidden quantities X from related observations Y, modeling X and Y as random variables. When estimating action values, X corresponds to the function parameters,  $\theta$  and the observations, Y, are the estimated returns,  $r_t + \gamma \max_a \hat{Q}_{\theta_t}(s_{t+1}, a)$ . Random noise is added to both of these to allow for parameters to change over time. The update rules are derived from Kalman Filtering Theory and not included here for the sake of brevity.

#### 5 Dialog System

Our system initiates the dialog by requesting the user for a command. The user can command the system to perform two actions: navigation and delivery. Navigation has a single parameter for the destination. For example “go to Alice’s office” would be a possible way to command the robot to perform a navigation command, whose location is a room that is the office of a person `alice`. Delivery has two parameters: the item to be delivered and the person to receive it. For example, “bring Alice a hamburger” would be a possible way to specify a delivery command whose patient is an item `hamburger` and recipient is a person `alice`.

The robot makes an initial guess of the desired action from the user’s response, and then may ask clarification questions in case of insufficient understanding. At each step, it can respond with one of four dialog acts: asking the user to repeat their command, confirming a command or an argument value, requesting a specific argument of a command, and executing an action (thereby ending the dialog). A sample dialog is shown in Table 1.

Table 1: An sample clarification dialog

ROBOT	How can I help?
USER	bring the coffee to dr morgan
ROBOT	Sorry I couldn’t understand that. Could you reword your original request?
USER	take the coffee to dr morgan
ROBOT	Sorry I couldn’t understand that. Could you reword your original request?
USER	give the coffee cup to dr morgan
ROBOT	You want me to bring coffee for George?
USER	no mallory morgan
ROBOT	Whom would you like me to bring something to?
USER	mallory morgan
ROBOT	What would you like me to bring?
USER	coffee
ROBOT	I brought coffee to Mallory. Was this the correct action?
USER	yes

Given a user response, a semantic parser is used to convert utterances to logical forms which are then grounded using world knowledge (e.g. resolving the representation of “*Alice’s office*” to a particular room). These grounded logical forms are then used to update the belief state maintained by the system. The next step to be taken by the system, given the belief state, is then chosen based on the current dialog policy. Once the conversation is complete, the parser and policy can be updated appropriately. These steps are outlined in greater detail in sections 5.1 and 5.2.

The dialog is considered a success if the final action taken is correct and a failure otherwise. The user also has the ability to prematurely end the dialog, and any conversation terminated in this manner is also considered a failure.

### 5.1 Semantic Parser Learning

Semantic parsing maps a natural language sentence such as “*Go to Alice’s office*” to a logical form expressed in  $\lambda$ -calculus such as:

$$\text{walk}(\text{the}(\lambda x.\text{office}(x) \wedge \text{possess}(\text{alice}, x) \wedge \text{person}(\text{alice}))) \quad (1)$$

Grounding against real-world knowledge, this will identify a room, say room 3512, which is an office that is owned by *alice*.

This formalism reduces the number of lexical entries the system needs to learn by exploiting compositional reasoning over language. For example, if the system learns that “*Alice Ashcraft*” and “*Alice*” both refer to the entity *alice*, no further lexical entries are required to resolve “*Go to Alice Ashcraft’s office*” to the same semantic form (1).

In our system, semantic parsing is performed using probabilistic CKY-parsing with a Combinatory Categorical Grammar (CCG) and meanings associated with lexical entries. Perceptron-style updates to parameter values, that minimize the log-likelihood of the training data, are used during training to weight parses to speed search and give confidence scores in parse hypotheses (Zettlemoyer and Collins, 2005).

The parser is trained using paired sentences and logical forms. A small supervised training set is used to initialize the parser. Training continues using pairs obtained through weak supervision collected from user dialogs (Thomason et al., 2015).

We use two such types of training pairs. The first consist of responses that are likely to correspond to the complete action, and the logical form induced by the action executed by the robot at the end of the dialog. Such responses are expected from the initial prompt to the user and questions that ask the user to repeat the command. We obtain multiple semantic parses for these responses, and parses that correspond to a complete command, and ground to the action finally taken by the robot, are paired with the response to form one set of training pairs. For example, from the conversation in Table 1, such training examples would be generated by pairing the responses “*bring the coffee to dr morgan*”, “*take the coffee to dr morgan*” and “*give the coffee cup to dr morgan*” with the semantic form `bring(mallory, coffee)`.

The second set of training pairs is obtained from the arguments of the action, such as the patient or location involved. This consists of responses to requests for specific arguments. Again, we consider multiple semantic parses for these responses, and select those that are of the correct syntactic form for a single argument value, and which ground to the corresponding argument value in the final action, to be paired with the response. For example, from the conversation in Table 1, such training examples would be generated by pairing the response “*mallory morgan*” with the semantic form `mallory`, and the response “*coffee*” with the semantic form `coffee`. These paired responses and semantic forms can then be used to retrain the parser between conversations.

This weak supervision may be somewhat noisy because it assumes that the form of the user’s response matches the expected response type for the question. However, this is unlikely to generate spurious training examples, because we additionally place constraints on the syntax of the response. For example, if we receive “*Go to Bob’s office*” as a response when we expect an argument value, since the response is an imperative sentence, not a noun phrase such as “*Bob’s office*”, no training example would be generated from it. Prior experimental results (Artzi and Zettlemoyer, 2011; Thomason et al., 2015) suggest that learning using such weak (potentially noisy) supervision from clarification dialogs is effective at improving semantic parsers.

## 5.2 Dialog Strategy Learning

We use a POMDP to model dialog and learn a policy (Young et al., 2013), adapting the Hidden Information State model (HIS) (Young et al., 2010) to track the belief state as the dialog progresses. The key idea behind this approach is to group states into equivalence classes called partitions, and maintain a probability for each partition instead of each state. States within a partition are those that are indistinguishable to the system given the current dialog.

More concretely, our belief state can be factored into two main components. The first is the action (such as navigation and delivery) and argument values of the goal (such as the patient or location) which the user is trying to convey,  $\mathbf{g} = \{g_a, g_{PAT}, g_{RCP}, g_{LOC}\}$ . Goal parameters are represented in terms of semantic roles - *patient* ( $g_{PAT}$ ), *recipient* ( $g_{RCP}$ ) and *location* ( $g_{LOC}$ ), to allow them to generalize across different actions. The second component contains information from the most recent user utterance,  $\mathbf{u} = \{u_t, u_a, u_{PAT}, u_{RCP}, u_{LOC}\}$ . Here,  $u_t$  is the type of the utterance – affirmation, denial, providing information about a complete action, or providing information about a specific argument. The components  $u_a$ ,  $u_{PAT}$ ,  $u_{RCP}$  and  $u_{LOC}$  respectively refer to the action, *patient*, *recipient* and *location* mentioned in the most recent user utterance, any of which can be `null`. This representation allows the method to be applicable to any action that can be expressed using up to 3 arguments.

After every user response, a beam of possible choices for  $\mathbf{u}$  can be obtained by grounding the beam of top-ranked parses from the semantic parser. Semantic type-checking is used to disallow violations such as `alice` serving as the location argument of a navigation. However, there are a large number of possible values for  $\mathbf{g}$  and we use the idea of partitions (Young et al., 2010) to track their probabilities in a tractable manner. A partition is a set of possible goals  $\mathbf{g}^{(i)}$  which are equally probable given the conversation so far. The probability of a partition is the sum of probabilities of all goals in the partition. Initially, all goals are in a single partition of probability 1.

When an utterance hypothesis  $\mathbf{u}$  is obtained, every partition currently maintained is split if needed into partitions that are either completely consistent or inconsistent with  $\mathbf{u}$ . For example, if a partition  $p$  has goals containing both navigation and deliv-

ery actions, and  $\mathbf{u}$  specifies a delivery action,  $p$  will have to be split into one partition  $p_1$  with all the navigation goals and another partition  $p_2$  with all the delivery goals. The probability mass of  $p$  is divided between  $p_1$  and  $p_2$  in proportion to their sizes, to maintain the invariant that the probability of a partition is the sum of the probabilities of the goals contained in it. Then, given the previous system action  $\mathbf{m}$ , The belief  $b(p, \mathbf{u})$  is calculated as in the HIS model as follows

$$b(p, \mathbf{u}) = k * P(\mathbf{u}) * T(\mathbf{m}, \mathbf{u}) * M(\mathbf{u}, \mathbf{m}, p) * b(p)$$

Here,  $P(\mathbf{u})$  is the probability of the utterance hypothesis  $\mathbf{u}$  given the user response, which is obtained from the semantic parser.  $T(\mathbf{m}, \mathbf{u})$  is the probability that the type of the utterance hypothesis  $\mathbf{u}_t$  is compatible with the previous system action  $\mathbf{m}$ , for example, if the system asks for the confirmation of a goal, the expected type of response is either affirmation or denial. This is determined by system parameters.  $M(\mathbf{u}, \mathbf{m}, p)$  is a 0-1 value indicating whether the action and argument values mentioned in the utterance, system action, and partition agree with each other (an example of where they do not is an utterance mentioning an action not present in any goal in the partition) and  $b(p)$  is the belief of partition  $p$  before the update, obtained by marginalizing out  $\mathbf{u}$  from  $b(p, \mathbf{u})$ .  $k$  is a normalization constant that allows the expression to become a valid probability distribution. We also track the number of dialog turns so far.

The belief state is a distribution over all possible hypotheses given the conversation so far. The HIS model allows tracking probabilities of the potentially large number of hypotheses. However, it is difficult to learn a policy over this large a state space in a reasonable number of dialogs. Thus, we learn a dialog policy over a summary state as in previous work (Young et al., 2010; Gašić and Young, 2014). Table 2 contains the features used to learn the policy. Also, the policy is learned over abstract dialog acts (ask user to rephrase the entire goal, ask for a specific parameter, confirm a full/partial goal, execute a goal), which are converted to a system response by using parameters from the most likely hypothesis.

It is important to note that while only the top two hypotheses are used by the policy to choose the next action, it is useful to maintain the belief of all hypotheses because a hypothesis that is initially of low probability may become the most probable after additional turns of dialog.

Probability of top hypothesis
Probability of second hypothesis
Number of goals allowed by the partition in the top hypothesis
Number of parameters of the partition in the top hypothesis, required by its action, that are uncertain (set to the maximum value if there is more than one possible action)
Number of dialog turns used so far
Do the top and second hypothesis use the same partition (0-1)
Type of last user utterance
Action of the partition in the top hypothesis, or <i>null</i> if this is not unique

Table 2: Features used in summary space

The choice of policy learning algorithm is important because learning POMDP policies is challenging and dialog applications exhibit properties not often encountered in other reinforcement learning applications (Daubigney et al., 2012). We use KTD-Q (Kalman Temporal Difference Q-learning (Geist and Pietquin, 2010)) to learn the dialog policy as it was designed to satisfy some of these properties and tested in a dialog system with simulated users (Pietquin et al., 2011). The properties we wished to be satisfied by the algorithm were the following:

- Low sample complexity in order to learn from limited user interaction.
- An off-policy algorithm to enable the use of existing dialog corpora to bootstrap the system, and crowdsourcing platforms such as Amazon Mechanical Turk during training and evaluation.
- A model-free rather than a model-based algorithm because it is difficult to design a good transition and observation model for this problem (Daubigney et al., 2012).
- Robustness to non-stationarity because the underlying language understanding component changes with time (Section 5.1), which is likely to change state transitions.

To learn the policy, we provided a high positive reward for correct completion of the task and a high negative reward when the robot chose to execute an incorrect action, or if the user terminated the dialog before the robot was confident about taking an action. The system was also given a per-turn reward of  $-1$  to encourage shorter dialogs.

## 6 Experimental Evaluation

The learning methods described above were applied to improve an initial dialog system using weak supervision from dialog interaction with real users. The dialog system was initialized using data from the conversation logs of Thomason et al. (2015), which also consist of interactions between a human user and a robot to which a high-level command must be communicated, and which asks clarifying questions when attempting to understand the dialog.

### 6.1 Initialization

The semantic parser was initialized using a small seed lexicon and trained on a small set of supervised examples constructed using templates for commands gathered from the conversation logs. While the parser can be used even if initialized using only a handful of hand-coded training examples, the increased robustness obtained by training on templated sentences results in less frustrating interaction during initial dialogs.

The RL component was first initialized with a  $Q$ -function approximation of the hand-coded policy of Thomason et al. (2015). The hand-coded policy was encoded in the form of if-then rules and had to be mapped to a  $Q$ -function appropriate for the KTD-Q algorithm, which assumes the  $Q$ -function is a probability distribution with a mean that is a linear function of the feature space. We obtain a set of “training points” for these linear weights by densely sampling the feature space. The hand coded policy is then used to identify the correct action for each of these feature vectors. The target for a training point is a high positive  $Q$  value when combined with the correct action and a 0 value when combined with any incorrect action. The weights were then initialized using linear regression over these examples. Finally, we trained the system on the above mentioned conversation logs, improving both the initial POMDP dialog policy and the semantic parser.

The simplest alternative to such an initialization would be to initialize the policy at random, but this would lead to a large number of frustrating dialogs before the system learns a reasonable policy. This can be avoided by training with a simulated user agent. However, such agents are not always realistic and their design requires parameters to be set ideally from existing conversation logs. However, since we use an off-policy algorithm, it is easier to

train it directly from conversation logs, rather than develop a sufficiently realistic simulated agent.

Since the KTD-Q algorithm is off-policy, it can be trained using tuples containing the belief state, action taken, next belief state, and reward obtained from these logs. We update the policy using such tuples both in the initial training phase from existing conversation logs, and when updating the policy after collecting batches of conversations in our experiments.

## 6.2 Platform and setup

Our experiments were done through Mechanical Turk as in previous work (Thomason et al., 2015; Wen et al., 2016). During the training phase, each user interacted with one of four dialog agents (described in section 6.3), selected uniformly at random. Users were not told of the presence of multiple agents and were not aware of which agent they were interacting with. They were given a prompt for either a navigation or delivery task and were asked to have a conversation with the agent to accomplish the given task. No restrictions were placed on the language they could employ. We use visual prompts for the tasks to avoid linguistic priming (e.g. a picture of a hamburger instead of the word “hamburger”). Before users could begin the task, we used a validation step to ensure they were sufficiently fluent in English and understood the objectives of the task. Training dialogs were acquired in 4 batches of 50 dialogs each across all agents. After each batch, agents were updated as described in section 6.3.

A final set of 100 test conversations were then conducted between Mechanical Turk users and the trained agents. These test tasks were novel in comparison to the training data in that although they used the same set of possible actions and argument values, the same combination of action and argument values had not been seen at training time. For example, if one of the test tasks involved delivery of a `hamburger` to `alice`, then there may have been tasks in the training set to deliver a `hamburger` to other people and there may have been tasks to deliver other items to `alice`, but there was no task that involved delivery of a `hamburger` to `alice` specifically.

## 6.3 Dialog agents

We compared four dialog agents. The first agent performed only parser learning (described in Section 5.1). Its dialog policy was always kept to be a

hand coded dialog policy similar to that of Thomason et al. (2015). This was the same hand-coded policy used to initialize the weights of the KTD-Q algorithm. Its parser was incrementally updated after each training batch. This agent is similar to the system used by Thomason et al. (2015) except that it uses the same state space as our other agents, to ensure that any differences in performance are not due to access to less information. Further, while Thomason et al. (2015) use only the top hypothesis from the parser to update the belief state, our agent uses a beam of parses, again to be more comparable to our other agents. In supplementary material, we also include an experiment which demonstrates that using multiple hypotheses from the semantic parser is more beneficial than using only a single one.

The second agent performed only dialog strategy learning. Its parser was always kept to be the initial parser that all agents started out with. Its policy was incrementally updated after each training batch using the KTD-Q algorithm. The third agent performed both parser and dialog learning; but instead of incrementally updating the parser and policy after each batch, they were trained at the end of the training phase using dialogs across all batches. This would not allow the dialog manager to see updated versions of the parser in batches after the first and adapt the policy towards the improving parser. We refer to this as *full* learning of parser and dialog policy. The fourth agent also performed both parser and dialog learning. Its parser and policy were updated incrementally after each training batch. Thus for the next training batch, the changes due to the improvement in the parser from the previous batch could, in theory, be demonstrated in the dialogs and hence contribute towards updating the policy in a manner consistent with it. We refer to this as *batchwise* learning of parser and dialog policy.

We did not include a system that performs no learning on either the parser or policy because it was shown by Thomason et al. (2015) that parser learning combined with a simple hand-coded policy outperforms this. We also did not attempt to update both parser and policy after each dialog because this forces all dialogs to be conducted in sequence, which does not allow us to fully leverage crowdsourcing platforms such as Mechanical Turk.

## 6.4 Experiment hypothesis

We hypothesized that the agent performing *batchwise* parser and policy learning would outperform the agents performing only parser or only dialog learning as we expect that improving both components is more beneficial. However, we did not necessarily expect the same result from *full* parser and dialog learning because it did not provide any chance to allow updates to propagate even indirectly from one component to another, exposing the RL algorithm to a more *non-stationary* environment. Hence, we also expected *batchwise* learning to outperform *full* learning.

## 6.5 Results and Discussion

The agents were evaluated on the test set using the following objective performance metrics: the fraction of successful dialogs (see 5) and the length of successful dialogs. We also included a survey at the end of the task asking users to rate on a 1–5 scale whether the robot understood them, and whether they felt the robot asked sensible questions.

Learning involved	% successful dialogs	Avg dialog length	Robot understood	Sensible questions
Parser	75	12.43	2.93	2.79
Dialog	59	11.73	2.55	2.91
Parser & Dialog - <i>full</i>	72	12.76	2.79	<b>3.28</b>
Parser & Dialog - <i>batchwise</i>	<b>78</b>	<b>10.61</b>	<b>3.30</b>	3.17

Table 3: Performance metrics for dialog agents tested. Differences in dialog success and subjective metrics are statistically significant according to an unpaired t-test with  $p < 0.05$ .

Table 3 gives the agents’ performance on these metrics. All differences in dialog success and the subjective metrics are statistically significant according to an unpaired t-test with  $p < 0.05$ . In dialog length, the improvement of the *batchwise* learning agent over the agents performing only parser or only dialog learning are statistically significant.

As expected, the agent performing *batchwise* parser and dialog learning outperforms the agents performing only parser or only dialog learning, in the latter case by a large margin. We believe the agent performing only parser learning performs much better than the agent performing only dialog

learning due to the relatively high sample complexity of reinforcement learning algorithms in general, especially in the partially observable setting. In contrast, the parser changes considerably even from a small number of examples. Also, we observe that *full* learning of both components does not in fact outperform only parser learning. We believe this is because the distribution of hypotheses obtained using the initial parser at training time is substantially different from that obtained using the updated parser at test time. We believe that *batchwise* training mitigates this problem because the distribution of hypotheses changes after each batch of training and the policy when updated at these points can adapt to some of these changes. The optimal size of the batch is a question for further experimentation. Using a larger batch is less likely to overfit updates to a single example but breaking the total budget of training dialogs into more batches allows the RL algorithm to see less drastic changes in the distribution of hypotheses from the parser.

We include an experiment in the supplementary material that quantifies the accuracy improvement of the parsers after training from dialogs. It is more difficult to quantitatively compare the policies before and after learning. Qualitatively, one of the noticeable differences is that the system tends to confirm or act upon lower probability hypotheses than is recommended by the initial hand-coded policy. This is possibly because as the parser improves, its top hypotheses are more likely to be correct, even if they are associated with a lower confidence score from the parser. A demonstration of this can be seen in tables 4 and 5. The learned policy results in a shorter dialog in the same situation because it allows the agent to act upon a hypothesis of lower probability. Also, the learned policy is stochastic, which is very helpful when the agent is not able to understand the user at all. For example, if the agent is unable to parse any of the initial instructions from the user, under a hand-coded policy, as its state has not changed, it would continue to repeat the question it had asked earlier, which prevents it from making any progress. However, in a stochastic policy, other more specific questions are likely to be substituted in between, and responses to these may allow the agent to make progress, which increases dialog success (table 6).

## 7 Conclusions

In this work, we have demonstrated that continuous dialog strategy learning and semantic parser learning can be successfully combined in a dialog system to enable an agent to better understand commands provided in natural language. Both the semantic parser and the dialog strategy can be automatically improved simultaneously using weak feedback provided during interaction with users rather than manually-labeled or artificially constructed training data. Ongoing parser learning could have confused the RL dialog learner by altering the underlying language understanding system while it was searching for an effective dialog policy. However, our results show that by using an appropriate RL algorithm and batchwise training regimen, this potential difficulty can be avoided, and both language understanding and dialog management can be improved simultaneously.

## Acknowledgements

We would like to thank the members of the UT Austin BWI group for several insightful discussions, and Subhashini Venugopalan for her help with revising the paper draft. This research was supported by NSF EAGER (IIS-1548567) and NRI (IIS-1637736) grants.

Table 4: The robot following the learned policy takes the action despite the lower confidence, leading to a shorter dialog.

ROBOT How can I help?  
 USER bring the hamburger to peggy  
 ROBOT What would you like me to bring?  
 USER the hamburger  
*The robot brought a hamburger to Peggy.*  
 ROBOT Was this the correct action?  
 USER yes

Table 5: The robot following the hand-coded policy confirms the action before taking it, leading to a longer dialog.

## Supplementary Material

### A Improvement in parser accuracy

The following experiment is an attempt to quantify the accuracy of the parsers after training from dialog. This was done by hand-annotating the semantic forms for commands from the test set used for the first experiment. The results can be seen in table 7. The parsers are evaluated in terms of *Recall@1*, which is the fraction of times the correct parse is the top parse predicted by the parser, and *Recall@10*, which is the fraction of times the correct parse occurs in the top 10 parses predicted by the parser.

Learning involved	<i>Recall@1</i>	<i>Recall@10</i>
None	0.564	0.611
Only parser	0.588	<b>0.671</b> *
Only dialog	0.564	0.623
Parser & dialog - <i>full</i>	0.588	<b>0.647</b> ^
Parser & dialog - <i>batchwise</i>	0.576	<b>0.670</b> *

Table 7: Comparison of performance of initial parser and parsers after updating various components, on paired commands and semantic forms. \* indicates that the difference in performance between this and the *Initial* parser on the same metric is statistically significant according to a paired t-test with  $p < 0.05$  and ^ indicates that the difference is trending significance ( $p < 0.1$ )

As expected, we observe that the initial parser (no learning) and the parser from the system performing only dialog learning, perform worse than the others, as the other systems update the parser used by these. The parser of the system performing only dialog learning is in fact a copy of the initial parser and was included only for completeness. Any difference in their performance is due to randomness. The parsers updated from dialogs improve in accuracy but the differences are found to be statistically significant only on *Recall@10*. The modest improvement is unsurprising given that the supervision provided is both noisy and weak. However, as seen in the main paper, even this modest improvement is sufficient to improve overall dialog success.

### B Importance of multiple parse hypotheses

Many NLP systems typically return a list of top- $n$  hypotheses, including semantic parsers. We use

the entire beam of top- $n$  parses when updating the state. This is expected to be beneficial in cases where that the correct hypothesis is not the top ranked but present in this beam. The following experiment demonstrates that using multiple parses when updating the state improves overall dialog success. We compared an agent that used the same parser and policy as in the batchwise training but only the top ranked parse from the parser to update its state, as opposed to a beam of parses when updating its state. These two systems differed in no other components.

Number of parses considered	% successful dialogs	Dialog length
1	0.59	9.17
10	<b>0.64</b>	12.18

Table 8: Comparison of an agent using only the top hypothesis from the semantic parser and another using the top 10 parses. All differences are statistically significant according to an unpaired t-test with  $p < 0.05$ .

Table 8 shows the usefulness of considering multiple hypotheses from the semantic parser. As expected, the agent using multiple parses performs the correct action a significantly higher fraction of times. The system using a single hypothesis has a shorter average length among its successful dialogs because it rarely succeeds in more complicated dialogs where the system needs repeated clarification or answers to multiple specific questions.

# Unsupervised AMR-Dependency Parse Alignment

## Abstract

In this paper, we introduce an Abstract Meaning Representation (AMR) to Dependency Parse aligner. Alignment is a preliminary step for AMR parsing, and our aligner improves current AMR parser performance. Our aligner involves several different features, including named entity tags and semantic role labels, and uses Expectation-Maximization training. Results show that our aligner reaches an 87.1% F-Score score with the experimental data, and enhances AMR parsing.

## 1 Introduction

Abstract Meaning Representation (AMR) (Banasescu et al., 2013) is a semantic representation that expresses the logical meaning of English sentences with rooted, directed, acyclic graphs. AMR associates semantic concepts with the nodes on a graph, while the relations are the label edges between concept nodes. Meanwhile, AMR relies heavily on predicate-argument relations from PropBank (Palmer et al., 2005), which share several edge labels. The representation also encodes rich information, like semantic roles (all the “ARGN” tags from PropBank), named entities (NE) (“person”, “location”, etc., concepts), wiki-links (“:wiki” tags), and co-reference (reuse of variables, e.g.,  $p$ ). An example AMR in PENMAN format (Matthiessen and Bateman, 1991) is shown in Figure 1.

The design of an AMR to English sentence aligner is the first step for implementation of an AMR parser, since AMR annotation does not contain links between each AMR concept and the original span of words. The basic alignment strategy is to link the AMR tokens (either concepts or edge labels) with their corresponding

```
(j / join-01
 :ARG0 (p / person :wiki -
 :name (p2 / name
 :op1 "Pierre" :op2 "Vinken")
 :age (t / temporal-quantity :quant 61
 :unit (y / year)))
 :ARG1 (b / board
 :ARG1-of (h / have-org-role-91
 :ARG0 p
 :ARG2 (d2 / director
 :mod (e / executive :polarity -))))
 :time (d / date-entity :month 11 :day 29))
```

Figure 1: The AMR annotation of sentence “Pierre Vinken, 61 years old, will join the board as a nonexecutive director Nov. 29.” in PENMAN format

span of words. Another strategy is to find the alignment from an AMR concept to a word node in a dependency parse tree, the goal of this paper. A dependency parse tree is a good structure for attaching more information, e.g. named entity tags, lemma, and semantic role labels, etc., and provides richer syntactic information than the span of words. An alignment between an AMR concept and a dependency node represents a correspondence between the meaning of this concept and its child concepts and the phrase governed by the dependency node (i.e., head word). An example alignment is shown in Figure 2. For example, the word node “Vinken” on the dependency parse side in Figure 2 links to the lexical concept of “Vinken” and, furthermore, links to the “ $p2/name$ ” and the “ $p/person$ ” concepts since “Vinken” is the head of the named entity “Pierre Vinken” and the head of the whole noun phrase “Pierre Vinken, 61 years old.”. In our work, we use Expectation-Maximization(EM) (Dempster et al., 1977) to train different feature probabilities, including rule-based features, lexical forms, relation labels, named entity tags, semantic role

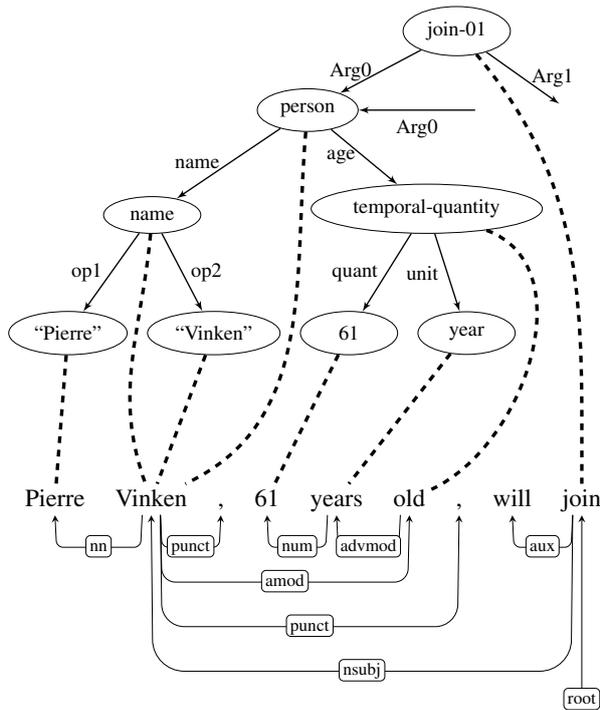

Figure 2: The alignment between a subgraph of an AMR (top) and a dependency parse (bottom) for the “Pierre Vinken” sentence. Dashed lines link dependency parse nodes and corresponding concepts.

labels, and global features, etc. Then EM processing incorporates all the individual probabilities and estimates the final alignments.

We will describe AMR-English sentence alignment in general, and review related work, in Section 2. Then the descriptions of our AMR-dependency parse features and alignment model are in Section 3. Our beam-search decoder is described in Section 4. Our experimental results are presented in Section 5, followed by our conclusion and discussion of future work (Section 6).

## 2 AMR-English Sentence Aligner

A preliminary step for an AMR parser is aligning AMR concepts and the original spans of words. JAMR (Flanigan et al., 2014) includes a heuristic alignment algorithm between AMR concepts and words or phrases from the original sentence. They use a set of alignment rules, like named entity, fuzzy named entity, data entity, etc., with a greedy strategy to match the alignments. This aligner achieves a 90%  $F_1$  score on hand aligned AMR-sentence pairs. On the other hand, the ISI Aligner (Pourdamghani et al., 2014) presents a

generative model to align AMR graphs to sentence strings. They propose a string-to-string alignment model which transfers the AMR expression to a linearized string representation as the initial step. Their training method is based on the IBM word alignment model (Brown et al., 1993) but they modify the objective function of the alignment model. IBM Model-4 with a symmetric method reaches the highest  $F_1$  score, 83.1%. When separating the alignments into roles (edge labels) and non-roles (concepts),  $F_1$  scores are 49.3% and 89.8%, respectively. In Werling’s AMR parser (Werling et al., 2015), they conceive of the alignment task as a linear programming relaxation of a boolean problem. The objective function is to maximize the sum of action reliability. Each concept is constrained to align to exactly one token in a sentence. This ensures that only adjacent nodes or nodes that share the same title refer to the same token. They hand-annotate 100 AMR parses, and their aligner achieves an accuracy of 83.2%. By providing alternative alignments to their graph-based AMR parser, their aligner achieves a better Smatch score than JAMR’s aligner.

However, two transition-based parsers which parse dependency parse tree structures into AMRs, e.g., the CAMR system (Wang et al., 2015; Wang et al., 2016) and the RIGA system (Barzdins and Gosko, 2016), tie for the best results in SemEval-2016 task 8 (May, 2016). It is important to note that the JAMR aligner was not designed to align between a dependency word node and an AMR concept where its alignment  $F_1$  score is only 69.8% (see Section 5.2). In order to deal with this problem, (Chen, 2015) proposed a preliminary aligner which estimates alignments by learning the feature probabilities of lexical (surface) forms, relations, named entities and semantic roles jointly. Besides the objective to obtain alignment between AMR concepts and original word spans, the estimation of these feature probabilities is also useful for further development of the AMR parser with these initial models. In our paper, we extend their previous work by adding rule-based and global features, and adding a beam-search algorithm at decoding time.

## 3 AMR-Dependency Parse Aligner

Our approach is an AMR-to-Dependency parse aligner, which represents one AMR as a list of

Concepts  $C = \langle c_1, c_2, \dots, c_{|C|} \rangle$ , and the corresponding dependency parse as a list of dependency word nodes  $D = \langle d_1, d_2, \dots, d_{|D|} \rangle$ . An alignment function  $a$  is designed to produce exactly one alignment to a dependency node  $d_{c_j}$  for each concept  $c_j$ , within a single sentence. Alternatively, we can view  $a$  as a mapping function that accepts one input variable concept  $c_j$  and outputs a dependency node  $d_{c_j}$  with which  $c_j$  is aligned.  $A$  is the alignment set that contains all different  $a_l$  that cover possible alignments within  $C$  and  $D$ . Our model adopts an asymmetric alignment direction, where one concept maps to exactly one dependency parse node, and each dependency parse node can be aligned by zero to multiple concepts. We denote dependency node  $d_c$  linked by concept  $c$  as  $d_c = a(c)$ .  $c^p$  is the parent concept of concept  $c$ , while  $c^{s_1}, c^{s_2}, \dots, c^{s_k}$  are the  $k$  child concepts of concept  $c$ .

### 3.1 Features

#### 3.1.1 Basic Features

Several of the AMR concepts use the word form directly. For example, the concept “join-01” in Figure 1 would align to the dependency node “join” naturally. Similarly, the leaf concepts usually align to identical terms in the dependency parse. In Figure 1, the names “Pierre” and “Vinken” are aligned to their word forms on the dependency parse leaves. Therefore, we design a straightforward rule-based probability,  $P_{rule}$ , which catches the appearance of the surface form.  $P_{rule}(c, d_c)$  is defined as the probability that the matching type for a given concept  $c$  and dependency node  $d_c$  are linked. The different types of rules, e.g., word, lemma, numbers, and date, etc., and their proportional applicability to both AMR concepts and leaves are listed in Table 1. For example, the rule “Date” type aligns concept “11” with word node “November” in Figure 1, while “Numbers” aligns concept “5” with word node “five”.  $P_{rule}$  decides which match type to apply by following a greedy matching strategy.

#### 3.1.2 External Features

To capture alignments for concepts which do not match any of the above basic rules, we design the following four external feature probabilities:

$$P_{Lemma}(c, d_c) = P(c|Word(d_c))$$

**Lemma Probability** represents the likelihood that a concept  $c$  aligns to a dependency word  $d_i$ . For

	Match Type	at Concept	at Leaf
(1)	Word	45.2%	73.4%
(2)	Word (case insensitive)	-	0.9%
(3)	Lemma (case insensitive)	10.8%	0.3%
(4)	Partial match with word	6.1%	8.2%
(5)	Partial match with lemma	0.2%	0.3%
(6)	Numbers	-	3.1%
(7)	Ordinal Numbers	-	2.8%
(8)	Date	-	4.3%
(9)	Others	37.7%	6.5%

Table 1: The rules and distribution of basic match types

example, in Figure 3a, the concept  $c = \text{“temporal-quantity”}$  is highly likely to align to the word node  $d_c = \text{“old”}$  since “old” is usually the head word of a phrase expressing age (“61 years old” here). Also, *have-org-role-91* can align to the word node “director” since “director” appears quite often with *have-org-role-91* (defined as roles in organizations). Besides, some special leaf concepts, like “:polarity -” (negative), and “:mode expressive” (which is used to mark exclamational word), also rely on this feature rather than the basic rules.

$P_{rel}(c, d_c, d_{c^p}) = P(AMRLabel(c)|Path(d_c, d_{c^p}))$   
**Relation Probability** is the conditional probability of the AMR relation label of  $c$ , given the parse tree path between  $d_c$  and  $d_{c^p}$ , where  $d_c$  and  $d_{c^p}$  represent the dependency nodes that are aligned by  $c$  and  $c^p$ , respectively. Parse tree path is the concatenation of all dependency tree and direction labels through the tree path between  $d_c$  and  $d_{c^p}$ . For example, the relation probability of  $c = 61$ ,  $d_c = \underline{61}$ , and  $d_{c^p} = \underline{old}$  in Figure 3b is  $P(quant|advmod \downarrow num \downarrow)$ . A parse tree path is a useful feature for extracting relations between any two tree nodes, e.g., Semantic Role Labeling (SRL) (Gildea and Jurafsky, 2002) and relation extraction (Bunescu and Mooney, 2005; Kambhatla, 2004; Xu et al., 2015), so we add relation probability to our model.

$$P_{NE}(c, d_c) = P(c|NamedEntity(d_c))$$

**Named Entity Probability** is the probability of the concept  $c$  conditioned on different named entity types (e.g., PERSON, DATE, ORGANIZA-

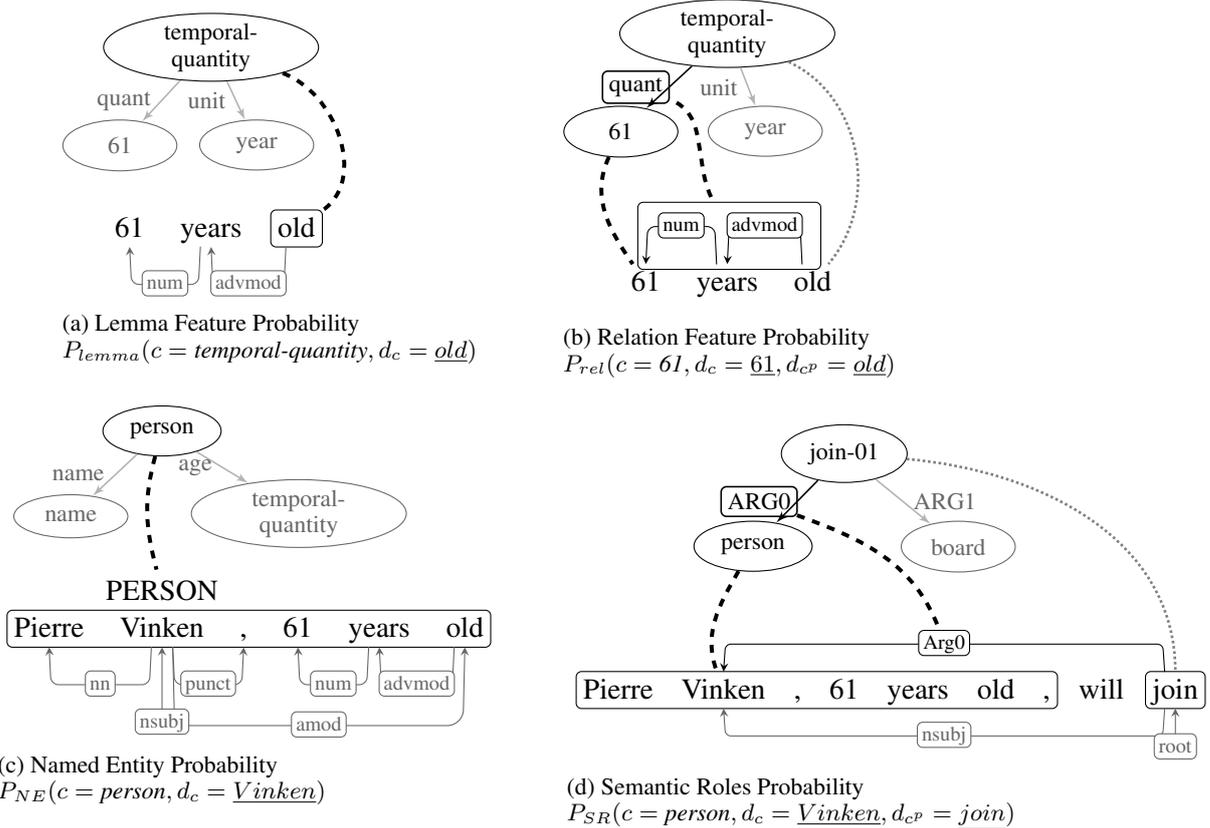

Figure 3: The sample of feature probabilities that are used in our aligner. Dashed lines link AMR concepts (top) and corresponding dependency parse nodes (bottom), while dense dashed lines link the parent AMR concepts and its corresponding dependency parse nodes.

TION, etc.). *NamedEntity*( $d$ ) indicates the named entity type of the phrase with  $d$  as the head word. For example, after named entity recognition (NER) tagging, the label assigned to “PERSON” is the dependency parse tree node “Vinken”. So the named entity probability of  $P_{NE}(c = \text{person}, d_c = \text{Vinken})$  in Figure 3c is  $P(\text{person} | \text{PERSON})$ . Since AMR contains a large amount of named entity information, we assume that a feature based on an external named entity module should improve the alignment accuracy.

$$P_{SR}(c, d_c, d_{cp}) = P(\text{AMRLabel}(c) | \text{SemanticRole}(d_{cp}, d_c))$$

**Semantic Role Probability** is the conditional probability of the AMR relation label of  $c$ , given the semantic role  $d_c$  if  $d_{cp}$  is a predicate and  $d_c$  is  $d_{cp}$ ’s argument. If a predicate-argument structure does not exist between  $d_{cp}$  and  $d_c$ , the semantic role probability is omitted. For example, in Figure 3d, the semantic role probability of  $P_{SR}(c = \text{person}, d_c = \text{Vinken}, d_{cp} = \text{join})$  is equal to  $P(\text{ARG0} | \text{Arg0})$ . Since AMR depends heavily on predicate-argument relations, external

predicate-argument information from an external SRL system should enhance the overall alignment accuracy.

The above four feature probabilities are learned by the EM algorithm (Section 3.2).

### 3.1.3 Global Feature

The above basic and external features capture local alignment information. However, to make sure that a concept is aligned to the correct phrase head word which represents the same sub-meaning, we need a global feature to calculate coverage. The design of our concept coverage feature is as follows:

$R_{CC}(c)$  **Overlapping Ratio** of the child concept aligned phrases to their parent concept aligned phrases plus the non-covered penalty. This ratio is defined as:

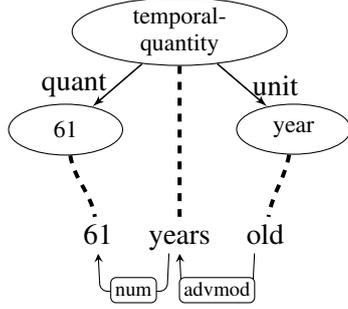

Figure 4: A sample of incorrect alignment. We use this sample to calculate its overlapping ratio ( $R_{cc}$ ) let  $c = \text{temporal-quantity}$

$$\begin{aligned}
 W(c) &= \{\underline{61}, \underline{year}\} \\
 W_{child}(c) &= \{\underline{61}\} \cup \{\underline{61}, \underline{year}, \underline{old}\} \\
 &= \{\underline{61}, \underline{year}, \underline{old}\} \\
 W_{child}(c) \cap W(c) &= \{\underline{61}, \underline{year}\} \\
 pen(c) &= \exp(-|\{\underline{old}\}|) = 0.37 \\
 R_{cc}(c) &= \left(\frac{2}{3}\right) \times pen(c) = 0.37
 \end{aligned}$$

$$R_{CC}(c) = \frac{|W_{child}(c) \cap W(c)|}{|W(c)|} \times pen(c)$$

$$W(c) = d_c$$

$$W_{child}(c) = \bigcup_{c^s_i \in child(c)} d_{c^s_i}$$

$$pen(c) = \exp(-|W_{child}(c) \setminus (W_{child}(c) \cap W(c))|)$$

where  $W$  refers to the set of words that the aligned dependency word node contains. The first term of  $R_{CC}$  ensures the child concepts contain the largest possible subspans of the parent concept span. The non-covered penalty term ( $pen$ ) is to prevent a child concept from aligning to a word node that contains a larger word span than the child’s parent concept. The  $pen$  term will increase exponentially if child concepts align to a larger word span. The back slash term “ $\setminus$ ” refers to set subtraction. We take Figure 4 as an example of an incorrect alignment example where the concept “*temporal-quantity*” aligns to “*year*” and the concept “*year*” aligns to “*old*”, the overlapping ratio of this alignment is 0.37 since it suffers a penalty. As we compare it with the correct alignment in Figure 3b, the overlapping ratio of this alignment is 0.67, which is much higher than the incorrect one.

### 3.2 Training with EM Algorithm

The objective function of our AMR-to-Dependency Parse aligner is listed as follows: Since our long term goal is to design a dependency parse to AMR parser, we define the objective function  $L_\theta$  as the probability that dependency parses transfer to AMR graphs for the AMR-to-Dependency Parse aligner:

$$\theta = \operatorname{argmax} L_\theta(\text{AMR}|\text{DEP}) \quad (1)$$

$$\begin{aligned}
 L_\theta(\text{AMR}|\text{DEP}) &= \prod_{\substack{(C,D,A) \\ \in \mathbb{S}}} P(C|D) \\
 &= \prod_{\substack{(C,D,A) \\ \in \mathbb{S}}} \sum_{a \in A} P(C, a|D) \quad (2)
 \end{aligned}$$

$$P(C, a|D) = \prod_{j=1}^{|C|} P(c_j | d_{c_j} = a(c_j), d_{c_j^p} = a(c_j^p)) \quad (3)$$

where  $\theta = (P_{lemma}, P_{rel}, P_{NE}, P_{SR})$  is the set of feature probabilities (parameters) we want to estimate, alignment set  $A$  is the latent variable we want to observe, and  $\mathbb{S}$  is the training sample that contains a set of tuples  $(C, D, A)$ , where  $C$  and  $D$  are a  $\langle \text{AMR}, \text{dependency parse} \rangle$  pair and  $A$  is their alignment combination set. In equation (3), the probability that dependency tree  $D$  translates to AMR  $C$  with an alignment combination  $a$  is equal to the product of all probabilities that concept  $c_j$  in  $C$  aligns to dependency node  $d_{c_j}$  and  $c_j^p$  aligns to dependency node  $d_{c_j^p}$ .

#### 3.2.1 Expectation-Step

The E-Step estimates all the different alignment probabilities of an input AMR and dependency parse pair by giving the product of feature probabilities. The alignment probability can be calculated using:

$$P(a|C, D) = \prod_{j=1}^{|C|} \frac{P(c_j | d_{c_j}, d_{c_j^p})}{\sum_{l=1}^{|D|} \sum_{i=1}^{|D|} P(c_j | d_i, d_l)} \quad (4)$$

$$\begin{aligned}
 P(c_j | d_i, d_l) &= P_{rule}(c_j, d_i) \times P_{lemma}(c_j, d_i) \\
 &\quad \times P_{rel}(c_j, d_i, d_l) \times P_{NE}(c_j, d_i) \times P_{SR}(c_j, d_i, d_l) \quad (5)
 \end{aligned}$$

The alignment probability is equal to the product of all tuple  $(c, d_c, d_{c^p})$ ’s aligning probabilities.

$P_{rule}$  is obtained by a simple calculation from the development set, while  $P_{lemma}$ ,  $P_{rel}$ ,  $P_{NE}$ , and  $P_{SR}$  are initialized uniformly before the first round of E-step. And these feature probabilities will be updated during the M-step.

### 3.2.2 Maximization-Step

In the M-Step, feature probabilities are re-estimated by collecting the count of all AMR-dependency parse pairs. The count of lemma ( $cnt_{lemma}$ ), relation ( $cnt_{rel}$ ), named entity ( $cnt_{NE}$ ), and semantic role ( $cnt_{SR}$ ) features are the normalized counts that are collected from the accumulating probability of all possible alignments from the E-step. Here we take the derivation of  $cnt_{lemma}$  as an example.  $cnt_{rel}$ ,  $cnt_{NE}$ , and  $cnt_{SR}$  can be obtained with similar equations:

$$cnt_{lemma}(c|Word(d_c); C, D) = \sum_{a \in A} \frac{P(c|d_c, d_{c_p})}{\sum_{i=0}^{|D|} \sum_{l=0}^{|D|} P(c|d_i, d_l)}$$

After we collect all counts for different features, the four feature probabilities,  $P_{lemma}$ ,  $P_{rel}$ ,  $P_{NE}$ , and  $P_{SR}$ , are updated with their feature counts. Here we show the update of  $P_{lemma}$  as an example. The rest of feature probability updates can be derived in the same way:

$$P_{lemma}(c, d) \leftarrow \sum_{\substack{C \in AMR, \\ D \in DEP}} \frac{cnt_{lemma}(c|Word(d); C, D)}{\sum_{j=1}^{|C|} cnt_{lemma}(c_j|Word(d); C, D)}$$

After this, we apply the newer feature probabilities to recalculate alignment probabilities in the E-step again. EM iterates the E and M-steps until convergence or certain criteria are met.

## 4 Decoding

At decoding time, we want to find the most likely alignment  $a$  for the given  $\langle C, D \rangle$ . By applying Equations (4) and (5), we define the search for alignments as follows:

$$\operatorname{argmax}_a P(a|C, D) = \operatorname{argmax}_a \prod_{j=1}^{|C|} R_{CC}(c_j) * P(c_j|d_i = a(c_j), d_l = a(c_j^p))$$

This decoding problem finds the alignment  $a$  that maximizes the likelihood, which we define in

		Sent.	Token	# of NE	# of Arg.
Gold	train	8,276	176,422	3,750	58,520
	dev.	409	8,695	415	2,574
	test	415	8,786	401	3,107
All	train	39,260	649,219	43,715	260,979
	dev.	409	8,695	580	2,574
	test	415	8,786	401	3,107

Table 2: The data split of the LDC DEFT AMR corpus. *Gold* refers to the sentences also appearing in OntoNotes 5.0 with gold annotations, while *All* refers to all sentences in DEFT AMR corpus with dependency parses, named entities, and semantic roles generated by ClearNLP. Number of tokens, named entities, and arguments(Arg.) in each data set are also presented

Equation (5). The overlapping ratio ( $R_{CC}$ ) is introduced to the likelihood function to ensure that a parent concept covers a wider word span range than its child concepts. A beam search algorithm is designed to extract the target alignment without exhaustively searching all of the candidate alignments (which has a complexity of  $O(|D|^{|C|})$ .) The beam search starts from leaf concepts and then walks through parent concepts after their child concepts have been traversed. When we go through concept  $c_j$ , we need to consider all the following likelihoods: 1) the accumulated likelihood for aligning to any dependency word node  $d_{c_j}$  from all the child concepts of  $c_j$ , and 2) the product of  $P_{lemma}$ ,  $P_{NE}$ ,  $P_{rel}$ ,  $P_{SR}$ , and  $R_{CC}$  for  $c_j$ . Instead of using during training,  $R_{CC}$  is only applied during decoding time. The probabilities are obtained simply from the product of all the above likelihoods. We keep the top- $|b|$  alignment probabilities and their aligned dependency node  $d_{c_j}$  for each  $c_j$  until we reach the root concept, where  $|b|$  is the beam size. Finally we can trace back and find the most likely alignment.

The running time for the beam search algorithm is  $O(|b| * |C| * |D|^2)$ .

## 5 Experiments and Results

### 5.1 Experimental Data

The LDC DEFT Phase 2 AMR Annotation Release 2.0<sup>1</sup> consists of AMRs with English sentence

<sup>1</sup>LDC DEFT Phase 2 AMR Annotation Release 2.0, Release date: March 10th, 2016. <https://catalog.ldc.upenn.edu/LDC2016E25>

pairs. Annotated selections from various genres (including newswire, discussion forum, other web logs, and television transcripts) are available, for a total of 39,260 sentences. This release uses the PropBank Unification frame files (Bonial et al., 2014; Bonial et al., 2016). To generate automatic dependency parses for all DEFT AMR Release data, we use ClearNLP (Choi and McCallum, 2013) to produce dependency parses. ClearNLP also labels semantic roles and named entity tags automatically on the generated dependency parses. This data set is named “All”. To compare the effect of applying automatic dependency parses to our aligner with gold dependency parses, we select the sentences which appear in the OntoNotes 5.0<sup>2</sup> release as well. The OntoNotes data contains TreeBanking, PropBanking, and Named Entity annotations. OntoNotes 5.0 also uses PropBank Unification frame files for PropBanking. This data set, containing a total of 8,276 of selected AMRs and their dependency parses from OntoNotes, is named “Gold”. To generate the development and test set, we manually align the AMR concepts and dependency word nodes. Since the manual alignment is time-consuming, “Gold” and “All” data share the same development/test set. Table 2 presents the statistics for the experimental data.<sup>3</sup>

## 5.2 Experiment Results

We run EM for 50 iterations and ensure the EM model converges. Afterwards, we use our decoding algorithm to find the alignments that maximize the likelihood. The test set data is used to evaluate performance.

We first evaluate the performance of our system with the external features added incrementally. Table 3 indicates the results. By running with the “Gold” data, the only feature that improves significantly over the baseline (rule-based and lexicon features only) is the semantic role feature. The named entity feature actually hurts performance. On the other hand, all the features contribute to the F-Score incrementally for “All”. Again, the semantic role feature still has the most positive impact against other features, and a significant improvement over the baseline.

As we compare the  $F_1$  score on training with

<sup>2</sup>LDC OntoNotes Release 5.0, Release date: October 16th, 2013 <https://catalog.ldc.upenn.edu/LDC2013T19>

<sup>3</sup>The manually aligned data and our aligner will be available after this paper gets accepted

Data	Feature	P	R	F-Score
Gold	L	84.0	85.0	84.5
	L + S	85.2	86.3	<b>85.7</b>
	L + S + R	82.8	83.8	83.3
	L + S + R + N	80.9	81.9	81.4
All	L	84.9	85.4	85.1
	L + S	85.7	87.4	86.5
	L + S + R	85.8	87.7	86.7
	L + S + R + N	86.3	88.0	<b>87.1</b>

Table 3: Incremental Feature Contributions for different features:  $L$ : lemma;  $R$ : relation;  $N$ : NE;  $S$ : semantic role.

“All” and “Gold” data set, training with “All” outperforms training with “Gold” data in all different feature combinations. We believe there are two reasons for this. First, the “All” data contains richer information than the “Gold” data. “All” has double the sentence size of “Gold”, and proportionally more named entity labels. Second, the automatic dependency parses do not hurt the performance of our aligner very much. We believe that our unsupervised alignment model works better with more data, even without access to gold standard dependency parses.

We then compare our aligner with three other aligners: JAMR, another version of unsupervised alignment (Chen, 2015), and ISI. To make them fit our test data, we design a heuristic method to force every unaligned concept (e.g., named entity and “:polarity -” concepts) to align to a dependency word node according to rule-based and global features (see Section 3.1). The alignment is counted as a correct match when the concept aligns to either the head word or the partial word span of a phrase. The alignments from concept relation to word span (apply in ISI) are discarded in our task. The results of the experiment are shown in Table 4. Our aligner achieves the best  $F_1$  score in both the “All” and “Gold” data sets, as it should, since it is designed to align AMRs to dependency parses, as was the Chen aligner. Our aligner performs better than the Chen aligner by around 28% in  $F_1$  score. We can conclude that the addition of rule-based feature, global features, and beam-search in decoding time helps the alignment task substantially.

## 5.3 Apply to AMR Parsing

To evaluate how alignment can enhance AMR parsing, we compare the parsing performance of

Data	Aligner	P	R	F-Score
Gold	Chen 2015	61.1	53.4	57.0
	JAMR	78.5	62.8	69.8
	ISI	78.6	71.4	74.9
	Ours	<b>85.2</b>	<b>86.3</b>	<b>85.7</b>
All	Chen 2015	62.4	55.5	58.7
	JAMR	80.2	65.9	72.4
	ISI	80.4	74.9	77.6
	Ours	<b>86.3</b>	<b>88.0</b>	<b>87.1</b>

Table 4: Results of different alignment models

the CAMR parser with different alignments produced by JAMR, ISI, and our aligner. To make the alignments fit the CAMR parser, we convert both ISI and our alignments to the original JAMR alignment format, word span to AMR concept. We get rid of the “:wiki” tag, which links the named entity to its Wikipedia page, to simplify the parsing task since we think the Wikify task (Mihalcea and Csomai, 2007) is basically different from the AMR parsing task. Smatch v2.0.2 is used to evaluate AMR parsing performance (Cai and Knight, 2012). The evaluation script is obtained from the SemEval 2016 Task 8 website<sup>4</sup>.

A comparison of parsing results is given in Table 5. We first train the parser with “Gold” Standard dependency parses and alignments from the different aligners. Results show that our aligner improves by a 2%  $F_1$  score over the two other aligners. Then we train the AMR Parser system with the “All” data set. The dependency parses attached with semantic roles and named entities generated by ClearNLP are also provided to CAMR as training data. CAMR use dependency parsing results from Stanford dependency parser (Klein and Manning, 2003) by default. Our aligner still achieves slightly better performance than the other two. Modifying the AMR parser to take advantage of parse node-concept alignments could potentially result in greater improvement, since CAMR takes the input alignments as word span to AMR concept.

#### 5.4 Error Analysis

To further understand the advantages and the disadvantages of our model, we go through all incorrect alignments and manually categorize 40% of them into different error types, with their propor-

<sup>4</sup><http://alt.qcri.org/semeval2016/task8/index.php?id=data-and-tools>

Data	Aligner	P	R	F-Score
Gold	JAMR	62.2	61.0	61.1
	ISI	65.3	63.9	64.5
	Ours	<b>68.6</b>	<b>64.2</b>	<b>66.4</b>
All	JAMR	64.2	63.0	63.1
	ISI	66.1	65.1	65.6
	Ours	<b>68.1</b>	<b>64.7</b>	<b>66.7</b>

Table 5: Comparison of using different alignments with CAMR Parser.

tion:

**Automatic Parsing Errors** - 3.8%: ClearNLP has a 92.96% unlabeled attachment score on the Penn English Treebank evaluation set (Marcus et al., 1993), Section 23, for dependency parsing. Therefore, when training our aligner on the “All” data set with dependency parses, named entities, and semantic roles generated by ClearNLP, incorrect parses occasionally show up. Since NE and semantic roles are attached to dependency parses, incorrect dependency parses cause additional NE and semantic roles alignment errors, on top of the dependency parse alignment errors.

**Long Distance Dependencies** - 14.2%: Long sentences with long distance dependencies always bring difficulty to NLP parsing tasks. Experimental results show that our model runs into troubles when nearby concepts align to dependency nodes which are far from each other. Co-reference is an example that is highly likely to align to long distance dependencies, and our model can not deal with it well.

**Duplicate Words** - 17.4%: When two identical concepts align to different word nodes, our model is confused by duplicate words. In Figure 5, there are two “first”s in the sentence. One refers to “first 6 rounds”, and the other refers to “first position”. However, our model faultily aligns both *ordinal-entity* concepts to the same “first” word node. Our model did not distinguish these two ordinal-entities since the lexicon and named entity tags of the two “first”s are identical.

**Meaning Coverage Errors** - 40.4%: We define a good alignment as a concept that aligns to the correct phrase head word which represents the same sub-meaning. So instead of aligning to a concept’s word lexicon, sometimes a concept aligns to its parent node (head word). However, the lexicon features dominate the alignment probability in our

```

Figure 5: The AMR annotation of sentence “In the first 6 rounds of competition, Mingxia Fu and Bin Chi are occupying the first and third positions respectively”

E-M calculation. That causes our model to tend to align a concept with its word form instead of its head word. For example, English light verb constructions (LVCs), e.g., *take a bath*, are thought to consist of a semantically general verb and a noun that denotes an event or state. AMR representation always drops light verb and uses eventive noun as concept. Our model sometimes aligns this eventive noun concept to its nominal word node, which is incorrect since the light verb on dependency parse covers the same sub-meaning and should be aligned.

## 6 Conclusion and Future Work

In this paper, we present an AMR-Dependency Parse aligner, which estimates the feature probabilities by running the EM algorithm. It can be used directly by AMR parser. Results show that our aligner performs better than other aligners, and improves AMR parser performance. The latent probabilities that we obtain during training, i.e., all the external feature sets, could also potentially benefit a parser. We plan to develop our own AMR parser, which will apply these external feature sets as the basic model. We also plan to continue to perfect our aligner via tuning the feature weights and learning techniques, and adding new features, like word embeddings and WordNet features.

## Abstract

This paper presents a method for improving semantic role labeling (SRL) using a large amount of automatically acquired knowledge. We acquire two varieties of knowledge, which we call surface case frames and deep case frames. Although the surface case frames are compiled from syntactic parses and can be used as rich syntactic knowledge, they have limited capability for resolving semantic ambiguity. To compensate the deficiency of the surface case frames, we compile deep case frames from automatic semantic roles. We also consider quality management for both types of knowledge in order to get rid of the noise brought from the automatic analyses. The experimental results show that Chinese SRL can be improved using automatically acquired knowledge and the quality management shows a positive effect on this task.

## 1 Introduction

Semantic role labeling (SRL) is regarded as a task that is intermediate between syntactic analysis and semantic analysis in natural language processing (NLP). The main goal of SRL is to extract a proposition from a sentence about *who* does *what* to *whom*, *when*, *where* and *why*. By using semantic roles, the complex expression of a sentence is then interpreted as an *event* and its *participants* (i.e., a predicate and arguments such as *agent*, *patient*, *locative*, *temporal* and *manner*). Unlike syntactic level surface cases (i.e., dependency labels such as subject and object), semantic roles can be regarded

as a deep case representation for predicates. Because of its ability to abstract the meaning of a sentence, SRL has been applied to many NLP applications, including information extraction (Christensen et al., 2010), question answering (Pizzato and Mollá, 2008) and machine translation (Liu and Gildea, 2010).

Semantically annotated corpora, such as FrameNet (Fillmore et al., 2001) and PropBank (Kingsbury and Palmer, 2002), make this type of automatic semantic structure analysis feasible by using supervised machine learning methods. However, supervised SRL methods have the following two major issues. Firstly, as a common issue in almost all the supervised approaches, it is expensive to enlarge manually annotated corpora to learn a more accurate model. Secondly, experiments show that automatic SRL systems strongly depend on syntactic information. In practice, these SRL systems suffer from errors propagated from the lower-level syntactic analyses, such as word segmentation, POS tagging, and dependency parsing. Although some studies use automatic analyses of unlabeled corpora to enrich the training data to solve the first problem (Fürstenaу and Lapata, 2009), accumulated errors in such automatic analysis inevitably cause negative effects. Especially, for some hard-to-analyze languages, such as Chinese, which is still difficult to precisely analyze word segmentations, the performance of SRL is always limited due to the above two problems.

In this paper, we focus on Chinese SRL and address the problems mentioned above by using high-quality knowledge automatically acquired from a large-scale raw corpus. We utilize two types of additional knowledge. The first type is compiled using automatic syntactic analysis (specifically, dependency parsing) and is named **surface case frames** which are not expressive in

\*The first author is now affiliated with Canon IT Solutions Inc.

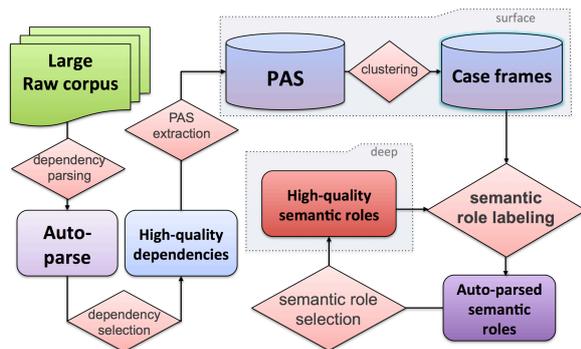

Figure 1: Overview of the framework

semantic level. In order to compensate the drawback of surface case frames, we also compile another type of knowledge using automatic semantic roles. We call this type of knowledge **deep case frames**. We illustrate the whole framework in Figure 1. The additional knowledge can provide not only syntactic information but also semantic information, both of which play crucial roles in SRL. Considering the inevitable noises from automatic analyses, we utilize an automatic selection method to select dependencies and semantic roles of high quality. In order to show that automatically extracted knowledge is beneficial and the quality management is indispensable, we compile both types of knowledge in different quality in our experiments and apply them to Chinese SRL.

## 2 Related work

The CoNLL-2009 shared task (Hajič et al., 2009) features a substantial number of studies on SRL that used Propbank as one of the resources. The participating systems can be categorized into two types: joint learning of syntactic parsing and SRL (Tang et al., 2009; Morante et al., 2009), which learns a unique model for syntactic parsing and SRL jointly. This type of framework has the ability to use SRL information in syntactic parsing for improvement, but needs a much larger search space for decoding. The other type is called SRL-only task (Zhao et al., 2009; Björkelund et al., 2009), which uses automatic morphological and syntactic information as the input in order to judge which token plays what kind of semantic role. Our work focuses on the second category of SRL. Our framework is based on those used by Björkelund et al. (2009) and Yang and Zong (2014).

There were several studies using additional knowledge to improve syntactic and semantic tasks. McClosky et al. (2006) used an addi-

tional unlabeled corpus to reduce data sparsity. In syntactic level of NLP, rich knowledge, such as predicate-argument structures and case frames, is strong backups for various kinds of tasks. Case frames, which clarify relations between a predicate and its arguments, can support tasks ranging from fundamental analysis, such as dependency parsing and word similarity calculation, to multilingual applications, such as machine translation. Japanese case frames have been successfully compiled (Kawahara and Kurohashi, 2006), where each case slot is represented as its case marker in Japanese such as ‘ga’, ‘wo’, and ‘ni’. For the case frames of other languages such as English and Chinese, because there are no such case markers that can help clarify syntactic structures, instead of using case markers like in Japanese, syntactic surface cases (i.e., subject, object, prepositional phrase, etc.) are used for argument representation (Jin et al., 2014). Case frames can be automatically acquired using a different method such as Chinese Restaurant Process (CRP) (Kawahara et al., 2014) for different languages. In our work, we employ such syntactic level knowledge, which uses surface cases as argument representation, to help SRL.

One basic idea of semi-supervised SRL is to automatically annotate unlabeled data using a simple classifier trained on original training data (Fürstenau and Lapata, 2009). Since there is a substantial amount of error propagation in the SRL pipeline, the additional automatic semantic roles are not guaranteed to be of good quality. Also, some studies assume that sentences that are syntactically and lexically similar are likely to share the same frame-semantic structure (Fürstenau and Lapata, 2009). This allows them to project semantic role information to unlabeled sentences using alignments. However, the computation of these alignments requires additional information such as word similarity, whose quality is language dependent. Less sparse features capturing lexical information of words can be also used for semi-supervised learning of SRL. Such lexical representation can be learned from unlabeled data (Bengio et al., 2003). Deschacht and Moens (2009) used word similarity learned from unlabeled data as additional features for SRL. Word embeddings have also been used in several NLP tasks including SRL (Collobert et al., 2011). Instead of using word-level lexical knowledge, our work uses syn-

tactic and semantic knowledge, i.e., case frames. Word embeddings can also be incorporated into our method but we leave this to our future work. Zapirain et al. (2009) used selectional preferences to improve SRL. This study is similar to our approaches but the quality of selectional preferences was not concerned at all.

### 3 SRL task description

In previous studies, SRL pipeline<sup>1</sup> can be divided into three main steps: predicate disambiguation (PD), argument identification (AI), and argument classification (AC). In the PD step, the main goal is to identify the “sense id” of each given predicate. The AI step mainly focuses on judging whether each argument is semantically related to each predicate in a sentence. Based on the results of the AI step, the AC step assigns a semantic role to each semantically related argument. Basically, the PD step and the AC step are regarded as multi-class classification problems while the AI step is a binary classification problem.

In the PD step, because the sense id for a certain predicate is meaningless for other predicates, classifiers for PD are trained separately for each predicate. We basically use the feature set proposed by Björkelund et al. (2009). During the prediction, there are some predicates which have not been seen in the training data. We label the sense of those unseen predicates using the default sense, which is ‘01’ in our work.

## 4 Applying high-quality surface case frames to SRL

### 4.1 High-quality dependency selection

Dependency parsing has been widely employed for knowledge acquisition related to predicate-argument structures. The dependency parsing performance determines the quality of acquired knowledge, regardless of target languages. Reducing dependency parsing errors and selecting high-quality dependencies are of primary importance. Jin et al. (2013) used a single set of dependency labeled corpus (a treebank), a part of which was used to train a base dependency parser. Another part of the labeled corpus was used to apply automatic dependency parsing. By comparing the

<sup>1</sup>Predicate identification (PI) was not concerned in the experiments because we use the data from CoNLL-2009 shared task, in which the target predicates are given.

gold standard data and the automatic parses, correct dependencies were collected as positive examples and incorrect dependencies were collected as negative examples. Then selecting high-quality dependencies was regarded as a binary classification problem. To conduct such binary classification, they employed a set of basic features from Yu et al. (2008). In addition to these basic features, Jin et al. (2013) considered context features that are thought to affect parsing performance. Since the input for high-quality dependency selection method is a dependency tree, tree features are used to identify dependency quality. Also, some dependency parsers output the score of each dependency (i.e., edge confidence value) during the parsing process. They used the real value of the score as an additional feature. We first apply this approach to select high-quality dependencies from automatic parses.

### 4.2 High-quality surface case frame construction

After applying dependency parsing on a large-scale raw corpus, predicate-argument structures (PASs) are extracted using the high-quality dependencies. Arguments are represented by their dependency labels (i.e., subject, object, etc.) For each predicate, all the PASs are clustered into different case frames to reflect different semantic usages. We show an example of case frames for the verb ‘谢’ in Table 1, which has multiple meanings. ‘谢(1)’ is the case frame used to represent the sense of ‘withering of flower’. Similarly, the sense of ‘谢’ which means ‘to thank’ is represented by case frame ‘谢(2)’. ‘谢(3)’ is the case frame for the sense of ‘curtain call’. In other words, case frames are knowledge that solves word sense disambiguation (WSD) by clustering the PASs. We applied the CRP method described by (Kawahara et al., 2014) for clustering the high-quality PASs to compile high-quality case frames.

### 4.3 Surface case features for SRL

From the surface case PASs, we extract four types of additional features, for both AI and AC step. These features are described in the upper part of Table 2. We use binned values (i.e., high, middle and low) for all of the feature values calculated from the knowledge. More specifically, for each type of feature, we define the first, second and third tertile of all the feature values as low, middle and high correspondingly. Surface case

verb	surface case	instance with frequency in original corpus
谢(1)	nsubj	花儿(flower):14, 花(flower):22
	ad	都(all):16, 也(also):6
谢(2)	nsubj	你们(you):1
	dobj	您(you):8, 我(me):6
	ad	怎么(how):8, 多(very):1
谢(3)	nsubj	大战(battle):1
	dobj	幕(curtain):6
	ad	圆满(successfully):2, 也(also):1, 正式(officially):1
...		

Table 1: Examples of Chinese surface case frames

frames are clustered PASs according to each predicate’s semantic usage. Therefore, instead of utilizing all the predicate-argument structures, it is intuitive to use the predicate-argument structures only from the corresponding case frames. So we also create four types of features extracted from case frames. These features are listed in the lower part of Table 2.

Note that a case frame ID and a PropBank sense ID do not correspond to each other. In practice, the number of case frames is always larger than the number of sense in PropBank for each verb. As a result, a mapping process that aligns case frame id(s) to PropBank verb sense is applied. First, we assign automatic dependency labels to the PropBank corpus using the Stanford parser. We then calculate the similarity between a PropBank sense and a case frame by measuring the PAS similarity. As shown in the left part of Figure 2, for a certain predicate with a sense ID in PropBank, we represent the predicate in each sense by using the collection of all the instances in each syntactic role slot. Each predicate with a sense ID is then transformed into a vector space, which we name PAS vector. The same transformation is applied to case frames. Then the cosine similarity between vectors transformed from a PropBank sense and case frames is calculated. A PAS vector is the concatenation of each syntactic role vector. To form a syntactic role vector, we simply take the average of weighted summation of the word vectors within the case slot. Word vectors are acquired using word2vec<sup>2</sup> from the same raw corpus that we use for knowledge acquisition (see Section 7.1). In our experiments, we only used syntactic role “subj” (subject) and “dobj” (direct object) because

these two syntactic roles are considered to be relatively more informative.

## 5 Main problem of surface case frames

In previous work (Kawahara and Kurohashi, 2006), case frames for Japanese are composed of all the instances and their corresponding case marker. For example, all the instances in “ga” case are basically the “subject” of the given predicate. Instances in “wo” case are basically the “direct object” of the given predicate. Other cases like “ni” can indicate “location”, “time” or “direction”. During the automatic PAS extraction for Japanese, there are also ambiguous case makers that can represent multiple cases. The most common one, for example, is “wa” case in Japanese. This case marker always functions as a topic marker. The argument in “wa” case is normally emphasized as the topic of the sentence. It can be equal to either “ga” case or “wo” case, and sometimes “ni” case. To avoid such ambiguous cases, one can simply discard all the instances in “wa” case to make case frames more precise.

For languages that lack such case markers (e.g., English and Chinese), case frames are composed of automatic syntactic roles (Jin et al., 2014). Such syntactic roles include “subject”, “direct object”, “indirect object” and “prepositional phrases”. Such surface cases have limitations on case representation especially for Chinese. Take the following sentences as examples.

- (1) 苹果 (apples) / 我 (I) / 吃了 (eaten) / 很多 (a lot).
- (2) 我 (I) / 苹果 (apples) / 吃了 (eaten) / 很多 (a lot).
- (3) 我 (I) / 吃了 (eaten) / 很多 (a lot) / 苹果 (apples).
- (4) 我 (I) / 吃了 (eaten) / 很多 (a lot).

<sup>2</sup><https://code.google.com/archive/p/word2vec/source/default/source>

feature	description
Freq	the co-occurrence frequency of a predicate-argument pair without considering the syntactic role of the argument
Pmi	the point-wise mutual information (PMI) value for each predicate-argument pair without considering the syntactic role of the argument
PAfreq	the frequency of a argument being a certain syntactic role of a predicate
PApmi	the PMI value of an argument with its syntactic role and the predicate
CFFreq	Freq value calculated only from within the corresponding case frames
CFPmi	Pmi value calculated only from within the corresponding case frames
CFPAfreq	PAFreq value calculated only from within the corresponding case frames
CFPami	PApmi value calculated only from within the corresponding case frames

Table 2: Surface case features for SRL

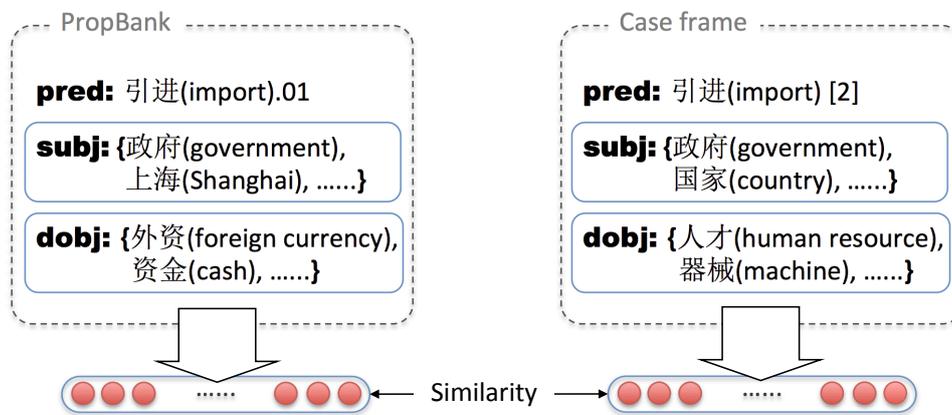

Figure 2: Overview of mapping case frames to PropBank sense

(5) 苹果 (apples) / 吃了 (eaten) / 很多 (a lot).

The first three sentences have the same meaning: “I have eaten a lot of apples.” However, as we can see from the sentences, the word “苹果 (apple)” which is a direct object of “吃了 (eaten)”, and the word “我 (I)” can be filled in various word orders. Also, because omissions occur frequently in Chinese, sentence 4 and 5 are also commonly used, which mean “I have eaten a lot” and “(I) have eaten a lot of apples”, respectively. Without considering the actual meaning of “我 (I)” and “苹果 (apples)”, both of them in sentence 4 and 5 are labeled as “subject” in the surface case representation following the syntactic grammar. If one tries to figure out which “subject” is actually in *Nominative Case* (which stands for the person/thing who provides the action) and which “subject” is in *Accusative Case* (which stands for the thing/person who receives/suffers from the action), it is always problematic because of the flexible word order and omission.

Although some studies found that applying simple mapping rules for *Nominative Case* and *Accusative Case* can achieve an overall high baseline for English, we found that this simple mapping cannot work well for Chinese. Here is an example which Chinese people are using for self-deprecating.

- (6) 中国 (Chinese) / 乒乓球 (table tennis) / 谁 (who) / 也 (ever) / 赢 (win) / 不了 (not): Nobody can win Chinese table tennis.
- (7) 中国 (Chinese) / 足球 (soccer) / 谁 (who) / 也 (ever) / 赢 (win) / 不了 (not): Chinese soccer cannot win anybody.

“Table tennis” and “soccer” should be labeled as *Accusative Case* and *Nominative Case* differently even though the predicate and the syntactic structure for both the sentences are identical.

Similar phenomena also occur in Japanese and make it difficult to analyze as well. However, in case of Japanese, it is possible to make use of the

morphemes attached to the predicate. For example, the following sentences are the Japanese translations for sentence 4 and 5.

- (8) 私が (I) / たくさん (a lot) / 食べた (eaten).  
(9) りんごが (apples) / たくさん (a lot) / 食べられた (eaten).

There is always an additional morpheme (e.g., “られた”) attached to the predicate in order to indicate its voice. In the above example, sentence 8 can be regarded as active voice and sentence 9 is in passive voice. Unfortunately, Chinese is a language that lacks morpheme information. There are very few such markers that indicate the transitivity, voice and tense. This makes it almost impossible for a system to automatically recognize the ambiguous syntactic roles. To solve this problem, based on the syntactic analysis, we apply an SRL process to discover a deeper level case representation.

## 6 Applying high-quality deep case frames to SRL

### 6.1 High-quality semantic role selection

Similar to the previous work described in Jin et al. (2013), instead of using all the SRL outputs, we propose to use only automatically generated semantic roles of high quality.

In particular, the standard training section of the human-annotated data is used to train a base SRL model (which include three sub-models for predicate sense disambiguation (PD), argument identification (AI) and argument classification (AC)). Then, another part of the human-annotated data is used to apply SRL using the base model. From these results, we acquire training data for semantic role selection by collecting each semantic role. We then judge the correctness of each semantic role according to the gold standard annotations. All correct semantic roles are used as positive examples and the incorrect ones are used as negative examples for semantic role selection. Judging whether an automatic semantic role is reliable can be regarded as a binary classification problem. We use SVMs to solve this problem. We use the feature set for SRL described in Jin et al. (2015) as basic features. It contains predicate features that are extracted from the target predicate; argument features which are extracted from each candidate argument. We also use surface case frames, which have a positive effect on SRL, as additional knowledge.

### 6.2 High-quality deep case frame construction

Due to the major issues described in Section 5, case frames constructed using surface cases may be problematic. For example, for the predicate “吃 (eat)”, both the argument “苹果 (apple)” and “我 (I)” are assigned to the same surface case “subject”. If one tries to use this kind of surface case knowledge for tasks that require semantic information, such as machine translation (MT), it may lead to a performance drop. So we propose to construct deep case frames that are relatively more representative than the surface case frames. By the deep case, we mean using the semantic roles for case frame construction.

Compared to syntactic analysis, SRL is mainly used to clarify deeper-level semantic relations (e.g., [*who*] do [*what kind of*] thing to [*whom*] in [*what time*]) in the sentence, which has a better representation for predicate-argument relations. On the other hand, this task is always based on the tasks in preceding levels, such as morphological analysis and syntactic parsing. Especially, the information provided by syntactic parsing is crucial to achieve a good performance in SRL. An SRL system also suffers from the training data size issue as most of the machine learning approaches do. Extensive human efforts are required in order to construct such training data. Sometimes, the requirements for annotators can be higher than those for syntactic analysis. These factors along with the automatic analysis errors propagated from the lower-level analyses make it almost impossible for an SRL system to achieve a high performance.

For predicate identification (PI), we regard every word with a POS tag beginning with “V” as a predicate. The PD step in the SRL pipeline assigns a sense ID (frame ID) to each predicate. This is equivalent to the unsupervised clustering for surface case frames and thus no additional clustering process is required. After argument identification and argument classification, we only use these semantic roles with high reliability. For each predicate with different frame IDs, we collect all the high-quality semantic roles to compose the deep case frames.

### 6.3 Using high-quality deep case frames for SRL

Syntactic information such as dependencies is essential for SRL. In Section 4, we used surface

feature	description
SRFreq	the co-occurrence frequency of a predicate-argument pair without considering the semantic role of the argument
SRPmi	the PMI value for each predicate-argument pair without considering the semantic role of the argument
SRPAfreq	the frequency of a argument being a certain semantic role of a predicate
SRPami	the PMI value of an argument with its semantic role and the predicate
DCFFreq	SRFreq value calculated only from within the corresponding deep case frame
DCFPmi	SRPmi value calculated only from within the corresponding deep case frame
DCFPafreq	SRPAfreq value calculated only from within the corresponding deep case frame
DCFPami	SRPami value calculated only from within the corresponding deep case frame

Table 3: Deep case features for SRL

case frames to provide additional knowledge especially syntactic-level knowledge, for an SRL system and gained a slight improvement as shown in Section 7. Deep case frames are compiled using automatic semantic roles that use semantic-level representation. Thus, we consider that using deep case frames as additional knowledge has a more direct impact on the performance on SRL. Similar to the method described in Section 4, we also propose a set of features extracted from deep case frames which are listed in Table 3. The first four features do not concern the predicate sense. These features are similar to the predicate-argument pair features described in Section 4. The rest four features are similar to the case frame features described in Section 4. However, because the deep case frame ID is identical to the PropBank ID, no mapping processes are needed.

## 7 Experiments

### 7.1 Experimental settings

For large-scale knowledge acquisition, 40 million sentences from Chinese Gigaword 5.0 (LDC2011T13)<sup>3</sup> were used.

For the high-quality dependency selection approach in the knowledge construction pipeline, the Stanford parser was used to apply dependency parsing. The training section of Chinese Treebank 7.0 was used to train the dependency parser and the official development section was used to train a classifier for high-quality dependency selection. Using the official evaluation section of CTB 7.0,

<sup>3</sup>We only used sentences written in simplified characters in Chinese Gigaword.

we evaluated the quality of those selected dependencies using unlabeled attachment score (UAS), which calculates the percentage of correctly identified dependency heads.

For SRL, we used the Chinese section of CoNLL-2009 shared task data (we substituted the syntactic dependencies and dependency labels produced by the Stanford parser). Automatically obtained morphological and syntactic information (the columns begin with “P”) was used. PD and AI, AC step are regarded as multi-class classification problems. We employed OPAL<sup>4</sup> to solve these problems. We set the options as follows: polynomial kernel with degree 2; passive aggressive I learner; 20 iterations. The base SRL system without using additional knowledge was used as a baseline. To examine the effect of different quality of knowledge, we used different set of PASs which were extracted under different dependency selection thresholds (20%, 50%, and 100%). The official script provided on the CoNLL-2009 shared task website was used for evaluation.

For semantic role selection, similar to dependency selection, the training section of CoNLL-2009 shared task data was used to train the base SRL model. The development section in CoNLL-2009 shared task data was used to apply automatic SRL and obtain training data for the semantic role selector. We evaluated the semantic role selection approach by calculating the percentage of correctly judged semantic roles (predicate senses are not counted). For deep case frame construction, we used the Stanford parser for syntactic analysis.

<sup>4</sup><http://www.tkl.iis.u-tokyo.ac.jp/~ynaga/opal/>

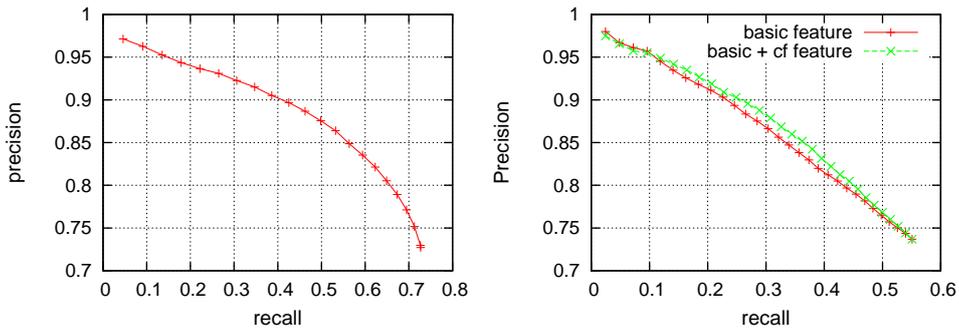

Figure 3: Precision-recall curve of dependency selection & semantic role selection

method	precision	recall	F1
baseline	80.66%	72.98%	76.63
baseline + surface case frames (100%)	79.86%	72.72%	76.12
baseline + surface case frames (50%)	80.40%	73.04%	76.54
baseline + surface case frames (20%)	80.73%	73.32%	<b>**76.85</b>
baseline + deep case frames (100%)	81.22%	73.55%	<b>**77.19</b>
baseline + deep case frames (50%)	81.30%	73.70%	<b>**77.31</b>
baseline + deep case frames (20%)	81.57%	73.68%	<b>**77.42</b>

Table 4: Evaluation results of Chinese SRL using surface and deep case frames. The \*\* mark and \* mark mean that the result is regarded as significant (with a p value < 0.01 and a p value < 0.05, respectively) using McNemar’s test.

The base SRL system was used to assign semantic roles. We applied the proposed framework to 40 million sentences from Chinese Gigaword 5.0. We constructed deep case frames of different quality (20%, 50%, and 100%) to extract extra features to support the base SRL system.

## 7.2 Experimental results

Figure 3 shows the precision-recall curves of dependency selection and semantic role selection. For dependency selection, we achieved a precision over 90% when lowering the recall to around 20%. For semantic role selection, using additional surface case frame features gains a slight improvement compared to the basic features.

Table 4 shows the experimental results of SRL using surface and deep case frames as additional features. Knowledge (n%) indicates that the top n% (according to the classifier) of the automatically extracted knowledge was used. ‘100%’ means that the selection step was not applied. It is worth pointing out that when using the baseline method, we achieved an F-value of around 79.4 on CoNLL-2009 shared task original data set (where the dependency labels follow the MaltParser style, which is different from the Stanford dependencies). This result has outperformed the best sys-

tem for Chinese SRL in CoNLL-2009 shared task, which was 78.60. When applying the baseline system on the substituted version of dataset for dependency label consistency with the additional knowledge, the baseline F-value drops to 76.63. As we can see from the results, using deep case frames gained more improvements than using surface case frames. This is because deep case frames are able to directly provide semantic-level information that is insufficient in the training data of the base SRL system. Furthermore, the results show that the high-quality semantic role selection approach has a positive effect on SRL.

## 8 Conclusion & future work

We proposed a method for using additional knowledge to improve Chinese SRL. To address the case ambiguity problem in the surface case representation, especially for Chinese, we utilized automatic semantic roles produced by an SRL system for a better representation. The experimental results showed a promising result for high-quality semantic role selection. Also, using high-quality deep case frames that are composed of semantic roles can significantly improve the baseline SRL system.

We plan to make use of other low-level knowledge such as word embeddings (Collobert et al., 2011) and word clusters (Koo et al., 2008) to improve dependency parsing and SRL. The recent SRL approaches are mostly point-wise. Features are extracted from only pairs of the predicate and an argument candidate. We plan to design a higher-order system to capture more global features following the idea of higher-order dependency parsing. Also, reranking is widely utilized in many SRL systems and we plan to combine our surface/deep case knowledge with a reranker in order to further improve Chinese SRL.

# Multi-level Representations for Fine-Grained Typing of Knowledge Base Entities

Yadollah Yaghoobzadeh and Hinrich Schütze  
Center for Information and Language Processing  
LMU Munich, Germany  
yadollah@cis.lmu.de

## Abstract

Entities are essential elements of natural language. In this paper, we present methods for learning multi-level representations of entities on three complementary levels: **character** (character patterns in entity names extracted, e.g., by neural networks), **word** (embeddings of words in entity names) and **entity** (entity embeddings). We investigate state-of-the-art learning methods on each level and find large differences, e.g., for deep learning models, traditional ngram features and the subword model of *fasttext* (Bojanowski et al., 2016) on the **character** level; for *word2vec* (Mikolov et al., 2013) on the **word** level; and for the order-aware model *wang2vec* (Ling et al., 2015a) on the **entity** level.

We confirm experimentally that each level of representation contributes complementary information and a joint representation of all three levels improves the existing embedding based baseline for fine-grained entity typing by a large margin. Additionally, we show that adding information from entity descriptions further improves multi-level representations of entities.

## 1 Introduction

Knowledge about entities is essential for understanding human language. This knowledge can be attributional (e.g., *canFly*, *isEdible*), type-based (e.g., *isFood*, *isPolitician*, *isDisease*) or relational (e.g., *marriedTo*, *bornIn*). Knowledge bases (KBs) are designed to store this information in a structured way, so that it can be queried easily. Examples of such KBs are Freebase (Bollacker et al., 2008), Wikipedia, Google knowledge graph and

YAGO (Suchanek et al., 2007). For automatic updating and completing the entity knowledge, text resources such as news, user forums, textbooks or any other data in the form of text are important sources. Therefore, information extraction methods have been introduced to extract knowledge about entities from text. In this paper, we focus on the extraction of entity types, i.e., assigning types to – or *typing* – entities. Type information can help extraction of relations by applying constraints on relation arguments.

We address a problem setting in which the following are given: a KB with a set of entities  $E$ , a set of types  $T$  and a membership function  $m : E \times T \mapsto \{0, 1\}$  such that  $m(e, t) = 1$  iff entity  $e$  has type  $t$ ; and a large corpus  $C$  in which mentions of  $E$  are annotated. In this setting, we address the task of *fine-grained entity typing*: we want to learn a probability function  $S(e, t)$  for a pair of entity  $e$  and type  $t$  and based on  $S(e, t)$  infer whether  $m(e, t) = 1$  holds, i.e., whether entity  $e$  is a member of type  $t$ .

We address this problem by learning a multi-level representation for an entity that contains the information necessary for typing it. One important source is the *contexts in which the entity is used*. We can take the standard method of learning embeddings for words and extend it to learning embeddings for entities. This requires the use of an entity linker and can be implemented by replacing all occurrences of the entity by a unique token. We refer to entity embeddings as *entity-level representations*. Previously, entity embeddings have been learned mostly using bag-of-word models like *word2vec* (e.g., by Wang et al. (2014) and Yaghoobzadeh and Schütze (2015)). We show below that order information is critical for high-quality entity embeddings.

Entity-level representations are often uninformative for rare entities, so that using only entity

embeddings is likely to produce poor results. In this paper, we use *entity names* as a source of information that is complementary to entity embeddings. We define an entity name as a noun phrase that is used to refer to an entity. We learn character and word level representations of entity names.

For the *character-level representation*, we adopt different character-level neural network architectures. Our intuition is that there is sub/cross word information, e.g., orthographic patterns, that is helpful to get better entity representations, especially for rare entities. A simple example is that a three-token sequence containing an initial like “P.” surrounded by two capitalized words (“Rolph P. Kugl”) is likely to refer to a person.

We compute the *word-level representation* as the sum of the embeddings of the words that make up the entity name. The sum of the embeddings accumulates evidence for a type/property over all constituents, e.g., a name containing “stadium”, “lake” or “cemetery” is likely to refer to a location. In this paper, we compute our word level representation with two types of word embeddings: (i) using only contextual information of words in the corpus, e.g., by `word2vec` (Mikolov et al., 2013) and (ii) using subword as well as contextual information of words, e.g., by Facebook’s recently released `fasttext` (Bojanowski et al., 2016).

In this paper, we integrate character-level and word-level with entity-level representations to improve the results of previous work on fine-grained typing of KB entities. We also show how descriptions of entities in a KB can be a complementary source of information to our multi-level representation to improve the results of entity typing, especially for rare entities.

Our main contributions in this paper are:

- We propose new methods for learning entity representations on three levels: character-level, word-level and entity-level.
- We show that these levels are complementary and a joint model that uses all three levels improves the state of the art on the task of fine-grained entity typing by a large margin.
- We experimentally show that an order dependent embedding is more informative than its bag-of-word counterpart for entity representation.

We release our dataset and source codes: [cistern.cis.lmu.de/figment2/](http://cistern.cis.lmu.de/figment2/).

## 2 Related Work

**Entity representation.** Two main sources of information used for learning entity representation are: (i) links and descriptions in KB, (ii) name and contexts in corpora. We focus on name and contexts in corpora, but we also include (Wikipedia) descriptions. We represent entities on three levels: entity, word and character. Our entity-level representation is similar to work on relation extraction (Wang et al., 2014; Wang and Li, 2016), entity linking (Yamada et al., 2016; Fang et al., 2016), and entity typing (Yaghoobzadeh and Schütze, 2015). Our word-level representation with distributional word embeddings is similarly used to represent entities for entity linking (Sun et al., 2015) and relation extraction (Socher et al., 2013; Wang et al., 2014). Novel entity representation methods we introduce in this paper are representation based on `fasttext` (Bojanowski et al., 2016) subword embeddings, several character-level representations, “order-aware” entity-level embeddings and the combination of several different representations into one multi-level representation.

**Character-subword level neural networks.** Character-level convolutional neural networks (CNNs) are applied by dos Santos and Zadrozny (2014) to part of speech (POS) tagging, by dos Santos and Guimarães (2015), Ma and Hovy (2016), and Chiu and Nichols (2016) to named entity recognition (NER), by Zhang et al. (2015) and Zhang and LeCun (2015) to sentiment analysis and text categorization, and by Kim et al. (2016) to language modeling (LM). Character-level LSTM is applied by Ling et al. (2015b) to LM and POS tagging, by Lample et al. (2016) to NER, by Ballesteros et al. (2015) to parsing morphologically rich languages, and by Cao and Rei (2016) to learning word embeddings. Bojanowski et al. (2016) learn word embeddings by representing words with the average of their character ngrams (subwords) embeddings. Similarly, Chen et al. (2015) extends `word2vec` for Chinese with joint modeling with characters.

**Fine-grained entity typing.** Our task is to infer fine-grained types of KB entities. KB completion is an application of this task. Yaghoobzadeh and Schütze (2015)’s FIGMENT system addresses this task with only contextual information; they do not use character-level and word-level features of entity names. Neelakantan and Chang (2015) and Xie et al. (2016) also address a similar task,

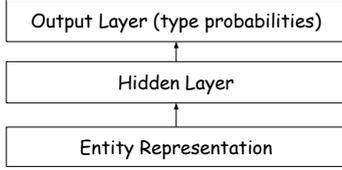

Figure 1: Schematic diagram of our architecture for entity classification. “Entity Representation” ( $\vec{v}(e)$ ) is the (one-level or multi-level) vector representation of entity. Size of output layer is  $|T|$ .

but they rely on entity descriptions in KBs, which in many settings are not available. The problem of Fine-grained mention typing (FGMT) (Yosef et al., 2012; Ling and Weld, 2012; Yogatama et al., 2015; Del Corro et al., 2015; Shimaoka et al., 2016; Ren et al., 2016) is related to our task. FGMT classifies single *mentions* of named entities to their context dependent types whereas we attempt to identify all types of a KB *entity* from the aggregation of all its mentions. FGMT can still be evaluated in our task by aggregating the mention level decisions but as we will show in our experiments for one system, i.e., FIGER (Ling and Weld, 2012), our entity embedding based models are better in entity typing.

### 3 Fine-grained entity typing

Given (i) a KB with a set of entities  $E$ , (ii) a set of types  $T$ , and (iii) a large corpus  $C$  in which mentions of  $E$  are linked, we address the task of *fine-grained entity typing* (Yaghoobzadeh and Schütze, 2015): predict whether entity  $e$  is a member of type  $t$  or not. To do so, we use a set of training examples to learn  $P(t|e)$ : the probability that entity  $e$  has type  $t$ . These probabilities can be used to assign *new types* to entities covered in the KB as well as typing *unknown entities*.

We learn  $P(t|e)$  with a general architecture; see Figure 1. The output layer has size  $|T|$ . Unit  $t$  of this layer outputs the probability for type  $t$ . “Entity Representation” ( $\vec{v}(e)$ ) is the vector representation of entity  $e$  – we will describe in detail in the rest of this section what forms  $\vec{v}(e)$  takes. We model  $P(t|e)$  as a multi-label classification, and train a multilayer perceptron (MLP) with one hidden layer:

$$[P(t_1|e) \dots P(t_T|e)] = \sigma(\mathbf{W}_{\text{out}} f(\mathbf{W}_{\text{in}} \vec{v}(e))) \quad (1)$$

where  $\mathbf{W}_{\text{in}} \in \mathbb{R}^{h \times d}$  is the weight matrix from

$\vec{v}(e) \in \mathbb{R}^d$  to the hidden layer with size  $h$ .  $f$  is the rectifier function.  $\mathbf{W}_{\text{out}} \in \mathbb{R}^{|T| \times h}$  is the weight matrix from hidden layer to output layer of size  $|T|$ .  $\sigma$  is the sigmoid function. Our objective is binary cross entropy summed over types:

$$\sum_t - (m_t \log p_t + (1 - m_t) \log (1 - p_t))$$

where  $m_t$  is the truth and  $p_t$  the prediction.

The key difficulty when trying to compute  $P(t|e)$  is in learning a good representation for entity  $e$ . We make use of contexts and name of  $e$  to represent its feature vector on the three levels of entity, word and character.

#### 3.1 Entity-level representation

Distributional representations or embeddings are commonly used for words. The underlying hypothesis is that words with similar meanings tend to occur in similar contexts (Harris, 1954) and therefore cooccur with similar context words. We can extend the distributional hypothesis to entities (cf. Wang et al. (2014), Yaghoobzadeh and Schütze (2015)): entities with similar meanings tend to have similar contexts. Thus, we can learn a  $d$  dimensional embedding  $\vec{v}(e)$  of entity  $e$  from a corpus in which all mentions of the entity have been replaced by a special identifier. We refer to these entity vectors as the *entity level representation* (ELR).

In previous work, order information of context words (relative position of words in the contexts) was generally ignored and objectives similar to the SkipGram (henceforth: *SKIP*) model were used to learn  $\vec{v}(e)$ . However, the bag-of-words context is difficult to distinguish for pairs of types like (restaurant,food) and (author,book). This suggests that *using order aware embedding models is important for entities*. Therefore, we apply Ling et al. (2015a)’s extended version of SKIP, Structured SKIP (SSKIP). It incorporates the order of context words into the objective. We compare it with SKIP embeddings in our experiments.

#### 3.2 Word-level representation

Words inside entity names are important sources of information for typing entities. We define the word-level representation (WLR) as the *average of the embeddings of the words* that the entity name contains  $\vec{v}(e) = 1/n \sum_{i=1}^n \vec{v}(w_i)$  where  $\vec{v}(w_i)$  is the embedding of the  $i^{\text{th}}$  word of an entity name

of length  $n$ . We opt for simple averaging since entity names often consist of a small number of words with clear semantics. Thus, averaging is a promising way of combining the information that each word contributes.

The word embedding,  $\vec{w}$ , itself can be learned from models with different granularity levels. Embedding models that consider words as atomic units in the corpus, e.g., SKIP and SSKIP, are word-level. On the other hand, embedding models that represent words with their character ngrams, e.g., *fasttext* (Bojanowski et al., 2016), are subword-level. Based on this, we consider and evaluate **word-level WLR (WWLR)** and **subword-level WLR (SWLR)** in this paper.<sup>1</sup>

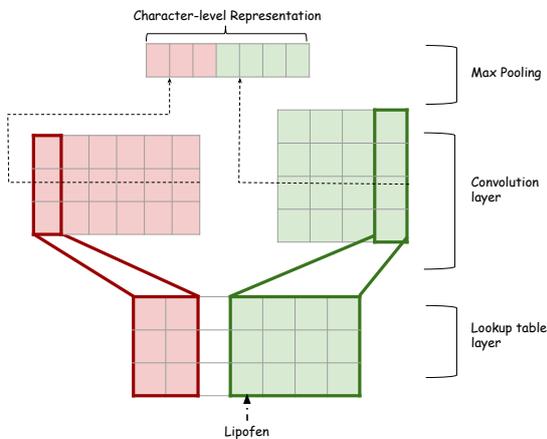

Figure 2: Example architecture for the character-level CNN with max pooling. The input is “Lipofen”. Character embedding size is three. There are three filters of width 2 and four filters of width 4.

### 3.3 Character-level representation

For computing the *character level representation* (CLR), we design models that try to type an entity based on the sequence of characters of its name. Our hypothesis is that names of entities of a specific type often have similar character patterns. Entities of type ETHNICITY often end in “ish” and “ian”, e.g., “Spanish” and “Russian”. Entities of type MEDICINE often end in “en”: “Lipofen”, “acetaminophen”. Also, some types tend to have specific cross-word shapes in their entities, e.g.,

<sup>1</sup>Subword models have properties of both character-level models (subwords are character ngrams) and of word-level models (they do not cross boundaries between words). They probably could be put in either category, but in our context fit the word-level category better because we see the granularity level with respect to the entities and not words.

PERSON names usually consist of two words, or MUSIC names are usually long, containing several words.

The first layer of the character-level models is a *lookup table* that maps each character to an embedding of size  $d_c$ . These embeddings capture similarities between characters, e.g., similarity in type of phoneme encoded (consonant/vowel) or similarity in case (lower/upper). The output of the lookup layer for an entity name is a matrix  $C \in \mathbb{R}^{l \times d_c}$  where  $l$  is the maximum length of a name and all names are padded to length  $l$ . This length  $l$  includes special start/end characters that bracket the entity name.

We experiment with four architectures to produce character-level representations in this paper: FORWARD (direct forwarding of character embeddings), CNNs, LSTMs and BiLSTMs. The output of each architecture then takes the place of the entity representation  $\vec{v}(e)$  in Figure 1.

**FORWARD** simply concatenates all rows of matrix  $C$ ; thus,  $\vec{v}(e) \in \mathbb{R}^{d_c * l}$ .

The **CNN** uses  $k$  filters of different window widths  $w$  to narrowly convolve  $C$ . For each filter  $H \in \mathbb{R}^{d_c \times w}$ , the result of the convolution of  $H$  over matrix  $C$  is feature map  $f \in \mathbb{R}^{l-w+1}$ :

$$f[i] = \text{rectifier}(C_{[:,i:i+w-1]} \odot H + b)$$

where *rectifier* is the activation function,  $b$  is the bias,  $C_{[:,i:i+w-1]}$  are the columns  $i$  to  $i + w - 1$  of  $C$ ,  $1 \leq w \leq 10$  are the window widths we consider and  $\odot$  is the sum of element-wise multiplication. Max pooling then gives us one feature for each filter. The concatenation of all these features is our representation:  $\vec{v}(e) \in \mathbb{R}^k$ . An example CNN architecture is show in Figure 2.

The input to the **LSTM** is the character sequence in matrix  $C$ , i.e.,  $x_1, \dots, x_l \in \mathbb{R}^{d_c}$ . It generates the state sequence  $h_1, \dots, h_{l+1}$  and the output is the last state  $\vec{v}(e) \in \mathbb{R}^{d_h}$ .<sup>2</sup>

The **BiLSTM** consists of two LSTMs, one going forward, one going backward. The first state of the backward LSTM is initialized as  $h_{l+1}$ , the last state of the forward LSTM. The BiLSTM entity representation is the concatenation of last states of forward and backward LSTMs, i.e.,  $\vec{v}(e) \in \mathbb{R}^{2*d_h}$ .

### 3.4 Multi-level representations

Our different levels of representations can give complementary information about entities.

<sup>2</sup>We use Blocks (van Merriënboer et al., 2015).

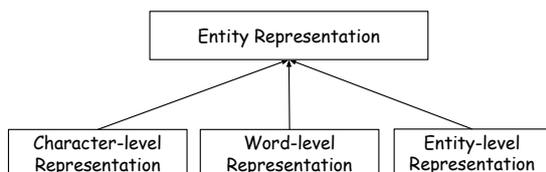

Figure 3: Multi-level representation

**WLR and CLR.** Both WLR models, SWLR and WWLR, do not have access to the cross-word character ngrams of entity names while CLR models do. Also, CLR is task specific by training on the entity typing dataset while WLR is generic. On the other hand, WWLR and SWLR models have access to information that CLR ignores: the tokenization of entity names into words and embeddings of these words. It is clear that words are particularly important character sequences since they often correspond to linguistic units with clearly identifiable semantics – which is not true for most character sequences. For many entities, the words they contain are a better basis for typing than the character sequence. For example, even if “nectarine” and “compote” did not occur in any names in the training corpus, we can still learn good word embeddings from their non-entity occurrences. This then allows us to correctly type the entity “Aunt Mary’s Nectarine Compote” as FOOD based on the sum of the word embeddings.

**WLR/CLR and ELR.** Representations from entity names, i.e., WLR and CLR, by themselves are limited because many classes of names can be used for different types of entities; e.g., person names do not contain hints as to whether they are referring to a politician or athlete. In contrast, the ELR embedding is based on an entity’s contexts, which are often informative for each entity and can distinguish politicians from athletes. On the other hand, not all entities have sufficiently many informative contexts in the corpus. For these entities, their name can be a complementary source of information and character/word level representations can increase typing accuracy.

Thus, we introduce joint models that use combinations of the three levels. Each multi-level model concatenates several levels. We train the constituent embeddings as follows. WLR and ELR are computed as described above and are not changed during training. CLR – produced by one of the character-level networks described above – is initialized randomly and then tuned during

training. Thus, it can focus on complementary information related to the task that is not already present in other levels. The schematic diagram of our multi-level representation is shown in Figure 3.

## 4 Experimental setup and results

### 4.1 Setup

**Entity datasets and corpus.** We address the task of fine-grained entity typing and use Yaghoobzadeh and Schütze (2015)’s FIGMENT dataset<sup>3</sup> for evaluation. The FIGMENT corpus is part of a version of ClueWeb in which Freebase entities are annotated using FACC1 (URL, 2016b; Gabrilovich et al., 2013). The FIGMENT entity datasets contain 200,000 Freebase entities that were mapped to 102 FIGER types (Ling and Weld, 2012). We use the same train (50%), dev (20%) and test (30%) partitions as Yaghoobzadeh and Schütze (2015) and extract the names from mentions of dataset entities in the corpus. We take the most frequent name for dev and test entities and three most frequent names for train (each one tagged with entity types).

**Adding parent types to refine entity dataset.** FIGMENT ignores that FIGER is a proper hierarchy of types; e.g., while HOSPITAL is a subtype of BUILDING according to FIGER, there are entities in FIGMENT that are hospitals, but not buildings.<sup>4</sup> Therefore, we modified the FIGMENT dataset by adding for each assigned type (e.g., HOSPITAL) its parents (e.g., BUILDING). This makes FIGMENT more consistent and eliminates spurious false negatives (BUILDING in the example).

We now describe our **baselines**: (i) BOW & NSL: hand-crafted features, (ii) FIGMENT (Yaghoobzadeh and Schütze, 2015) and (iii) adapted version of FIGER (Ling and Weld, 2012).

We implement the following two feature sets from the literature as a *hand-crafted baseline* for our character and word level models. (i) *BOW*: individual words of entity name (both as-is and lowercased); (ii) *NSL* (ngram-shape-length): shape and length of the entity name (cf. Ling and Weld (2012)), character  $n$ -grams,  $1 \leq n \leq n_{\max}$ ,  $n_{\max} = 5$  (we also tried  $n_{\max} = 7$ , but results were worse on dev) and normalized character  $n$ -grams: lowercased, digits replaced by “7”, punctuation replaced by “.”. These features are represented as a sparse

<sup>3</sup>[cistern.cis.lmu.de/figment/](http://cistern.cis.lmu.de/figment/)

<sup>4</sup>See [github.com/xiaoling/figer](https://github.com/xiaoling/figer) for FIGER

binary vector  $\vec{v}(e)$  that is input to the architecture in Figure 1.

*FIGMENT* is the model for entity typing presented by Yaghoobzadeh and Schütze (2015). The authors only use entity-level representations for entities trained by SkipGram, so the *FIGMENT* baseline corresponds to the entity-level result shown as ELR(SKIP) in the tables.

The third baseline is using an existing mention-level entity typing system, *FIGER* (Ling and Weld, 2012). *FIGER* uses a wide variety of features on different levels (including parsing-based features) from contexts of entity mentions as well as the mentions themselves and returns a score for each mention-type instance in the corpus. We provide the ClueWeb/FACC1 segmentation of entities, so *FIGER* does not need to recognize entities.<sup>5</sup> We use the trained model provided by the authors and normalize *FIGER* scores using softmax to make them comparable for aggregation. We experimented with different aggregation functions (including maximum and k-largest-scores for a type), but we use the average of scores since it gave us the best result on dev. We call this baseline AGG-*FIGER*.

**Distributional embeddings.** For WWLR and ELR, we use SkipGram model in `word2vec` and SSkip model in `wang2vec` (Ling et al., 2015a) to learn embeddings for words, entities and types. To obtain embeddings for all three in the same space, we process ClueWeb/FACC1 as follows. For each sentence  $s$ , we add three copies:  $s$  itself, a copy of  $s$  in which each entity is replaced with its Freebase identifier (MID) and a copy in which each entity (not test entities though) is replaced with an ID indicating its notable type. The resulting corpus contains around 4 billion tokens and 1.5 billion types.

We run SKIP and SSkip with the same setup (200 dimensions, 10 negative samples, window size 5, word frequency threshold of 100)<sup>6</sup> on this corpus to learn embeddings for words, entities and *FIGER* types. Having entities and types in the same vector space, we can add another feature vector  $\vec{v}(e) \in \mathbb{R}^{|T|}$  (referred to as TC below): for each entity, we compute cosine similarity of its entity vector with all type vectors.

For SWLR, we use `fasttext`<sup>7</sup> to learn word

<sup>5</sup>Mention typing is separated from recognition in *FIGER* model. So it can use our segmentation of entities.

<sup>6</sup>The threshold does not apply for MIDs.

<sup>7</sup>[github.com/facebookresearch/fastText](https://github.com/facebookresearch/fastText)

embeddings from the ClueWeb/FACC1 corpus. We use similar settings as our WWLR SKIP and SSkip embeddings and keep the defaults of other hyperparameters. Since the trained model of `fasttext` is applicable for new words, we apply the model to get embeddings for the filtered rare words as well.

AVG-DES	$h_{mlp} = 400$
MuLR+AVG-DES	$d_c = 10, w = [1, \dots, 7]$ $n = 50, h_{mlp} = 1000$

Table 1: Hyperparameters of different models.  $w$  is the filter size.  $n$  is the number of CNN feature maps for each filter size.  $d_c$  is the character embedding size.  $d_h$  is the LSTM hidden state size.  $h_{mlp}$  is the number of hidden units in the MLP.

Our **hyperparameter values** are given in Table 1. The values are optimized on dev. We use AdaGrad and minibatch training. For each experiment, we select the best model on dev.

We use these **evaluation measures**: (i) accuracy: an entity is correct if all its types and no incorrect types are assigned to it; (ii) micro average  $F_1$ :  $F_1$  of all type-entity assignment decisions; (iii) entity macro average  $F_1$ :  $F_1$  of types assigned to an entity, averaged over entities; (iv) type macro average  $F_1$ :  $F_1$  of entities assigned to a type, averaged over types.

The assignment decision is based on thresholding the probability function  $P(t|e)$ . For each model and type, we select the threshold that maximizes  $F_1$  of entities assigned to the type on dev.

Table 2: Accuracy (acc), micro (mic) and macro (mac)  $F_1$  on test for all, head and tail entities.

## 4.2 Results

Table 2 gives results on the test entities for all (about 60,000 entities), head (frequency > 100; about 12,200) and tail (frequency < 5; about 10,000). *MFT* (line 1) is the most frequent type baseline that ranks types according to their frequency in the train entities. Each level of representation is separated with dashed lines, and – unless noted otherwise – the best of each level is joined in multi level representations.<sup>8</sup>

**Character-level models** are on lines 2-6. The order of systems is: CNN > NSL > BiLSTM > LSTM > FORWARD. The results show that complex neural networks are more effective than simple forwarding. BiLSTM works better than LSTM, confirming other related work. CNNs probably work better than LSTMs because there are few complex non-local dependencies in the sequence, but many important local features. CNNs with maxpooling can more straightforwardly capture local and position-independent features. CNN also beats NSL baseline; a possible reason is that CNN – an automatic method of feature learning

<sup>8</sup>For accuracy measure: in the following ordered lists of sets,  $A < B$  means that all members (row numbers in Table 2) of  $A$  are significantly worse than all members of  $B$ :  $\{1\} < \{2\} < \{3, \dots, 11\} < \{12, 13\} < \{14, 15, 16\} < \{17, \dots, 23\}$ . Test of equal proportions,  $\alpha < 0.05$ . See Table 6 in the appendix for more details.

– is more robust than hand engineered feature based NSL. We show more detailed results in Section 4.3.

**Word-level models** are on lines 7-10. BOW performs worse than WWLR because it cannot deal well with sparseness. SSKIP uses word order information in WWLR and performs better than SKIP. SWLR uses subword information and performs better than WWLR, especially for tail entities. Integrating subword information improves the quality of embeddings for rare words and mitigates the problem of unknown words.

**Joint word-character level models** are on lines 11-13. WWLR+CLR(CNN) and SWLR+CLR(CNN) beat the component models. This confirms our underlying assumption in designing the complementary multi-level models. BOW problem with rare words does not allow its joint model with NSL to work better than NSL. WWLR+CLR(CNN) works better than BOW+CLR(NSL) by 10% micro  $F_1$ , again due to the limits of BOW compared to WWLR. Interestingly WWLR+CLR works better than SWLR+CLR and this suggests that WWLR is indeed richer than SWLR when CLR mitigates its problem with rare/unknown words

**Entity-level models** are on lines 14–15 and they are better than all previous models on lines

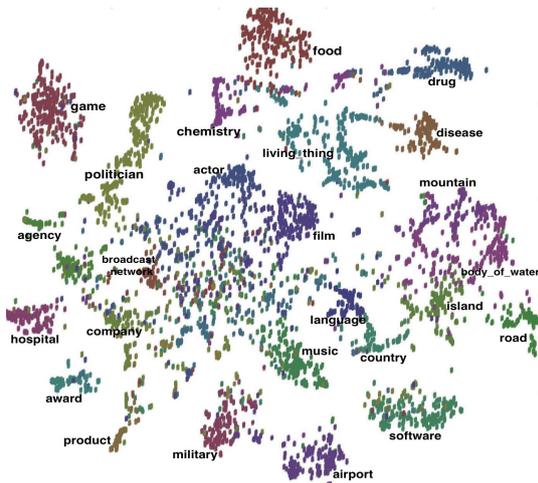

Figure 4: t-SNE result of entity-level representations

1–13. This shows the power of entity-level embeddings. In Figure 4, a t-SNE (Van der Maaten and Hinton, 2008) visualization of ELR(SKIP) embeddings using different colors for entity types shows that entities of the same type are clustered together. SSKIP works marginally better than SKIP for ELR, especially for tail entities, confirming our hypothesis that order information is important for a good distributional entity representation. This is also confirming the results of Yaghoobzadeh and Schütze (2016), where they also get better entity typing results with SSKIP compared to SKIP. They propose to use entity typing as an extrinsic evaluation for embedding models.

**Joint entity, word, and character level models** are on lines 16-23. The AGG-FIGER baseline works better than the systems on lines 1-13, but worse than ELRs. This is probably due to the fact that AGG-FIGER is optimized for mention typing and it is trained using distant supervision assumption. Parallel to our work, Yaghoobzadeh et al. (2017) optimize a mention typing model for our entity typing task by introducing multi instance learning algorithms, resulting comparable performance to ELR(SKIP). We will investigate their method in future.

Joining CLR with ELR (line 17) results in large improvements, especially for tail entities (5% micro  $F_1$ ). This demonstrates that for rare entities, contextual information is often not sufficient for an informative representation, hence name features are important. This is also true for the joint models of WWLR/SWLR and ELR (lines 18-19). Joining WWLR works better than

CLR, and SWLR is slightly better than WWLR. Joint models of WWLR/SWLR with ELR+CLR gives more improvements, and SWLR is again slightly better than WWLR. ELR+WWLR+CLR and ELR+SWLR+CLR, are better than their two-level counterparts, again confirming that these levels are complementary.

We get a further boost, especially for tail entities, by also including TC (type cosine) in the combinations (lines 22-23). This demonstrates the potential advantage of having a common representation space for entities and types. Our best model, ELR+SWLR+CLR+TC (line 22), which we refer to as MuLR in the other tables, beats our initial baselines (ELR and AGG-FIGER) by large margins, e.g., in tail entities improvements are more than 8% in micro F1.

Table 3 shows **type macro  $F_1$**  for MuLR (ELR+SWLR+CLR+TC) and two baselines. There are 11 head types (those with  $\geq 3000$  train entities) and 36 tail types (those with  $< 200$  train entities). These results again confirm the superiority of our multi-level models over the baselines: AGG-FIGER and ELR, the best single-level model baseline.

### 4.3 Analysis

**Unknown vs. known entities.** To analyze the complementarity of character and word level representations, as well as more fine-grained comparison of our models and the baselines, we divide test entities into *known entities* – at least one word of the entity’s name appears in a train entity – and *unknown entities* (the complement). There are 45,000 (resp. 15,000) known (resp. unknown) test entities.

Table 4 shows that the CNN works only slightly better (by 0.3%) than NSL on known entities, but works much better on unknown entities (by 3.3%), justifying our preference for deep learning CLR models. As expected, BOW works relatively well for known entities and really poorly for unknown entities. SWLR beats CLR models as well as BOW. The reason is that in our setup, word embeddings are induced on the entire corpus using an unsupervised algorithm. Thus, even for many words that did not occur in train, SWLR has access to informative representations of words. The joint model, SWLR+CLR(CNN), is significantly better than BOW+CLR(NSL) again due to limits of BOW. SWLR+CLR(CNN) is better than SWLR

in unknown entities.

**Case study of LIVING-THING.** To understand the interplay of different levels better, we perform a case study of the type LIVING-THING. Living beings that are not humans belong to this type.

WLRs incorrectly assign “Walter Leaf” (PERSON) and “Along Came A Spider” (MUSIC) to LIVING-THING because these names contain a word referring to a LIVING-THING (“leaf”, “spider”), but the entity itself is not a LIVING-THING. In these cases, the averaging of embeddings that WLR performs is misleading. The CLR(CNN) types these two entities correctly because their names contain character ngram/shape patterns that are indicative of PERSON and MUSIC.

ELR incorrectly assigns “Zumpango” (CITY) and “Lake Kasumigaura” (LOCATION) to LIVING-THING because these entities are rare and words associated with living things (e.g., “wildlife”) dominate in their contexts. However, CLR(CNN) and WLR enable the joint model to type the two entities correctly: “Zumpango” because of the informative suffix “-go” and “Lake Kasumigaura” because of the informative word “Lake”.

While some of the **remaining errors** of our best system MuLR are due to the inherent difficulty of entity typing (e.g., it is difficult to correctly type a one-word entity that occurs once and whose name is not informative), many other errors are due to artifacts of our setup. First, ClueWeb/FACCI is the result of an automatic entity linking system and any entity linking errors propagate to our models. Second, due to the incompleteness of Freebase (Yaghoobzadeh and Schütze, 2015), many entities in the FIGMENT dataset are incompletely annotated, resulting in correctly typed entities being evaluated as incorrect.

**Adding another source: description-based embeddings.** While in this paper, we focus on the contexts and names of entities, there is a textual source of information about entities in KBs which we can also make use of: descriptions of entities. We extract Wikipedia descriptions of FIGMENT entities filtering out the entities ( $\sim 40,000$  out of  $\sim 200,000$ ) without description.

We then build a simple entity representation by averaging the embeddings of the top  $k$  words (wrt tf-idf) of the description (henceforth, AVG-DES).<sup>9</sup> This representation is used as input in Figure 1 to train the MLP. We also train our best multi-

<sup>9</sup> $k = 20$  gives the best results on dev.

entities:	all	head	tail
AVG-DES	.773	.791	.745
MuLR	.825	.846	.757
MuLR+AVG-DES	<b>.873</b>	<b>.877</b>	<b>.852</b>

Table 5: Micro average  $F_1$  results of MuLR and description based model and their joint.

level model as well as the joint of the two on this smaller dataset. Since the descriptions are coming from Wikipedia, we use 300-dimensional Glove (URL, 2016a) embeddings pretrained on Wikipedia+Gigaword to get more coverage of words. For MuLR, we still use the embeddings we trained before.

Results are shown in Table 5. While for head entities, MuLR works marginally better, the difference is very small in tail entities. The joint model of the two (by concatenation of vectors) improves the micro F1, with clear boost for tail entities. This suggests that for tail entities, the contextual and name information is not enough by itself and some keywords from descriptions can be really helpful. Integrating more complex description-based embeddings, e.g., by using CNN (Xie et al., 2016), may improve the results further. We leave it for future work.

## 5 Conclusion

In this paper, we have introduced representations of entities on different levels: character, word and entity. The character level representation is learned from the entity name. The word level representation is computed from the embeddings of the words  $w_i$  in the entity name where the embedding of  $w_i$  is derived from the corpus contexts of  $w_i$ . The entity level representation of entity  $e_i$  is derived from the corpus contexts of  $e_i$ . Our experiments show that each of these levels contributes complementary information for the task of fine-grained typing of entities. The joint model of all three levels beats the state-of-the-art baseline by large margins. We further showed that extracting some keywords from Wikipedia descriptions of entities, when available, can considerably improve entity representations, especially for rare entities. We believe that our findings can be transferred to other tasks where entity representation matters.

## Abstract

In this paper, we present ContrastMedium, an algorithm that transforms noisy semantic networks into full-fledged, clean taxonomies. ContrastMedium is able to identify the embedded taxonomy structure from a noisy knowledge graph without explicit human supervision such as, for instance, a set of manually selected input root and leaf concepts. This is achieved by leveraging structural information from a companion reference taxonomy, to which the input knowledge graph is linked (either automatically or manually). When used in conjunction with methods for hypernym acquisition and knowledge base linking, our methodology provides a complete solution for end-to-end taxonomy induction. We conduct experiments using automatically acquired knowledge graphs, as well as a SemEval benchmark, and show that our method is able to achieve high performance on the task of taxonomy induction.

## 1 Introduction

Recent years have witnessed an impressive amount of work on automatic construction of wide-coverage knowledge resources. Web-scale open information extraction systems like NELL (Carlson et al., 2010) or ReVerb (Fader et al., 2011) have been successful in acquiring massive amounts of machine-readable knowledge by effectively tapping large amounts of text from Web pages. However, the output of these systems does not consist of a clean, fully-semanticized output. Such output, on the other hand, could be provided by the vocabulary of large-scale ontologies like DBpedia (Bizer et al., 2009) or YAGO (Hoffart et al., 2013) and the integration of open and

closed information extraction approaches (Dutta et al., 2014). The use of an encyclopedia-centric (e.g., Wikipedia-based) dictionary of entities leads to poor coverage of domain-specific terminologies (Faralli and Navigli, 2013). This can be alleviated by constructing knowledge bases of ever increasing coverage and complexity from the Web (Wu et al., 2012; Gupta et al., 2014; Dong et al., 2014) or by community efforts (Bollacker et al., 2008). However, the focus on large size and wide coverage at entity level has led all these resources to avoid the complementary problem of curating and maintaining a clean taxonomic backbone with as minimal supervision as possible. That is, no resource, to date, integrates structured information from existing wide-coverage knowledge graphs with empirical evidence from text for the explicit goal of building full-fledged taxonomies consisting of a clean and fully-connected directed acyclic graph (DAG). This is despite the fact that taxonomies have been known for a long time to provide valid tools to represent domain-specific knowledge with dozens of scientific, industrial and social applications (Glass and Vessey, 1995).

In taxonomy induction, the required domain knowledge can be acquired with many different methods for hypernym extraction, ranging from simple lexical patterns (Hearst, 1992; Oakes, 2005; Kozareva and Hovy, 2010) to statistical and machine learning techniques (Caraballo, 1999; Agirre et al., 2000; Ritter et al., 2009; Velardi et al., 2013). Recent efforts, such as Microsoft’s Probase (Wu et al., 2012) or the WebIsaDB (Seitner et al., 2016) similarly focus on ‘local’ extraction of single hypernym relations, and do not address the problem of how to combine these single relations into a coherent taxonomy. When taxonomies are automatically acquired, their cleaning (also called “pruning”) becomes a mandatory step (Velardi et al., 2013).

The contributions of this paper are two-fold:

1. We introduce a new algorithm, named ContrastMedium, which, given a noisy knowledge graph and its (possibly automatically generated) links to a companion taxonomy, is able to output a full-fledged taxonomy. Information from the reference taxonomy is projected onto the input noisy graph to automatically acquire topological clues, which are then used to drive the cleaning process. The reference taxonomy provides us with ground-truth taxonomic relations that make our knowledge-based method not truly unsupervised *sensu stricto*. However, the availability of resources like, for instance, WordNet (Fellbaum, 1998) or BabelNet (Navigli and Ponzetto, 2012) implies that these requirements are trivially satisfied;
2. We combine our approach with an unsupervised framework for knowledge acquisition from text (Faralli et al., 2016) to provide a full end-to-end pipeline for taxonomy induction from scratch.

## 2 Related Work

Knowledge Bases (KBs) can be created in many different ways depending on the availability of external resources and specific application needs. Recently, much work in Natural Language Processing focused on Knowledge Base Completion (Nickel et al., 2016a, KBC), the task of enriching and refining existing KBs. Many different methods have been explored for KBC, including exploitation of resources such as text corpora (Snow et al., 2006; Mintz et al., 2009; Aprosio et al., 2013) or other KBs (Wang et al., 2012; Bryl and Bizer, 2014) for acquiring additional knowledge. Alternative approaches, in contrast, primarily rely on existing information from the KB itself (Socher et al., 2013; Nickel et al., 2016b) used as ground-truth to simultaneously learn continuous representations of KB concepts and relations, which are used to infer additional KB relations. Finally, Open Information Extraction methods looked at ways to extract large amounts of facts from Web-scale corpora in order to acquire open-domain KBs (Etzioni et al., 2011; Faruqui and Kumar, 2015, *inter alia*);

In this paper, we focus on a different, yet complementary task, which is a necessary step when inducing novel KBs from scratch, namely extracting clean taxonomies from noisy knowl-

edge graphs. State-of-the-art algorithms differ by the amount of human supervision required and their ability to respect some topological properties while pruning. Approaches like those of Kozareva and Hovy (2010), Velardi et al. (2013) and Kapanipathi et al. (2014), for instance, apply different topological pruning strategies that require to specify the root and leaf concept nodes of the KB in advance – i.e., a predefined set of abstract top-level concepts and lower terminological nodes, respectively. The approach of Faralli et al. (2015) avoids such supervision on the basis of an iterative method that uses an efficient variant of topological sorting (Tarjan, 1972) for cycle pruning. Such lack of supervision, however, comes at the cost of not being able to preserve the original connectivity between the top (abstract) and the bottom (instance) concepts. Random edge removal (Faralli et al., 2015), in fact, can lead to disconnected components, a problem shared with the OntoLearn Reloaded approach (Velardi et al., 2013), which cannot ensure such property when used to approximate the solution for a large noisy graph.

Our work goes one step beyond the previous contributions by presenting a new efficient algorithm that is able to extract a clean taxonomy from a noisy knowledge graph without needing to know in advance – that is, having to manually specify – the top-level and leaf concepts of the taxonomy, while preserving the overall connectivity of the graph. We achieve this by projecting the information from a reference KB such as, for instance, WordNet (Fellbaum, 1998), onto the input noisy KB on the basis of pre-existing KB links – which in turn can be automatically generated with high precision using any of the existing solutions for KB mapping (Navigli and Ponzetto, 2012; Faralli et al., 2016, *inter alia*) or by relying on ground truth information from the Linguistic Linked Open Data cloud (Chiarcos et al., 2012).

Some aspects of the proposed approach – namely, the propagation of the nodes’ weights through the graph, which we metaphorically represent as the flow of a contrast medium across nodes (Section 3.3) – are somewhat similar in spirit to spreading activation (Collins and Loftus, 1975) and random walks on graphs (Lovász, 1993) approaches. However, in contrast to spreading activation approaches we leverage the graph directionality in order to reach all the possible nodes within the same connected components. More-

over, in contrast to random walks on graphs our method is deterministic in nature. Here, we argue for the choice of a deterministic approach, like ours, that does not require tuning of parameters: its termination is guaranteed by the number of iterations, which we bind by the maximal diameter  $|E|$  for a graph  $G = (V, E)$ . Generally, random walk algorithms would provide an approximation that may lead to a less precise estimation of the order induced by the contrast medium level.

### 3 The ContrastMedium Algorithm

#### 3.1 Problem Statement

Our work builds upon the notion of a **noisy knowledge graph** (NKG), which consists of a directed graph  $G = (V, E)$  where  $V$  is a set of concepts and  $E$  the set of labelled binary semantic relations – e.g., those found between synsets like, for instance, hypernymy or meronymy within a semantic network like WordNet. In a NKG we assume both  $V$  and  $E$  to have been acquired automatically, e.g., in order to induce a domain-aware or a general purpose knowledge base. Additionally, we consider for our purposes the **hypernymy graph**  $T = (T_V, T_E)$  of  $G$ , the subgraph made up of the hypernymy (i.e., *isa*-labeled) edges of  $E$ . Since  $T$  is a subgraph of  $G$ , we can expect that the former inherits a certain amount of noise from the latter.

Noise within hypernymy graphs can be further classified into: i) *noisy nodes*, the concepts that do not belong to a specific target vocabulary, e.g., domain concepts for domain-specific KBs, such as *Jaguar Cars* within a zoological taxonomy; ii) *noisy edges*, the wrongly-acquired relations between unrelated concepts or out-of-domain relations, e.g., *Jaguar Cars isa Feline*; iii) *cycles of hypernymy relations*, such as those derived from counts over very large corpora (Seitner et al., 2016), e.g., *jaguar (Panthera onca) → feline → animal → jaguar (Panthera onca)*. We accordingly define the task of extracting a clean taxonomy from a NKG as that of pruning the cycles, as well as the noisy edges and nodes, from the hypernymy subgraph  $T$  of  $G$ .

#### 3.2 Resources Used

In order to enable end-to-end taxonomy induction from scratch, we combine our general approach with existing KBs that have been automatically induced from text and linked to reference lexical knowledge bases on the basis of unsuper-

vised methods. To this end, we use the linked disambiguated distributional KBs from Faralli et al. (2016)<sup>1</sup>, which are built in three steps:

- 1) **Learning a JoBimText model.** Initially, a sense inventory is created from a large text collection using the pipeline of the JoBimText project (Biemann and Riedl, 2013).<sup>2</sup> The resulting structure contains disambiguated proto-concepts (i.e., senses), their similar and related terms, as well as aggregated contextual clues per proto-concept.
- 2) **Disambiguation of related terms.** Similar terms and hypernyms associated with a proto-concept are fully disambiguated based on the partial disambiguation from step (1). The result is a proto-conceptualization (PCZ), where all terms have a sense identifier.
- 3) **Linking to a lexical resource.** The PCZ is automatically aligned with an existing lexical resource (LR) such as WordNet or BabelNet. For example, `bridge:NN:3` is linked to the Babel synset `bn:00013077n` (the ‘infrastructure’ sense). That is, a mapping between the two sense inventories is created to combine them into a new extended sense inventory, a *hybrid aligned resource*.

Table 1 shows the proto-conceptualization entries for the polysemous terms *bridge* and *link*, namely their figurative (“bridge:NN:2” and “link:NN:1”) and concrete ‘infrastructure’ (“bridge:NN:3” and “link:NN:0”) senses, respectively. JoBimText models provide sense distinctions that are only partially disambiguated: the list of similar and hypernyms terms of each sense, in fact, does not carry sense information. Consequently, a semantic closure procedure is applied in order to obtain a PCZ and arrive at sense representation in which all terms get assigned a unique, best-fitting sense identifier (see Faralli et al. (2016) for details).

PCZs consist of a rich, yet noisy, disambiguated semantic network automatically induced from large amounts of text: links to existing lexical resources provide us a source of external supervision that can be leveraged to clean them and turn them into full-fledged taxonomies. Steps 1–3 are unsupervised by nature. Consequently, when

<sup>1</sup><https://madata.bib.uni-mannheim.de/171/>

<sup>2</sup><http://www.jobimtext.org>

entry	similar terms	hypernyms
bridge:NN:2	gap:NN:2, divide:NN:2, link:NN:1, ...	issue:NN:2, topic:NN:3, ...
bridge:NN:3	road:NN:0, highway:NN:1, overpass:NN:3 ...	infrastructure:NN:1, project:NN:1, ...
link:NN:0	connection:NN:3, correlation:NN:1, linkage:NN:1 ...	service:NN:6, feature:NN:0, ...
link:NN:1	relationship:NN:1, interaction:NN:1, divide:NN:0 ...	problem:NN:1, topic:NN:3 ...

Table 1: Excerpt of a proto-conceptualization (PCZ) for the words “bridge:NN” and “link:NN”.

combined with our algorithm they provide a complete framework for fully unsupervised taxonomy induction from scratch. Note, however, that our approach offers a general solution to the problem of taxonomy cleaning. In an additional set of experiments, we apply it to different automatically generated taxonomies from a SemEval task in a more controlled setting where we rely on a few manually created KB links only.

### 3.3 The ContrastMedium Algorithm

At its core, our algorithm relies on the notion of a **linked noisy knowledge graph** (LNKG). This consists of a quintuple  $(G, KB, KB_{root}, \lambda, M)$  where: i)  $G = (V_G, E_G)$  is a noisy knowledge graph; ii)  $KB = (V_{KB}, E_{KB})$  is a companion knowledge base providing a ground-truth taxonomy; iii)  $KB_{root}$  is the root node of the reference knowledge base  $KB$  (if several top-level nodes exist, an artificial root can be created by connecting them all); iv)  $\lambda$  is a conventional symbol to represent the “undefined concept”, i.e., a place-holder for empty mappings; v)  $M : V_G \rightarrow V_{KB} \cup \{\lambda\}$  is the function, which maps nodes of  $V_G$  into nodes of  $V_{KB}$  or into the undefined concept  $\lambda$ . The key ideas behind ContrastMedium are:

- Identification of important topological clues from the companion knowledge base  $KB$  in order to hierarchically sort the concepts in  $G$ . For our purposes,  $KB$  is expected to be able to provide ground-truth taxonomic relations that can be safely projected onto  $G$  to guide the cleaning process: that is, we assume it to be reasonably clean. In contrast, we do not make any assumption on how  $KB$  has been created: our approach can be used with either manually created taxonomies like WordNet or (semi-)automatically induced ones, provided they are of sufficient quality. Hence, our method is knowledge-based without the need of further supervision other than that contained in  $KB$ ;
- Projection of topological clues from  $KB$  back onto the LNKG  $G$  on the basis of the links

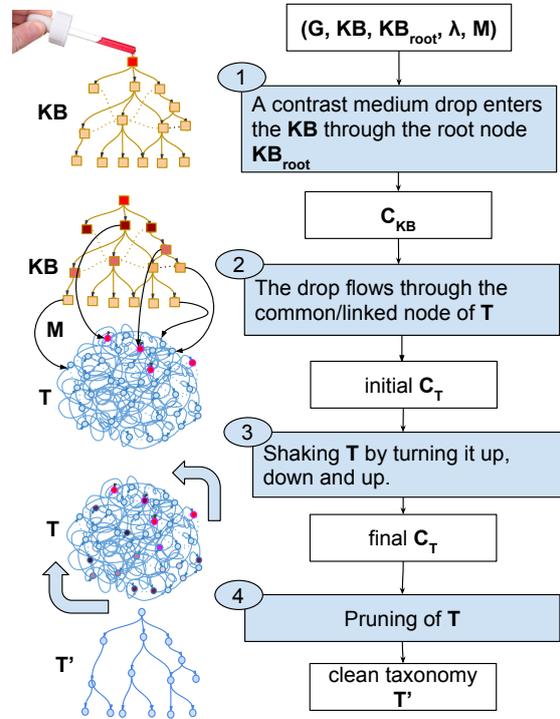

Figure 1: ContrastMedium: algorithm workflow.

found in the mapping  $M$ . Similarly to the case of the reference knowledge base, we do not make any assumption on how the links between  $G$  and  $KB$  have been created: while there exists different methods to automatically link (lexical) knowledge bases (Navigli and Ponzetto, 2012; Faralli et al., 2016), we later show that it is also possible to achieve state-of-the-art performance with a few manually given links;

- Propagation of the topological clues across the entire NKG  $G$ . That is, to cope with the partial coverage of automatic mappings, as well as the need to reduce the number of manually created KB links, we apply a signal propagation technique that solely relies on the structure of  $G$ ;
- To make use of the resulting topological clues to drive the taxonomy pruning process. That is, propagated topological clues from  $KB$  are additionally leveraged to ensure that the output

---

**ALGORITHM 1:** The ContrastMedium algorithm.

**Input:**  $(G = (V, E), KB = (V_{KB}, E_{KB}), KB_{root}, \lambda, M)$   
**Output:** hypernymy graph  $T'$  of  $G$ , s.t.  $T'$  has no cycles.  
// Estimating clues from KB (Fig. 1, step 1)  
1  $\forall x \in V_{KB}: C_{KB}(x) = 0;$   
2 injectContrastMedium( $KB, KB_{root}$ );  
// Transferring clues from KB to G (Fig. 1, step 2)  
3  $T = (V_T, E_T) \leftarrow \text{hypernymyGraph}(G);$   
4  $\forall x \in V_T: C_T(x) = 0;$   
5 transferClues( $M, KB, T, C_{KB}, C_T$ );  
// Shaking the graph  $T$  (Fig. 1, step 3)  
6 shake(UP,  $T, C_T$ ); // propagate through in-edges  
7 shake(DOWN,  $T, C_T$ ); // propagate through out-edges  
8 shake(UP,  $T, C_T$ ); // propagate through in-edges  
// Pruning the graph  $T$  (Fig. 1, step 4)  
9  $T' = \text{prune}(T, C_T);$   
10 return  $T'$ ;

---

results in a proper taxonomic structure.

We rely on the metaphor of a contrast medium (CM) to describe our approach, which is summarized in Figure 1. In the context of clinical analysis, a CM is injected into the human body to highlight specific complex internal body structures (in general, the venous system). In a similar fashion, we detect the topological structure of a graph by propagating a certain amount of CM that we initially inject through the node  $KB_{root}$  of the companion knowledge base  $KB$ . The highlighted structure indicates the distance of a node with respect to the node  $KB_{root}$ . Then the lowest values of contrast medium indicate the leaf terminological nodes. The observed quantities are then transferred to corresponding nodes of the noisy graph by the mapping  $M$ . Next, the medium is propagated by ‘shaking’ the noisy graph. We let the fluid reach all the components  $G$  by alternating two phases of propagation: letting the CM to flow through both incoming (‘shake up’); and outgoing (‘shake down’) edges. At the end, we use the partial order induced by the observed node level of CM to drive the pruning phase, and ‘stretch’ the original NKG  $G$  into a proper DAG.

Our approach is presented in Algorithms 1 and 2.<sup>3</sup> It consists of the following main steps:

**1) CM injection** Cf. Figure 1, block 1 and Algorithm 1, lines 1-2. We initially define the function  $C_{KB} : V_{KB} \rightarrow [0.0 - 1.0]$  and assign a zero contrast medium level to all the nodes of the  $KB$  graph  $C_{KB}(x) = 0, x \in V_{KB}$  (line 1). Next,

<sup>3</sup>A demo is available at <http://web.informatik.uni-mannheim.de/faralli/cm.html> with examples of the application of ContrastMedium to a few simple LNKGs.

---

**ALGORITHM 2:** The Shake routine.

**Input:** *direction* may be UP or DOWN,  
 $graph = (V_{graph}, E_{graph}), C_{graph}$   
**Output:** the updated  $C_{graph}$   
1 **foreach**  $x \in V_{graph}$  **do**  
2 |  $Current_{graph}(x) = C_{graph}(x); Flown_{graph} = 0.0;$   
// iteratively propagates the CM  
3 **for**  $i = 0$  to  $|E_{graph}| - 1$  **do**  
4 | **foreach**  $x \in V_{graph}$  **do**  
5 | |  $InOut_{graph}(x) = 0.0;$   
6 | **foreach**  $x$  s.t.  $Current_{graph}(x) > 0.0$  **do**  
7 | |  $CMlevel = Current_{graph}(x);$   
8 | | **if** *direction* == DOWN **then**  
9 | | |  $O = \text{outgoingEdges}(x, graph);$   
10 | | | **foreach**  $(x, y) \in O$  **do**  
11 | | | |  $InOut_{graph}(y) += \frac{CMlevel}{\max(|O|, 1)};$   
12 | | | **else**  
13 | | | |  $I = \text{incomingEdges}(x, graph);$   
14 | | | | **foreach**  $(y, x) \in I$  **do**  
15 | | | | |  $InOut_{graph}(y) += \frac{CMlevel}{\max(|I|, 1)};$   
16 | | |  $Flown_{graph}(x) += CMlevel;$   
17 | | **foreach**  $x \in V_{graph}$  **do**  
18 | | |  $Current_{graph}(x) = InOut_{graph}(x);$   
19 **foreach**  $x \in V_{graph}$  **do**  
20 |  $C_{graph}(x) = Flown_{graph}(x);$

---

we call the routine ‘injectContrastMedium’ which: 1) assigns an initial contrast level equals to 1.0 to the node  $KB_{root}$  of the  $KB$  graph; ii) uses the routine ‘Shake’ with the direction parameter equals to ‘DOWN’ (see Algorithm 2 and Step 3 ‘Graph shaking’ for more details) to let the CM drop through  $KB$ . In practice, the shaking routine implements a node contrast medium level propagation algorithm following the outgoing (‘down’) or the incoming (‘up’) edges of the graph.

**2) CM transfer** Cf. Figure 1, block 2 and Algorithm 1, lines 3-5. In the next phase, we first extract the hypernymy subgraph  $T = (V_T, E_T)$  of  $G$  (see Section 3.1) and then follow the links in the mapping  $M$  to transfer the contrast medium levels, i.e.,  $C_T(y) = C_{KB}(x)$  (s.t.  $x \in V_{KB}, y \in V_T, (y \rightarrow x) \in M$ ).

**3) Graph shaking** Cf. Figure 1, block 3 and Algorithm 1, lines 6-8. After having transferred the CM to the target hypernym graph  $T$  of  $G$ , we shake  $T$  to let the CM flow by traversing the incoming, the outgoing, and finally the incoming edges again – see Algorithm 2 for details on the ‘Shake’ routine. Note that these two kinds of propagation are needed since the CM needs to be propagated through all the nodes of the graph to highlight the topological clues we are searching for. In particular, in Algorithm 2 at each iteration  $t$  for each node  $x \in V_{graph}$ , depending on

the value of the parameter *direction* (line 8 and line 12): i) we observe a CM level for the node  $x$  (line 7); ii) if *direction* == DOWN (lines 9-11) we traverse all the outgoing edges  $(x, y)$  of  $x$  and propagate the observed CM level of  $x$ , otherwise (*direction* == UP, lines 13-15) we traverse the incoming edges  $(y, x)$  and propagate the CM level to the nodes  $y$ ; iii) the value of  $Flown_{graph}(x)$  is incremented by the observed CM level (line 16); iv) for each node  $x$  we reset the current observed value of the CM level with the portion of the liquid which has flown from the incoming or the outgoing edges during the propagation (lines 17-18).

Depending on the propagation direction, we have two different behaviours for the CM. When exiting a node  $x$  through out the outgoing edges (*direction* == DOWN) we increment the level of contrast medium of the reached nodes by the observed value of  $x$  divided by number of outgoing edges of  $x$ . By converse, when we climb (*direction* == UP) across the incoming edges of a node  $x$  we increment the CM level of the reached node by the observed CM quantity of  $x$  divided by the number of incoming edges of  $x$ .

Note that the sequence UP/DOWN/UP and the specular DOWN/UP/DOWN are the only ones from the 8 possible combinations which can guarantee the contrast medium to flow on the entire graph. We simply selected the first sequence since the final rank places candidate root nodes on the top (and candidate leaf nodes on the bottom).

**4) Pruning** Cf. Figure 1, block 4 and Algorithm 1, lines 9. Finally, we create a clean taxonomy  $T'$  by pruning the graph  $T$  on the basis of the contrast levels found in  $C_T$ . CM levels in  $C_T$  can be used to induce a order of the nodes that, intuitively, captures the level of conceptual abstraction for the nodes in  $T$ . We use them to produce a clean taxonomy as follows. We first sort the nodes  $v \in V_T$  in a list  $S = s_0, s_1, \dots, s_{|V_T|-1}$  by the decreasing resulting CM level value in  $C_T$ . The nodes with a higher level of contrast medium are candidates to be at the top level while the ones at the end of the list are candidates to be leaf nodes of the output taxonomy. Next, the pruning routine starts from a graph  $T' = (V_{T'} = V_T, E_{T'} = \emptyset)$  and for each node  $s \in S$  (from the last node to the first) add to  $E_{T'}$  all the edges of the kind  $e = (y, s)$  where a path from  $y$  to  $s$  does not exists in  $T$  and with  $y$  belonging to one of the following: i) the set of peers  $\{x \in S \text{ s.t. } C_T(x) = C_T(s)\}$ ; ii) the

ascending ordered list of preceding ( $x \in S \text{ s.t. } C_T(x) > C_T(s)$ ); iii) the ascending ordered list of following ( $x \in S \text{ s.t. } C_T(x) < C_T(s)$ )

**Complexity analysis.** The propagation step (Figure 1, blocks 1 and 3; Algorithm 2) costs  $O(|E| * |V|)$  since we iteratively analyze all the nodes of  $V$  for a number  $|E|$  of iterations. The final step of pruning (Figure 1, block 4), instead, can have a time cost  $O(|V|^2 * (|E| + |V|))$ , since, in the worst case, the algorithm must analyse all the possible pairs of vertices, and then test the existence of a directed path between the candidate pairs of nodes.

## 4 Experiments

We perform two sets of experiments. We first evaluate our approach when applied to large, automatically induced noisy knowledge graphs (Section 4.1) and then quantify the impact it can have to further improve the quality of the output of state-of-the-art taxonomy induction systems (Section 4.2).

### 4.1 Experiment 1: Pruning existing LNKG

We first apply ContrastMedium to a variety of knowledge graphs that have been automatically acquired and linked to reference KBs like WordNet and BabelNet using unsupervised methods (Section 3.2). Our research questions (RQs) are:

**RQ1** Can we use ContrastMedium as component of a complete framework for fully unsupervised taxonomy induction from scratch?

**RQ2** What is the quality of the resulting taxonomies?

#### 4.1.1 Experimental Setting

We apply our pruning algorithm to the automatically acquired KBs presented by Faralli et al. (2016). These noisy knowledge graphs have been induced from large text corpora and include both taxonomic and other (i.e., related, topically associative) semantic relations (cf. Table 1), as well as automatically induced mappings to lexical knowledge bases like WordNet and BabelNet. These NKGs have been induced from a 100 million sentence news corpus (*news*) and from a 35 million sentence Wikipedia corpus (*wiki*), using different parameter values to generate sense inventories of different granularities (e.g., 1.8 vs. 6.0 average senses per term for the wiki-p1.8 and wiki-p6.0 datasets, respectively). Table 2 shows some of

dataset	senses		polysemy		hypernyms		links	hypernymy graph	
	#	avg.	max	#	avg.	#	$ V_T $	$ E_T $	
news-p1.6	332k	1.6	18	15k	6.9	60k	170k	1.538k	
news-p2.3	461k	2.3	17	15k	5.8	95k	225k	1.871k	
wiki-p1.8	368k	1.8	15	15k	4.4	67k	185k	1.167k	
wiki-p6.0	1.5M	6.0	36	52k	1.7	279k	394k	1.901k	

Table 2: Dimensions of the four datasets adopted as linked noisy knowledge graphs (Faralli et al., 2016).

the dimensions for each of the four NKGs – number of senses, average and maximum sense polysemy, number and average hypernyms per sense, the number of linked senses to WordNet concepts (i.e., “links”), and the number of nodes and edges for the corresponding hypernymy graph. Since our algorithm primarily focuses on conceptual hierarchical (taxonomic) structures – referred to as the TBox in Knowledge Representation – we use the WordNet mappings only, since the manual inspection of the BabelNet mappings revealed that they are focused primarily on instances (that is, ABox statements). In order to have a complete quintuple for each NKG, we selected, for the companion KB, the top  $KB_{root}$  concept `entity` of the WordNet taxonomy (SynsetID SID-00001740-N).

#### 4.1.2 Measures

We benchmark ContrastMedium using a variety of metrics that are meant to capture structural properties of the output taxonomies (to describe the impact of pruning on the original NKGs), as well as an estimation of their overall quality.

**Edge compression:** the ratio of the number of pruned edges over the total number of edges:

$$C_{E_G, G'} = \frac{|E_G| - |E_{G'}|}{|E_G|}$$

where  $E_G$  and  $E_{G'}$  represent the number of edges found within the input ( $G$ ) and pruned ( $G'$ ) taxonomy, respectively.

**Pruning accuracy:** the performance on a 3-way classification task to automatically detect the level of granularity of a concept as a proxy to quantify the overall quality of the output taxonomies. Pruning accuracy is estimated using gold-standard annotations that are created from a random sample of 1,000 nodes for each NKG. Two annotators with previous experience in knowledge acquisition and engineering were asked to provide for each

concept whether it can be classified as: i) a root, top-level abstract concept – i.e., any of `entity`, `object`, etc. and more in general nodes that correspond to abstract concepts that we can expect to be part of a core ontology such as, for instance, DOLCE (Gangemi et al., 2002); ii) a leaf terminological node (i.e., instances such as `Lady Gaga` or `Porsche 911`); iii) or a middle-level concept (e.g., `celebrity` or `cars`, concepts not fitting into any of the previous classes). An adjudication procedure was used to resolve any discrepancy between the two annotators: the inter-annotator agreement after adjudication is  $\kappa = 0.657$  (Fleiss, 1971), with most disagreement occurring on the identification of abstract, core ontology concepts.

A local 3-way classification task provides a rather crude way to estimate the performance on inducing hierarchical structures like taxonomies. Here, we use it primarily to benchmark how well ContrastMedium compares against other, structure-agnostic algorithms used within state-of-the-art solutions such as, for instance, Tarjan’s topological sorting (Section 2), which only break cycles in a random fashion.

Given ground-truth concept granularity judgements, we compute standard accuracy for each of the three classes. That is, we compare the system outputs against the gold standards and obtain three accuracy measures: one for the root nodes ( $A_R$ ), one for the nodes ‘in the middle’ ( $A_M$ ) and finally one for the leaf nodes ( $A_L$ ). For example a true positive root node is a node annotated as a root node in the gold standard and having no incoming edges in the pruned graph.

**Error Reduction (ER):** finally, we compute the relative error reduction of ContrastMedium against other, baseline approaches as:

$$\frac{Baseline_{errors}/|sample| - CM_{errors}/|sample|}{Baseline_{errors}/|sample|}$$

As *baseline* we use the approach of Faralli et al.

dataset	Pruned Knowledge Graph						Pruning accuracy						ER
	ContrastMedium			Tarjan (baseline)			ContrastMedium			Tarjan (baseline)			
	$ V_{G'} $	$ E_{G'} $	$C_{E_{G},G'}$	$ V_{G'} $	$ E_{G'} $	$C_{E_{G},G'}$	$A_R$	$A_M$	$A_L$	$A_R$	$A_M$	$A_L$	
news-p1.6	170k	1.536k	0.15%	170k	1.535k	0.18%	<b>98.9</b>	<b>98.3</b>	<b>99.3</b>	93.3	94.6	95.3	0.62
news-p2.3	225k	1.867k	0.19%	225k	1.866k	0.23%	<b>98.7</b>	<b>98.7</b>	<b>99.9</b>	95.7	94.7	95.6	0.50
wiki-p1.8	183k	1.165k	0.18%	183k	1.164k	0.22%	<b>97.6</b>	<b>94.7</b>	<b>97.3</b>	93.1	87.3	94.1	0.41
wiki-p6.0	394k	1.897k	0.18%	394k	1.896k	0.21%	<b>95.9</b>	<b>94.3</b>	<b>98.3</b>	89.5	90.1	92.8	0.50

Table 3: Structural analysis, pruning accuracies and error reduction (ER) for the four LNKGs.

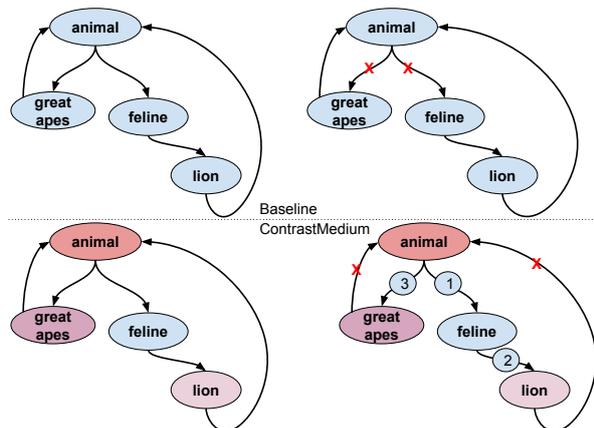

Figure 2: An example noisy graph and the different solutions provided by ContrastMedium and the baseline.

(2015) based on Tarjan’s topological sorting (Section 2), which iteratively searches for a cycle (until no cycle can be found) and randomly removes an edge from it. To the best of our knowledge, this is the only algorithm that we can fairly compare with, since alternative solutions all need to know the sets of root and leaf nodes in advance.

### 4.1.3 Results and discussion

Table 3 summarizes the performance of ContrastMedium on the four automatically acquired NKGs. The results show that the pruning impact of our approach is lower than that of the baseline (an average of 1K edges of difference, cf. columns 3 and 6), which also determines higher edge compression  $C_{E_{G},G'}$  values for the baseline method. Despite being less aggressive in terms of the number of edges pruned, ContrastMedium outperforms the Tarjan-based algorithm on all datasets in terms of accuracy. Thanks to our method, in fact, we are able to achieve, even despite the baseline already reaching very high performance levels (well above 90% accuracy), improvements of up to 6 points, with an overall error reduction between around 40% and 60%. To provide an

intuition of why ContrastMedium clearly outperforms the baseline approach, we provide in Figure 2 an exemplified depiction of a typical case on which the baseline fails (based on a manually inspected random sample). In our example, the Tarjan baseline first detects the cycle  $C_1 = (\text{lion} \rightarrow \text{animal} \rightarrow \text{feline} \rightarrow \text{lion})$  and randomly decides to break it by removing the edge  $(\text{animal} \rightarrow \text{feline})$ . Next, it detects the cycle  $C_2 = (\text{animal} \rightarrow \text{great apes} \rightarrow \text{animal})$  and randomly decides to break it by removing the edge  $(\text{animal} \rightarrow \text{great apes})$ . ContrastMedium, instead, after the shaking of the graph can leverage the partial ordering of the nodes (based on the concept granularity of the corresponding concepts) to select the edges  $(\text{animal}, \text{feline})$ ,  $(\text{feline}, \text{lion})$  and  $(\text{animal}, \text{great apes})$ , while removing all remaining wrong and redundant edges.

## 4.2 Experiment 2: SemEval-15 task 17

We next evaluate the overall impact of our approach within an existing benchmark for the taxonomy induction task. Intuitively, most of the benefits from our method derive from the “gold standard” information of the companion KB, and its linking to the NKG, which act as a source of supervision. Consequently, we address the research question of how much (pseudo-)supervision our method needs in terms of KB links, and whether it can be used to improve the state-of-the-art on the task of taxonomy induction.

### 4.2.1 Experimental Setting

We use the benchmark data from the SemEval-15 task 17 “Taxonomy Extraction Evaluation: TExEval” (Bordea et al., 2015), since it provides us with gold-standard datasets and system outputs within a standard, easy-to-reproduce setting. Initially, we select from the participating systems<sup>4</sup> the two best performing taxonomies based on the Cumula-

<sup>4</sup>Cf. Table “Comparative Evaluation” at <http://alt.qcri.org/semeval2015/task17/index.php?id=evaluation>

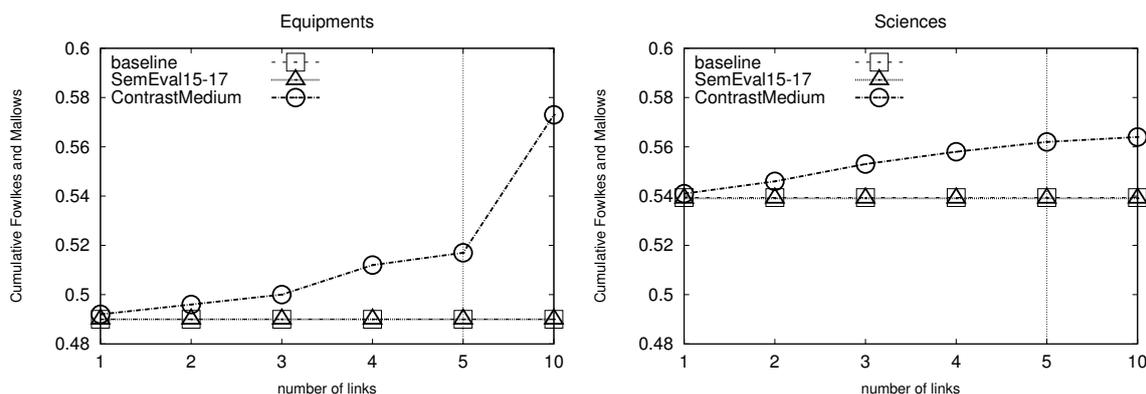

Figure 3: Performance on the SemEval-15 TExEval dataset (Cumulative Fowlkes&Mallows measure).

tive Fowlkes&Mallows (CF&M) measure (Velardi et al., 2012), the *Equipments* and *Sciences* taxonomies from the INRIASAC and the LT3 teams respectively. We next apply our approach to these taxonomies, in order to clean them in a post-processing fashion. By selecting the top-systems we can see how far we can advance the state-of-the-art overall. Besides, these two taxonomies are also the ones containing the highest number of cycles, giving the application of our cleaning algorithm a more challenging (and meaningful) setting. To remove the effects of automatic linking and quantify the amount of manual efforts needed by our approach, 10 random concepts from each of these resources are manually linked to WordNet, and the taxonomies subsequently pruned using ContrastMedium and the baseline. We then evaluate performance following the task’s experimental setting and compute the CF&M measure for different levels of manually-created KB links.

#### 4.2.2 Results and discussion

In Table 3, we report the performance on the SemEval task for the two selected input taxonomies. Results on the structural similarities of the pruned taxonomies with the gold standard ones, computed using the CF&M measure, indicate that, thanks to ContrastMedium and with a minimal human effort – the creation of just a few KB links (up to 10), which are needed only when automatic linking is not available – it is possible to boost the quality of taxonomies using state-of-art methods by a large margin. For instance, in the case of the *Equipments* taxonomy, we improve up to 7 points. The baseline, which only breaks cycles, is not able to reassess the graph structure and only provides very small improvements to the submitted NKGs.

Overall, the results show that ContrastMedium leads to competitive performance on a hard, realistic benchmark such as TExEval, achieving the best overall results for both taxonomies. That is, our algorithm is able to improve the state-of-the-art on taxonomy induction by additionally boosting the quality of existing top-performing systems for this task: this is achieved on the basis of a minimally supervised approach that only requires a few links to a reference KB, which is used to provide ground-truth taxonomic relations and guide the cleaning process.

## 5 Conclusions

In this paper, we presented ContrastMedium, a novel algorithm that can be applied to automatically linked noisy knowledge graphs to provide an end-to-end solution for fully unsupervised taxonomy induction from scratch, i.e., without any human effort. Our results indicate that ContrastMedium can be successfully applied to a wide range of automatically acquired KBs, ranging from large linked noisy knowledge graphs all the way to small-scale induced taxonomies to produce high-quality *isa* hierarchies that achieve state-of-the-art results on SemEval benchmarks. As future work, we plan to improve the scalability of the algorithm, in particular its time complexity order, and apply it to Web-scale resources like the WebIsaDB (Seitner et al., 2016) or state-of-the-art approaches like TAXI (Panchenko et al., 2016), as well as to publicly release the created resources.

## Abstract

Building knowledge bases (KB) automatically from text corpora is crucial for many applications such as question answering and web search. The problem is very challenging and has been divided into sub-problems such as mention and named entity recognition, entity linking and relation extraction. However, combining these components has shown to be under-constrained and often produces KBs with supersize entities and common-sense errors in relations (a person has multiple birthdates). The errors are difficult to resolve solely with IE tools but become obvious with world knowledge at the corpus level. By analyzing Freebase and a large text collection, we found that per-relation cardinality and the popularity of entities follow the power-law distribution favoring flat long tails with low-frequency instances. We present a probabilistic joint inference algorithm to incorporate this world knowledge during KB construction. Our approach yields state-of-the-art performance on the TAC Cold Start task, and 42% and 19.4% relative improvements in F1 over our baseline on Cold Start hop-1 and all-hop queries respectively.

## 1 Introduction

Automatically transforming a large corpus into a structured knowledge base (KB) has long been a goal of information extraction (IE) research. KB population incorporates many IE tasks including named entity recognition, entity linking and relation extraction, each of which rely on deeper linguistic analysis, e.g., syntactic parsing or anaphora resolution. Since 2012, NIST <sup>1</sup> has run an open shared task in KB population (KBP) under TAC <sup>2</sup>. Most participating systems (Mayfield et al., 2014; Min et al., 2015; Roth et al., 2015; Angeli et al., 2014; Nguyen et al., 2014; Monahan and Carpenter, 2012) combine many independent components to perform the full task.

As will be familiar to most IE researchers, the individual components are not perfect. When combined into a pipeline, errors compound. We found that a KB produced with a simple combination of state-of-the-art IE components (Ramshaw et al., 2011) is very sensitive to component-level errors (Grishman, 2013).

Table 1 illustrates a real entity coreference mistake. *Barack Obama* and *Ehud Barak* were incorrectly linked because of ambiguous context and high lexical overlap. The mistake leads to erroneous facts about employment, familial relations, etc. We see additional mistakes when we review the names in those entities with the most mentions: the *U.S.* entity contains more than 20,000 mentions. 85% are correct (e.g., *United States, U.S.*), but there is a long tail of incorrect yet infrequent (each accounting for < 1%) mentions linked to the entity e.g., *North America, Latin American*. We also see counter-intuitive errors in relation extraction: 5% of person entities have multiple birthdates; the KB asserts 8 spouses for an infrequently

---

<sup>1</sup>U.S. National Institute of Standards and Technology

<sup>2</sup>Text Analysis Conference: [www.nist.gov/tac/](http://www.nist.gov/tac/)

mentioned entity. Similar errors have been reported in (McNamee et al., 2013) and (Singh et al., 2013b).

Named mentions of PER: <i>Barack Obama</i> : <i>Barack, Barack Obama, Ehud Barak, Barak</i>
Text: <i>Barak endorses Barack, ... Defense Minister Ehud Barak said Barack Obama has been the most supportive president on Israeli security</i>

Table 1: Example of entity linking errors.

Analyzing these errors suggests a limitation of performing KB population solely with IE tools. These mistakes only become obvious in the context of external world knowledge with the full set of facts extracted from many documents, e.g. when applying our expectations about the cardinality of a relation. With just a single document, resolving these mistakes requires challenging inference (Ji et al., 2005).

In this paper, we present a probabilistic framework to incorporate real-world knowledge into Cold Start KB population. Our contributions include:

- Identifying from real world datasets that entity popularity and each relation’s cardinality follow the power-law distribution with long tails of low-frequency instances.
- Defining a corpus-level joint objective for KBP that incorporates multiple IE components and prior world knowledge on entity popularity and per-relation cardinalities, and showing the prior knowledge helps to reduce errors.
- Outperforming the top-ranked entry in Cold Start 2015.

The paper is organized as follows: we first introduce the Cold Start KBP task, then present the joint probabilistic framework, followed by analysis of the world knowledge and how to incorporate it. We then describe our inference algorithm. Lastly, we present experimental results, related work, and conclude with suggestions for future research.

## 2 Cold Start KBP

The schema consists of 3 entity types (person, organization, and GPE) and 42 slots (relation classes)<sup>3</sup>. Systems start with an empty KB (cold start) and populate it according to the schema with

<sup>3</sup>We will use *slot* and *relation* interchangeably in this paper.

information extracted from the corpus. All facts in the KB must be grounded with justifying text from the corpus.

A KB entity is defined as a cluster of mentions that refer to the same real-world entity, e.g., *Smith*, *John Smith*, and *John H Smith* are 3 mentions for the entity *John\_H\_Smith*. Every named mention of an entity is recorded. A relation is a triplet (*subject*, *slot*, *object*), where *subject* and *object* are entities,<sup>4</sup> and *slot* is the relation between them. For example, (*Bart Simpson*, *per:siblings*, *Lisa Simpson*) is the relation *Bart Simpson is a sibling of Lisa Simpson*. A relation’s provenance points to up to 4 snippets in the corpus that justify the relation. The evaluation process is described in the Experiments Section.

## 3 A Probabilistic Framework

Following most Cold Start KBP systems (Mayfield et al., 2014; Min et al., 2015; Roth et al., 2015; Angeli et al., 2014; Nguyen et al., 2014; Monahan and Carpenter, 2012), our baseline uses a cascade of NLP components from document-level analysis to corpus-level aggregation. We run BBN’s SERIF (Ramshaw et al., 2011) for mention, value and name tagging, coreference resolution, sentence-level relation extraction, alongside other analysis such as syntactic parses. Then we aggregate entities with entity discovery and linking and relations with relation extraction.

Given a set of pre-trained NLP components, the process is essentially an inference task. We introduce the following notation:

- $M$  is the list of mentions
- $E$  is the set of entities to populate the KB
- $R$  is the set of relation types.
- $x_i$  is the observed text for mention  $i$ ,  $x_i \in M$
- $u_i$  is entity ID from the KB assigned to mention  $i$ ,  $i \in \{1, 2, \dots, |M|\}$ ,  $u_i \in \{1, 2, \dots, |E|\}$
- $z_{i,j} = r$  indicates the relation  $r$  between a pair of mentions  $x_i, x_j \in M$  and  $r \in R \cup \{Other\}$
- $y_{i,j}^r$  is an indicator variable:  $y_{i,j}^r = 1$  if a relation  $r \in R$  exist between entity pair  $\langle e_i, e_j \rangle$ ,  $i, j \in \{1, 2, \dots, |E|\}$ , and 0 otherwise.

The key steps in the pipeline are the following:

**Mention extraction:** We use a structured perceptron model (Ramshaw et al., 2011) to extract named mentions  $M$ .

<sup>4</sup>A small number of the relations take values not entities. We do not differentiate in this work.

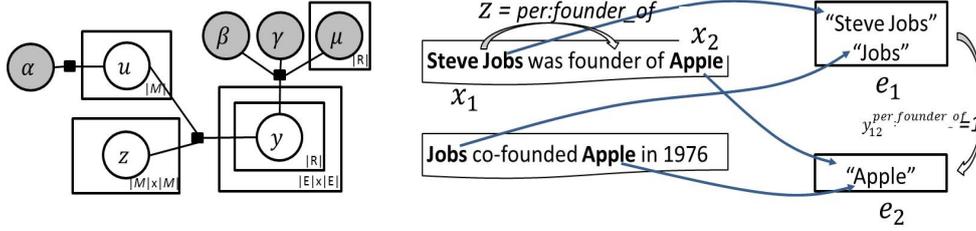

Figure 1: A simplified plate model of the probabilistic model(left), and an example (right) illustrates the KB construction process with aligned variables. The plate model only shows RE and EDL factors, and factors incorporating world knowledge. The example(right) compensates by showing the process without priors.

**Entity Discovery & Linking (EDL):** This step creates a candidate entity set  $E$  for the KB and infers which document entity (represented by its named mentions) is associated with which KB entity, i.e. assigning values for  $\{u_i\}$ . We use a sieve-like (Raghunathan et al., 2010) algorithm for in-document coreference. For simplicity, we only model EDL of names<sup>5</sup>.

We define potential functions over variables  $\{u_i\}$  for each pair of mention  $x_i$  and the  $j$ th entity  $e_j$ :

$$\Psi_i^{EDL}(u_i = j|x_i) = \exp(\sum_k \theta_k \phi_k(u_i = j|x_i))$$

The baseline system solves the EDL problem by inferring  $u_i^* = \arg \max \Psi_i^{EDL}(u_i)$ . It uses a name database collected from Freebase (Bollacker et al., 2008) and GeoNames<sup>6</sup>. First, it clusters novel names to create new candidate entities in addition to entries in the name database. A novel name is defined as a name that could not be resolved to a database entry. It then rescans the corpus and links each document-level entity to a corpus-level entity (an entry in the name database or a novel name). The EDL model  $\Psi^{EDL}$  uses features such as string edit distance and indicators representing whether appearing in the same name variant set.  $\{\theta_k\}$  and  $\{\phi_k\}$  are the weights and feature functions respectively.

**Mention-level Relation Extraction (MRE):** This step infers which relation  $z_{i,j} = r (r \in R \cup \{Other\})$  exists between each pair of mentions  $\langle x_i, x_j \rangle$ , we define potential functions:

$$\Psi_{i,j}^{MRE}(z_{i,j} = r|x_i, x_j) = \exp(\sum_k \theta'_k \phi'_k(z_{i,j} = r|x_i, x_j))$$

We run several relation finding algorithms (Min et al., 2015), including statistical models trained

<sup>5</sup>Decisions made for named mentions will be applied to the corresponding document-level entities.

<sup>6</sup>[www.geonames.org](http://www.geonames.org)

from ACE<sup>7</sup> relation annotation and distant supervision (Mintz et al., 2009) in which we align Freebase pairs into Gigaword (Parker et al., 2011) to generate training examples, and a pattern matcher with a few hand-written patterns that capture local contexts.

To train a log-linear model  $\Psi^{MRE}$  for combining these algorithms and to tune the confidences of their extractions, we follow (Viswanathan et al., 2015) and train a stacked classifier using output and confidences of the extractors. We use assessment datasets from TAC Cold Start KBP 2013 and 2014, and Slot Filling evaluations in 2013 and 2014. The features we used are: source algorithm name, slot, confidence score (if exists), argument mention level (*pronoun, name, or nominal*), lexical sequence between pair of arguments, propositional path between the pair of arguments.  $\{\theta'_k\}$  and  $\{\phi'_k\}$  are the weights and feature functions respectively.

**Relation Extraction (RE):** This aggregation step infers which relations exist between each pair of entities at the KB level, i.e. assigning values for  $\{y_{i,j}^r\}$ . We define the potential functions over the indicator variables  $\{y_{i,j}^r\}$ , by looking at all pairs of mentions  $x_m, x_n \in M$ , their potential to have a relation  $r$  and likelihood to be associated with entities  $e_i, e_j \in E$ :

$$\begin{aligned} \Psi_{i,j,r}^{RE}(y_{i,j}^r = 1|x) = \\ \max_{\langle m,n \rangle} (\Psi_m^{EDL}(u_m = i|x_m) \Psi_n^{EDL}(u_n = j|x_n) \\ \Psi_{m,n}^{MRE}(z_{m,n} = r|x_m, x_n)) \end{aligned}$$

and  $\Psi_{i,j,r}^{RE}(y_{i,j}^r = 0|x) = \Psi_0^{RE}$  where  $\Psi_0^{RE}$  is a parameter learned from previously seen data. The aggregation from a set of  $z_{m,n}$  to a set of  $y_{i,j}$  is similar to noisy-or relation aggregation (Hoffmann et al., 2011; Riedel et al., 2010; Sur-

<sup>7</sup>[itl.nist.gov/iad/mig/tests/ace/2005/](http://itl.nist.gov/iad/mig/tests/ace/2005/)

deanu et al., 2012) and supports overlapping relations (Hoffmann et al., 2011; Surdeanu et al., 2012).

**The joint distribution** defined over the full set of variables  $u, y$  is:

$$Pr(u, y|x) \propto \prod_m \Psi_m^{EDL}(u_m|x_m) \cdot \prod_{i,j,r} \Psi_{i,j,r}^{RE}(y_{ij}^r|x)$$

The Cold Start KBP problem can be seen as finding the maximum a posteriori (MAP) configuration:

$$(u^*, y^*) = \arg \max_{(u,y)} Pr(u, y|x)$$

The baseline system approximates the solution by solving in 2 separate stages: solve EDL by fixing  $u_m^* = \arg \max_{1 \leq i \leq |E|} \Psi_m^{EDL}(u_m = i|x_m)$  for all  $x_m$ , then solve RE by fixing  $y_{i,j}^{*r} = \arg \max_{\delta \in \{0,1\}} \Psi_{i,j,r}^{RE}(y_{i,j}^r = \delta|x, u^*)$  for all  $i, j, r$ . The potential  $\Psi_{i,j,r}^{RE}(y_{i,j}^r = 1|x, u^*)$  is a relaxed form for  $\Psi_{i,j,r}^{RE}(y_{i,j}^r = 1|x)$ :

$$\begin{aligned} & \Psi_{i,j,r}^{RE}(y_{i,j}^r = 1|x, u^*) = \\ & \max_{\substack{m,n: \\ (u_m^*, u_n^*) = (i,j)}} (\Psi_m^{EDL}(u_m^* = i|x_m) \Psi_n^{EDL}(u_n^* = j|x_n)) \\ & \Psi_{m,n}^{MRE}(z_{m,n} = r|x_m, x_n) \end{aligned}$$

In the relaxed form, the optimization problem required for estimating the potential of  $y_{i,j}^{*r}$  is limited to search only over pairs of mentions  $x_m, x_n$  which are now associated with the entities  $e_i, e_j$ , i.e.  $u_m = i$  and  $u_n = j$ , instead of enumerating over all pairs of mentions. This can be done efficiently.

## 4 Incorporating World Knowledge

We incorporate world knowledge related to *entity popularity* and a set of *per-relation cardinalities* as additional factors in the objective. To learn these factors' form, we analyze real-world datasets and find that both factors follow the power-law distribution with long tails of low-frequency instances.

### 4.1 Entity Popularity

We define *entity popularity* (EP) as the number of mentions of an entity in a corpus. Entities vary in *popularity*— famous people (e.g. politicians, athletes), countries, and large organizations will be mentioned frequently in news, while other entities— a small city, the local valedictorian may only be mentioned a few times. Ideally, we would

model the EP distribution with counts from a large corpus annotated for names and cross-document entity coreference. As we are not aware of any such resource, we look at two approximations:

**Name variants (NV)**: We collect name variants (e.g., *UN and United Nations*) for PER and ORG from Freebase and for GPE from GeoNames.

**Name Mentions (NM)**: From a 50K document sample of Gigaword, for each entity, we search for exact matches to its name variants, and count these matches to estimate the number of entity mentions.

Figure 2 (left) plots the per-entity relationship between the count of NM and NV with rank. Both follow the power-law distribution (i.e. the plots are close to straight lines in a log-log scale). In other words, most entities have only a small number of variants and are mentioned only a few times. A handful of popular entities are mentioned frequently and have many variants<sup>8</sup>. The size of entities in the Kripke (Finin et al., 2014) system follows power-law distribution, further supporting our findings.

Formally, we define for  $i$ th entity the popularity variable  $q_i(u) = \sum_m I(u_m = i)$  and the potential for EP factor  $\Psi_i^{EP}(u)$  as follows:

$$\Psi_i^{EP}(u) \propto \exp(\theta^{EP}(q_i(u)))$$

in which  $\theta^{EP}(q_i(u)) = \alpha \ln(q_i)$ .

The parameter  $\alpha > 0$  is initially fit from Freebase entities and then finetuned with TAC 2014 dataset to reflect real-world distributions. The EP term favors EDL solutions  $u$  with a popularity distribution that follows a power-law with a long tail of low-frequency entities.

### 4.2 Relation Cardinality

We define relation  $r$ 's *cardinality* regarding  $e_i$  as the number of entities or values associated with  $e_i$  through  $r$ . For example, if *John Smith* has 3 children, the cardinality of  $r=per:children$  regarding  $e_i=John\ Smith$  is 3. Formally, we notate the set of variables  $\{y_{ij}^r\}$  as  $y_i^r$ , and the cardinality of a relation  $r$  of entity  $e_i$  as  $d_i^r = \sum_j y_{ij}^r$ .

Per-relation cardinalities (RC) often reflect real world constraints— people have at most one birthdate and typically no more than 5 siblings. To understand the cardinality constraints for the Cold Start relations, we use Freebase, a large, manually

<sup>8</sup>We confirm that a few entities have many variants e.g. for *Elizabeth II*, 364 variants including *Elizabeth II of the UK*, *Her Majesty the Queen*, *Queen of Australia*, etc.

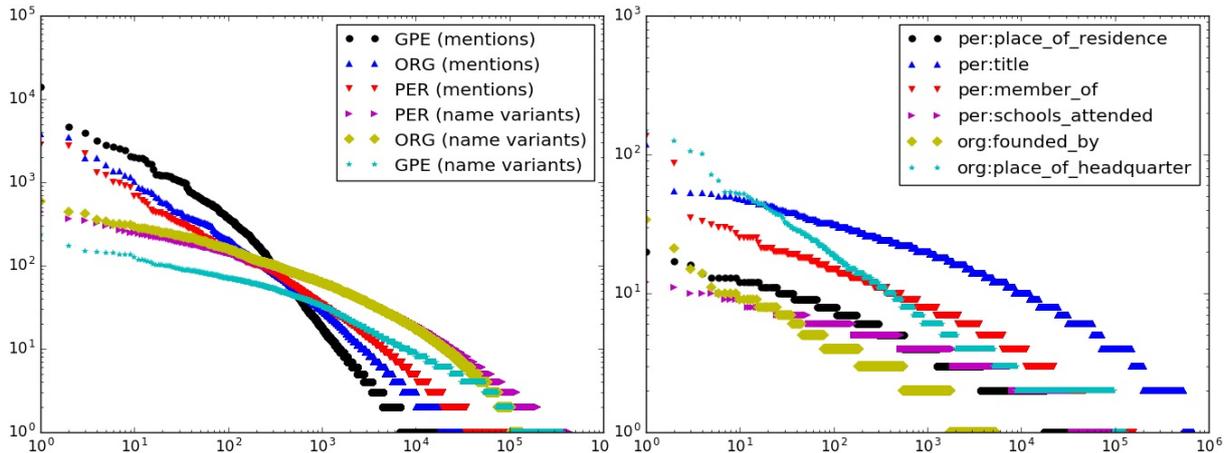

Figure 2: Real-world entity popularity (left) and per-relation cardinality (right) both follow the power-law distribution.  $x$ -axis shows ranks and  $y$ -axis shows counts (both are in log scale). The Left figure plots both numbers of name variants and numbers of mentions to ranks for PER, ORG and GPE.

curated KB. We align Freebase to the TAC schema following (Chen et al., 2010) and then generate a cardinality for each relation for all entities. The relationship between RC and RC-rank for the the 6 most frequent relations is plotted in Figure 2 (right). For these relations, RC closely resembles a power-law distribution. To favor both power-law and a soft size-limit on cardinality, we define the following potentials for RC factors for each relation-entity pair:

$$\Psi_{i,r}^{RC}(y^r) \propto \exp(\theta^{RC}(d_i^r))$$

in which  $\theta^{RC}(d_i^r) = \beta \ln(d_i^r) - \gamma(\max(d_i^r - \mu^r, 0))^2$  with parameters  $\beta, \gamma > 0$ , and  $\mu^r$  as the mean of the cardinalities of a relation  $r$  (estimated from Freebase). The first term in the potential has the power-law assumption, while the second term penalizes large cardinalities for going beyond the mean  $\mu^r$ .

### 4.3 Incorporating Prior World Knowledge

Incorporating the EP and per-relation RC terms into the joint distribution, we obtain the joint objective:

$$Pr^*(u, y|x) \propto Pr(u, y|x) \cdot \prod_{1 \leq i \leq |E|} \Psi_i^{EP}(u) \cdot \prod_{\substack{1 \leq i \leq |E| \\ r \in R}} \Psi_{i,r}^{RC}(y_i^r)$$

with  $Pr(u, y|x)$  as the baseline objective. A simplified plate diagram is shown in Figure 1.

#### Learning constraints for real-world corpora:

As we’re not aware of any large corpus annotated exhaustively with entities and relations, we fit the parameters of the constraints initially from

Freebase entities and relations, and then fine-tune them using empirical utility maximization (Jansche, 2005; Ye et al., 2012) for TAC Cold Start all-hop F1 with grid search in the parameter space, using previous years’ TAC assessment. Freebase is used in initialization because of its scale while finetuning with TAC assessment ensures the factors to more appropriately represent the underlying distribution of entity popularity and relation cardinality in a real-world corpus.

## 5 Jointly Inferring Entities and Relations

The problem of Cold Start KBP becomes finding a MAP assignment of  $u$  and  $y$  for  $Pr^*(u, y|x)$ . Finding the exact solution is hard, as many terms in the objective involve large groups of variables. We propose Algorithm 1 as an approximate heuristic. Line 1 generates an initial KB by approximating a solution for the baseline objective  $Pr(u, y|x)$  (Section 3), but tends to overlink entities and over-aggregate relations. Lines 2-8 iteratively refine the KB by searching over the  $(u, y)$ -space using operation  $o \in \{\text{SplitE}, \text{PruneR}\}$ . At  $t$ -th iteration, it performs the operation  $o$  with the highest potential gain  $\Delta \ln Pr^*(o(u^t, y^t)|x)$ . The process is repeated until the gain is smaller than a very small value  $\epsilon$ .

**SplitE:** splits an entity  $e_i$  into two entities. Since there are an exponential number of possible SplitE actions, we uses the following two heuristics: 1) cluster name mentions by their string forms, and find an “outlier” cluster of mentions, 2) rank  $e_i$ ’s mentions  $\{x_m : u_m^* = i\}$  by their local EDL potential  $\Psi_m^{EDL}(u_m^*|x_m)$  and find the lowest-ranked mention as an “outlier”. After find-

**Input :**  $x, \alpha, \beta, \gamma, \mu^r$  for  $r \in R$

**Output:**  $u, y$

```

1  $(u^0, y^0) = \arg \max_{(u,y)} Pr(u, y|x)$ 
2  $t \leftarrow 0$ 
3 repeat
4    $o = \arg \max_o \Delta \ln Pr^*(o(u^t, y^t)|x)$ 
5   if  $o! = null$  then
6      $(u^{t+1}, y^{t+1}) \leftarrow Execute(o(u^t, y^t))$ 
7      $t \leftarrow t + 1$ 
8 until  $\Delta \ln Pr^*(o(u^t, y^t)|x) < \epsilon;$ 
Algorithm 1: The MAP inference algorithm

```

ing an ‘‘outlier’’ mention cluster of  $e_i$ , we divide it into two entities:  $e_g$  with the ‘‘core’’ mentions, and  $e_h$  with the ‘‘outlier’’ mention cluster. We repeat the process to find all outlier entities and separate them from the entity. Relation arguments will be reattached to the new entities accordingly. We only consider a short list of most popular entities and split each using the heuristics described above.

**PruneR:** removes a batch of relations ( $Y = \{y_{i,j}^r\}$ ) by setting 0:  $y_{i,j}^r \leftarrow 0$  for each  $y_{i,j}^r \in Y$ . The batch is generated with the following steps: first select a set of entity-relation pairs  $(e_i, r)$  with the highest cardinality  $d_i^r = \sum_j y_{i,j}^r$ , then repeatedly select the associated relation with the lowest potential  $j^* = \arg \min_{j: y_{i,j}^r=1} \Psi^{RE}(y_{i,j}^r|x)$ . Each  $y_{i,j}^r$  will be added into the batch until its size reaches 50.

We define the gain for SplitE and PruneR as:

$$\begin{aligned} \Delta \ln Pr^*(SplitE(e_g, e_h \leftarrow e_i)|x) = & \\ & \sum_m (\ln \Psi_m^{EDL}(g) + \ln \Psi_m^{EDL}(h) - \ln \Psi_m^{EDL}(i)) \\ & + \sum_{r \in R} (\ln \Psi_g^{RE} + \ln \Psi_h^{RE} - \ln \Psi_i^{RE}) \\ & + \ln \Psi_r^{RC}(y^r) - \ln \Psi_r^{RC}(y^r) \\ & + \ln \Psi_g^{EP}(u') + \ln \Psi_h^{EP}(u') - \ln \Psi_i^{EP}(u) \end{aligned}$$

$$\begin{aligned} \Delta \ln Pr^*(PruneR(Y)|x) = & \\ & \sum_{r \in R} (\ln \Psi_r^{RC}(y^r) - \ln \Psi_r^{RC}(y^r)) \\ & + \sum_{y_{i,j}^r \in Y} (\ln \Psi_0^{RE} - \ln(\Psi_{i,j,r}^{RE}(y_{ij}^r = 1|x))) \end{aligned}$$

in which  $\Psi_m^{EDL}(i)$  is short for  $\Psi_m^{EDL}(u_m = i|x_m)$  with  $m$  ranges over IDs of mentions in  $e_i$ , and  $\Psi_i^{RE}$  is the sum of the RE factors which are related to entity  $e_i$ .  $y', u'$  are the assignment to  $y, u$  if a SplitE or a PruneR operation is executed. We also use the short form  $\Psi_r^{RC}(y^r)$  as the sum of the RC factors which have changed because of a SplitE or a PruneR operation.

Since the gain is only computed for the short-listed entities and relations, and we only calcu-

late the subset of factors (EDL, RE, RC, and EP) related to the operation,  $\Delta \ln Pr^*(SplitE|x)$  and  $\Delta \ln Pr^*(PruneR|x)$  can be calculated efficiently.

## 6 Experiments

We evaluate our system with resources provided to TAC 2015 participants, including 1) a source corpus of 50,000 documents from newswire and discussion forums, 2) a query set consisting of 317 hop-0 entities (expanded to 1,148 hop-0 entry-point mentions and 8,191 hop-1 queries), 3) LDC<sup>9</sup> assessment of participant responses from automatic submissions<sup>10</sup> and a manually created submission<sup>11</sup>, and 4) software that retrieves answers from a KB and measure performance with the assessment. Additionally, we use TAC 2013 and 2014 datasets for tuning parameters and training stacked classifiers.  $\alpha = 10, \beta = 5, \gamma = 0.1$  are set empirically following Section 4.3. We run each experiment 20 times and average the scores.

### 6.1 Queries, Assessment, and Scoring

We briefly describe the evaluation process and scoring metrics. More details appear in (Mayfield, 2014). The Cold Start evaluation measures KB-quality by probing the KB with two types of queries. The queries are either at **hop-0** (e.g., *which organization(s) is(are) founded by Bill Gates?*) or **hop-1** (e.g., *in which city(-ies) the organization(s) founded by Bill Gates is(are) headquartered?*). More formally, the evaluation software tries to find an entity  $e_0$  in the submitted KB that covers the entry-point mention of a hop-0 query  $q_0$ , then finds all relational triples matching  $(e_0, r_1, ?)$ .  $X$ , the set of entities matching the open variable, is reviewed by annotators for: (a) assessment of correctness and (b) the identification of non-redundant subset  $X'$ . The software generates an hop-1 query  $q_1 = x'$  for each  $x' \in X'$ , finds the entity  $e_1$  that aligns with  $q_1$ , and then finds triples matching  $(e_1, r_2, ?)$ . This results in response set  $Y$ , the set of entities matching the second open variable. Set  $Y$  is assessed by LDC in the same manner as Set  $X$ . The process is performed over all submitted KBs<sup>12</sup>. The answers in  $X$  (hop-0)

<sup>9</sup><https://www ldc.upenn.edu/>

<sup>10</sup>20 teams participants in the task with >50 KBs submitted.

<sup>11</sup>created by time-limited LDC annotators

<sup>12</sup>LDC generates the time-limited manual run directly from text queries, but treats the responses identically for assessment

Systems	CS-SF								CS-LDC-MAX							
	Hop-0				Hop-1				Hop-0				Hop-1			
	P	R	F1	Ign	P	R	F1	Ign	P	R	F1	Ign	P	R	F1	Ign
TAC rank1	48	30	37	0	31	17	22	0	50	35	40	0	28	20	23	0
offset-based	50	31	38	64	31	18	23	23	52	35	42	19	30	21	24	6
string-match	49	31	38	13	32	19	24	11	52	36	42	6	29	21	25	3
assess	<b>50</b>	<b>31</b>	<b>39</b>	0	<b>32</b>	<b>19</b>	23	0	<b>53</b>	<b>37</b>	<b>43</b>	0	<b>29</b>	<b>21</b>	<b>24</b>	0

Table 2: CS-SF and CS-LDC-Max micro-averaged precision, recall and F1 of hop-0 and hop-1 queries for the TAC 2015 top-ranked KB submission (Min et al., 2015) and our KBC+E+R system (3 bottom rows) using various post-hoc scoring techniques (offset-based, string-match and assess). *Ign* is the number of unassessed answers.

are correct when sufficiently justified in the source corpus. The answers in  $Y$  (hop-1) are correct only if both the element of  $X$  that generated the response is correct and the response in  $Y$  is justified in the text.

NIST reports two metrics, **CS-SF** and **CS-LDC-MAX**, which differ in the treatment of multiple entry-point mentions for a single real-world entity. CS-SF treats each distinct mention as an independent query. CS-LDC-MAX takes only the entry-point mention which maximizes system performance for a given query-entity (i.e. either the responses for *Bill Gates* or *William Gates*). For both metrics, NIST calculates micro-averaged precision, recall, and F1 over all queries. As mentioned above, the official evaluation is a human post-hoc assessment of KB output. A system developed outside of the evaluation window, e.g., our proposed algorithm, will likely include responses for which truth is not known, which are ignored by the scoring software. Table 2 compares the TAC top-ranked system to our full configuration using three post-hoc scoring strategies: strict **offset-based** match, **string-match** match, and **assess** in which we apply the offset-based metric using additional internally performed assessments. For the ablation study in Table 3, we use the official scorer’s **string-match** mode. A small number of responses are ignored (**Ign**) even in string-match mode. We further account for these responses by re-estimating precision for hop-0 and hop-1 assuming that the precision of the ignored responses at hop-1 is the same as the hop-0 precision<sup>13</sup>. When this optimistic estimate differs from reported precision, we report it in parentheses.

<sup>13</sup>This overestimates the hop-1 precision which is lower than hop-0 precision because of error compounding.

## 6.2 Results and Discussion

Table 2 compares our full system (KBC+E+R) to the top performing system in TAC Cold Start 2015 using three different approaches to post-hoc scoring. Without manual effort, our joint modeling approach exceeds the performance of the top-ranked system, which uses a cascade of manually-specified rules (Min et al., 2015). Our system obtains 5.4% and 4.8% relative improvement in hop-0 and hop-1 CS-SF F1 over the top-ranked system. Improvement is observed in both hop-0 and hop-1 and with both CS-SF and CS-LDC-MAX showing that the improvement is robust. A sign test shows that the improvements are significant with  $p < 0.01$ .

Systems	Hop-0			Hop-1		
	P	R	F1	P	R	F1
KBC	45	<b>33</b>	37.9	14(16)	<b>21</b>	17
KBC+E	45	32	37.9	18(21)	21	19
KBC+R	49	32	38.2	27	19	23
KBC+E+R	<b>49</b>	31	38.4	<b>32</b>	19	<b>24</b>

Table 3: CS-SF scores (string-match) for different priors: KBC (baseline: no world knowledge), KBC+E (only entity-based factors), KBC+R (only relation-based factors), KBC+E+R (both sets of factors). Numbers in parentheses indicate the optimistic estimate when it differs from the number reported by the scoring software.

Table 3 ablates each type of world knowledge to show the impact of entity and relation-based factors independently when compared to a version of our system without world knowledge. As expected, the impact of world knowledge is seen in improvements in precision at minor costs to recall. Both types of world knowledge have higher impact on hop-1 than hop-0 as hop-1 measures the formation of the KB with multiple hops in relations. Adding the relation factors has a larger

impact than adding the entity factors because our splitting of entities is conservative (only affects  $< 0.1\%$  entities) while relations' factors removes 7.3% relations. The two classes of factors appear to have largely independent impacts—combining them yields a large improvement. In total, adding prior world knowledge yields relative improvements of 9% in hop-0 precision, 131% on hop-1 precision, 42% on hop-1 F1, and 19.4% on all-hop F1 over the baseline. A sign test shows the improvements are significant with  $p < 0.01$ .

**Reduction of errors:** With relation factors added (KBC+R and KBC+E+R), 7.3% relations (out of 243K) are removed by **PruneR** with minimal recall loss. The median number of fillers for relations for the top 1% entities drops, e.g. *per:title* from 7 to 5, *per:employee\_or\_member\_of* from 5 to 2, and *per:city\_of\_birth* from 3 to 1. Inspection shows that our approach addresses many obvious mistakes: *U.K.* is removed as a response to (*Securities and Exchange Commission(SEC)*, *org:country\_of\_headquarters*, ?) while *U.S.* remains. The error, caused by *UK's SEC* which means *UK's* analog to the *SEC* of *US*, is very hard to resolve without world knowledge. With cardinality constraints that favor only one *country\_of\_headquarters* for an ORG and *U.K.* has a lower confidence than *U.S.* as a filler, the model identifies *U.K.* as an incorrect answer.

With entity factors added (KBC+E+R and KBC+E), the model favors a larger amount of smaller but more precise entities. It generates 4% new entities (out of 212K) by splitting the largest  $< 0.1\%$  entities with the **SplitE** heuristics described in section 5. For example, the entity *Australia* is splitted into 3 entities, *Australia* and two outliers *West Aussie* and *Australian Capital Territory*. It also singles out entities such as *South America*, *Idaho*, *Colorado* from the giant *U.S.* entity with  $> 20,000$  mentions. When querying the KB facts related to *U.S.*, erroneous answers that would otherwise be reported through relations associated with *South America* or the *U.S.* states will be removed.

## 7 Related Work

**Cold Start KBP** The TAC Cold Start KBP workshop has attracted many text-based KBP systems (McNamee et al., 2012; McNamee et al., 2013; Mayfield et al., 2014; Min et al., 2015; Roth et al., 2015; Angeli et al., 2014; Nguyen et al., 2014; Monahan and Carpenter, 2012).

KELVIN (Mayfield et al., 2014) and BBN system (Min et al., 2015) both use hand-crafted rules to limit the number of fillers, e.g., remove less precise relations if a *person* has more than 8 (current and ex-) spouses. (Wolfe et al., 2015) and (He and Grishman, 2015) proposed interactive tools for KB construction with human guidance.

**Knowledge Base Completion** With the recent popularity of structured KBs such as Freebase (Bollacker et al., 2008), YAGO (Suchanek et al., 2007) and above-mentioned KBP techniques, there is a growing interest in completing a partially-complete KB with tensor decomposition (Chang et al., 2014), matrix factorization (Riedel et al., 2013), graph random walk (Lao et al., 2011; Lao et al., 2012; Gardner et al., 2014), neural networks (Socher et al., 2013; Neelakantan et al., 2015; Dong et al., 2014) and others (Guu et al., 2015; Gardner et al., 2013; Das et al., 2016). Knowledge Vault (Dong et al., 2014) pushes it further by combining many extraction components while estimating the confidence of their extractions and scales it to the Web. Model combination (Viswanathan et al., 2015) and confidence estimation (Wick et al., 2013; Li and Grishman, 2013) is related to our model for combining extraction components. The work described here differs from KB completion tasks in its requirement that the initial KB is empty and that all information in the KB be grounded in a text corpus.

**Joint Modeling and Inference for IE** To address the problem of compounding errors with multiple NLP components for IE, several papers (Finkel and Manning, 2009; Mccallum and Jensen, 2003; Finkel et al., 2006; Yao et al., 2010; Singh et al., 2009; Poon and Domingos, 2007; Wellner et al., 2004; Poon and Vanderwende, 2010; Riedel and McCallum, 2011; Chen et al., 2014; Kate and Mooney, 2010; Miwa and Sasaki, 2014) propose joint modeling and inference for IE. (Roth and Yih, 2007) use the ILP framework to enforce manually-specified constraints between entity and relation identification, while (Yu and Lam, 2010) models these two tasks in encyclopedia articles using a discriminative probabilistic model. (Li and Ji, 2014) jointly extracts entity mentions and relations with a structured perception with beam search. (Singh et al., 2013a) performs joint inference for entity, relation and coreference with an extension of the belief propagation algorithm. The work described here differs in its use of world knowledge. The joint modeling and

inference for IE is not comparable but complementary to our method, therefore can be incorporated into our system for further gain.

## 8 Conclusion and Future Work

We present a joint probabilistic framework for end-to-end Cold Start KBP with prior world knowledge. Experiments show it surpassing the best-performing system at the NIST TAC 2015 Cold Start evaluation. We plan to investigate additional world knowledge in the near future.

# Generalizing to Unseen Entities and Entity Pairs with Row-less Universal Schema

Patrick Verga, Arvind Neelakantan and Andrew McCallum

College of Information and Computer Sciences

University of Massachusetts Amherst

{pat, arvind, mccallum}@cs.umass.edu

## Abstract

Universal schema predicts the types of entities and relations in a knowledge base (KB) by jointly embedding the union of all available schema types—not only types from multiple structured databases (such as Freebase or Wikipedia infoboxes), but also types expressed as textual patterns from raw text. This prediction is typically modeled as a matrix completion problem, with one type per column, and either one or two entities per row (in the case of entity types or binary relation types, respectively). Factorizing this sparsely observed matrix yields a learned vector embedding for each row and each column. In this paper we explore the problem of making predictions for entities or entity-pairs unseen at training time (and hence without a pre-learned row embedding). We propose an approach having no per-row parameters at all; rather we produce a row vector on the fly using a learned aggregation function of the vectors of the observed columns for that row. We experiment with various aggregation functions, including neural network attention models. Our approach can be understood as a natural language database, in that questions about KB entities are answered by attending to textual or database evidence. In experiments predicting both relations and entity types, we demonstrate that despite having an order of magnitude fewer parameters than traditional universal schema, we can match the accuracy of the traditional model, and more importantly, we can now make predictions about unseen rows with nearly the same accuracy as rows available at training time.

## 1 Introduction

Automatic knowledge base construction (AKBC) is the task of building a structured knowledge base (KB) of facts using raw text evidence, and often an initial seed KB to be augmented (Carlson et al., 2010; Suchanek et al., 2007; Bollacker et al., 2008). KBs generally contain entity type facts such as *Sundar Pichai IsA Person* and relation facts such as *CEO.Of(Sundar Pichai,*

*Google)*. Extracted facts about entities, and their types and relations are useful for many downstream tasks such as question answering (Bordes et al., 2014) and semantic parsing (Berant et al., 2013; Kwiatkowski et al., 2013).

An effective approach to AKBC is universal schema, which predicts the types of entities and relations in a knowledge base (KB) by jointly embedding the union of all available schema types—not only types from multiple structured databases (such as Freebase or Wikipedia infoboxes), but also types expressed as textual patterns from raw text. This prediction is typically modeled as a matrix completion problem. In the standard formulation for relation extraction (Riedel et al., 2013), entity pairs and relations occupy the rows and columns of the matrix respectively (Figure 1a). Analogously in entity type prediction (Yao et al., 2013), entities and types occupy the rows and columns of the matrix respectively (Figure 1b). The row and column entries are represented as learned vectors with compatibility determined by a scoring function.

In its original form, universal schema can reason only about row entries and column entries explicitly seen during training. Unseen rows and columns observed at test time do not have a learned embedding. This problem is referred to as the *cold-start* problem in recommendation systems (Schein et al., 2002).

Recently Toutanova et al. (2015) and Verga et al. (2016) proposed ‘column-less’ versions of universal schema models that generalize to unseen column entries. They learn compositional pattern encoders to parameterize the column matrix in place of individual column embeddings. However, these models still do not generalize to unseen row entries.

In this work, we present a ‘row-less’ extension of universal schema that generalizes to unseen entities and entity pairs. Rather than representing each row entry with an explicit dense vector, we encode each entity or entity pair as aggregate functions over their observed column entries. This is beneficial because when new entities are mentioned in text documents and subsequently added to the KB, we can directly reason on the observed text evidence to infer new binary relations and entity types for the new entities. This avoids the cumbersome effort of re-training the whole model from scratch to learn embeddings for the new entities.

To construct the row representation, we compare various aggregation functions in our experiments. We consider query independent and dependent aggregation functions. We find that query dependent attentional models that selectively focus on relevant evidence outperform the query independent alternatives. The query dependent attention mechanism also helps in providing a direct connection between the prediction and its provenance. Additionally, our models have a much smaller memory footprint since they do not store explicit row representations.

It is important to note that our approach is different from sentence level classifiers that predict KB relations and entity types using a single sentence as evidence. First, we pool information from multiple pieces of evidence coming from both text and annotated KB facts, rather than considering a single sentence at test time. Second, our methods are not limited to a fixed schema but instead predict a richer set of labels (KB types and textual), enabling easier downstream processing closer to natural language interaction with the KB. Finally, our model gains additional training signal from multi-task learning of textual and KB types. Since universal schema leverages large amounts of unlabeled text we desire the benefits of entity pair modeling, and row-less universal schema facilitates learning entity pair representations without the drawbacks of the traditional one-embedding-per-pair approach.

The majority of current embedding methods for KB entity type prediction operate with explicit entity representations (Yao et al., 2013; Neelakantan and Chang, 2015) and hence, cannot generalize to unseen entities. In relation extraction, entity-level models (Nickel et al., 2011; García-Durán et al., 2016; Yang et al., 2015; Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015; Socher et al., 2013) can handle unseen entity pairs at test time. These models learn representations for the entities instead of entity pairs. Hence, these methods still cannot generalize to predict relations between an entity pair if even one of the entities is unseen. Moreover, Toutanova et al. (2015) and Riedel et al. (2013) observe that the entity pair model outperforms entity models in cases where the entity pair was seen at training time.

Most similar to this work, Neelakantan et al. (2015) classify KB relations by finding the maximum scoring path between two entities. This model is also ‘row-less’ and does not directly model entities or entity pairs. There are several important differences in this work. Neelakantan et al. (2015) learn per-relation classifiers to predict only a small set of KB relations, while we instead predict all relations, including textual relations. We also explore aggregation functions that pool evidence from multiple paths while Neelakantan et al. (2015) only chose the maximum scoring path. Additionally, we demonstrate that our models can perform on par with those with explicit row representations while Neelakantan et al. (2015) did not perform

this comparison.

In this paper we investigate universal schema models without explicit row representations on two tasks: entity type prediction and relation extraction. We use entity type and relation facts from Freebase (Bollacker et al., 2008) augmented with textual relations and types from Clueweb text (Orr et al., 2013; Gabrilovich et al., 2013). We explore multiple aggregation functions and find that an attention-based aggregation function outperforms several simpler functions and matches a model using explicit row representations with an order of magnitude fewer parameters. More importantly, we then demonstrate that our ‘row-less’ models accurately predict relations on unseen entity pairs and types on unseen entities.

## 2 Background: Universal Schema

Universal schema (Riedel et al., 2013; Yao et al., 2013) relation extraction and entity type prediction is typically modeled as a matrix completion task. In relation extraction, entity pairs and relations occupy the rows and columns of the matrix (Figure 1-a), while in entity type prediction, entities and types occupy the rows and columns of the matrix (Figure 1-b). During training, we observe some positive entries in the matrix and at test time, we predict the missing cells in the matrix. This is achieved by decomposing the observed matrix into two low-rank matrices resulting in embeddings for each column entry and each row entry. Test time prediction is performed using the learned low-rank column and row representations.

Let  $T$  be the training set consisting of examples of the form  $(r, c)$ , where row  $r \in U$  and column  $c \in V$ , denote an entity pair and relation type in the relation extraction task, or entity and entity type in the entity type prediction task. Let  $v(r) \in \mathbb{R}^d$  and  $v(c) \in \mathbb{R}^d$  be the vector representations or embeddings of row  $r \in U$  and column  $c \in V$  that are learned during training. Given a positive example,  $(r, c) \in T$  in training, the probability of observing the fact is given by,

$$P(y_{r,c} = 1) = \sigma(v(r) \cdot v(c)) \quad (1)$$

where  $y_{r,c}$  is a binary random variable that is equal to 1 when  $(r, c)$  is a fact and 0 otherwise, and  $\sigma$  is the sigmoid function. The embeddings are learned using Bayesian Personalized Ranking (BPR) (Rendle et al., 2009) in which the probability of the observed triples are ranked above unobserved triples.

## 3 Model

In this section, we describe the model, discuss the different aggregation functions and give details on the training objective.

### 3.1 ‘Row-less’ Universal Schema

While column-less universal schema addresses reasoning over arbitrary textual patterns, it is still limited to

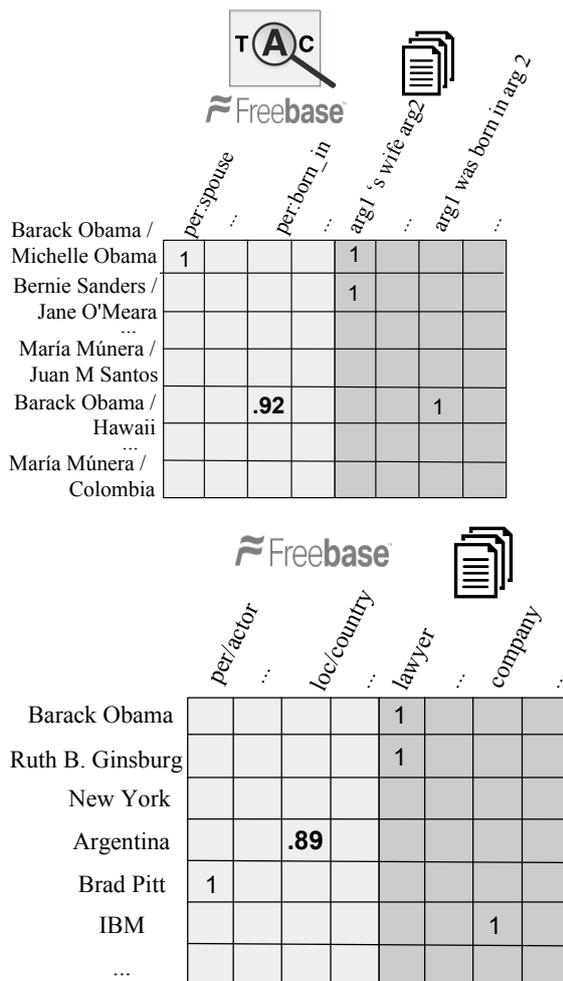

Figure 1: Universal schema matrix. a: Relation extraction. Relation types are represented as columns and entity pairs as rows of a matrix. Both KB relation types and textual patterns from raw text are jointly embedded in the same space. b: Entity type prediction. Entity types are represented as columns and entities as rows of a matrix.

reasoning over row entries seen at training time. Verga et al. (2016) use column-less universal schema for relation extraction. They address the problem of unseen row entries by using universal schema as a sentence classifier – directly comparing a textual relation to a KB relation to perform relation extraction. However, this approach is unsatisfactory for two reasons. The first is that this creates an inconsistency between training and testing. The model is trained to predict compatibility between rows and columns, but at test time it predicts compatibility between relations directly. Second, it considers only a single piece of evidence in making its prediction.

We address both of these concerns in our ‘row-less’ universal schema. Rather than explicitly encoding each row, we encode the row as a learned aggregation over their observed columns (Figure 2). A row contains an

entity for type prediction and an entity pair for relation extraction while a column contains a relation type for relation extraction and an entity type for type prediction. A learned row embedding can be seen as a summarization of all columns observed with that particular row. Instead of modeling this summarization as a single embedding, we reconstruct a row representation from an aggregate of its column embeddings, essentially learning a mixture model rather than a single centroid.

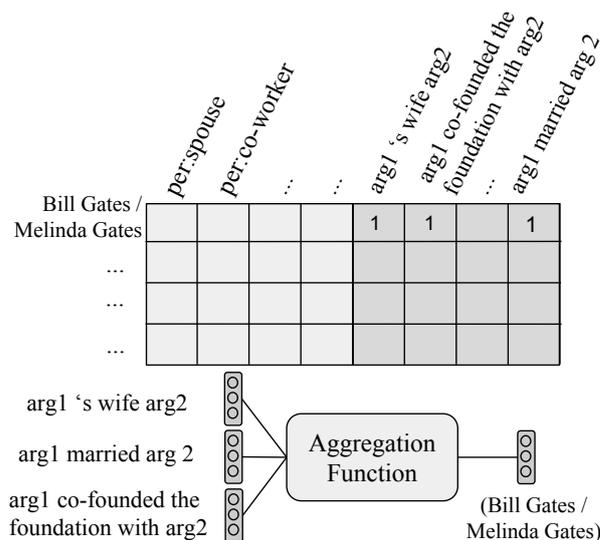

Figure 2: Row-less universal schema for relation extraction encodes an entity pair as an aggregation of its observed relation types.

### 3.2 Aggregation Functions

In this work we examine four aggregation functions to construct the representations for the row. Let  $v(\cdot)$  denote a function that returns the vector representation for rows and columns. To model the probability between row  $r$  and column  $c$ , we consider the set  $V(\bar{r})$  which contains the set of column entries that are observed with row  $r$  at training time, i.e.,

$$\forall \bar{c} \in V(\bar{r}), (r, \bar{c}) \in T$$

The first two aggregation functions create a single representation for each row independent of the query. **Mean Pool** creates a single centroid for the row by averaging all of its column vectors,

$$v(r) = \sum_{\bar{c} \in V(\bar{r})} v(\bar{c})$$

While this formulation intuitively makes sense as an approximation for the explicit row representation, averaging large numbers of embeddings can lead to a noisy representation.

**Max Pool** also creates a single representation for the row by taking a dimension-wise max over the observed column vectors:

$$v(r)_i = \max_{\bar{c} \in V(\bar{r})} v(\bar{c})_i, \forall i \in 1, 2, \dots, d$$

where  $a_i$  denotes the  $i^{th}$  dimension of vector  $a$ . Both mean pool and max pool are query-independent and form the same representation for the row regardless of the query relation.

We also examine two query-specific aggregation functions. These models are more expressive than a single vector forced to act as a centroid to all possible columns observed with that particular row. For example, the entity pair Bill and Melinda Gates could hold the relation ‘per:spouse’ or ‘per:co-worker’. A query-specific aggregation mechanism can produce separate representations for this entity pair dependent on the query.

The **Max Relation** aggregation function represents the row as its most similar column to the query vector of interest. Given a query relation  $c$ ,

$$c_{max} = \operatorname{argmax}_{\bar{c} \in V(\bar{r})} v(\bar{c}) \cdot v(c) \\ v(r) = v(c_{max})$$

A similar strategy has been successfully applied in previous work (Weston et al., 2013; Neelakantan et al., 2014; Neelakantan et al., 2015) for different tasks. This model has the advantage of creating a query-specific entity pair representation, but is more susceptible to noisy training data as a single incorrect piece of evidence could be used to form a prediction.

Finally, we look at an **Attention** aggregation function over columns (Figure 3) which is similar to a single-layer memory network (Sukhbaatar et al., 2015). The *soft attention* mechanism has been used to selectively focus on relevant parts in many different models (Bahdanau et al., 2015; Graves et al., 2014; Neelakantan et al., 2016).

In this model the query is scored with an input representation of each column embedding followed by a softmax, giving a weighting over each relation type. This output is then used to get a weighted sum over a set of output representations for each column resulting in a query-specific vector representation of the row. Given a query relation  $c$ ,

$$\operatorname{score}_{\bar{c}} = v(c) \cdot v(\bar{c}), \forall \bar{c} \in V(\bar{r}) \\ p_{\bar{c}} = \frac{\exp(\operatorname{score}_{\bar{c}})}{\sum_{\bar{c} \in V(\bar{r})} \exp(\operatorname{score}_{\bar{c}})}, \forall \bar{c} \in V(\bar{r}) \\ v(r) = \sum_{\bar{c} \in V(\bar{r})} p_{\bar{c}} \times v(\bar{c})$$

The model pools relevant information over the entire set of observed columns and selects the most salient aspects to the query.

Model	Parameters
Entity Embeddings	3.7 e6
Attention	3.1 e5
Mean Pool/Max Pool/Max Relation	1.5 e5

Table 1: Number of parameters for the different models on the entity type dataset.

### 3.3 Training

The vector representation of the rows and the columns are the parameters of the model. Riedel et al. (2013)

use Bayesian Personalized Ranking (BPR) (Rendle et al., 2009) to train their universal schema models. BPR ranks the probability of observed triples above unobserved triples rather than explicitly modeling unobserved edges as negative. Each training example is an (entity pair, relation type) or (entity, entity type) pair observed in the training text corpora or KB.

Rather than BPR, Toutanova et al. (2015) use 200 negative samples to approximate the negative log likelihood<sup>1</sup>. In our experiments, we use the sampled approximate negative log likelihood which outperformed BPR in early experiments.

Each example in the training procedure consists of a row-column pair observed in the training set. For a positive example  $(r, c) \in T$ , we construct the set  $V(\bar{r})$  containing all the other column entries apart from  $c$  that are observed with row  $r$ .

To make training faster and more robust, we add ‘pattern dropout’ for entity pairs with many mentions. We set  $V(\bar{r})$  to be  $m$  randomly sampled mentions for entity pairs with greater than  $m$  total mentions. In our experiments we set  $m = 10$  and at test time we use all mentions. We then use  $V(\bar{r})$  to obtain the aggregated row representation as discussed above.

We randomly sample 200 columns unobserved with row  $r$  to act as the negative samples. All models are implemented in Torch<sup>2</sup> and are trained using Adam (Kingma and Ba, 2015) with default momentum related hyperparameters.

## 4 Related Work

Relation extraction for KB completion has a long history. Mintz et al. (2009) train per relation linear classifiers using features derived from the sentences in which the entity pair is mentioned. Most of the embedding-based methods learn representations for entities (Nickel et al., 2011; Socher et al., 2013; Bordes et al., 2013) whereas Riedel et al. (2013) use entity pair representations.

‘Column-less’ versions of Universal Schema have been proposed (Toutanova et al., 2015; Verga et al., 2016). These models can generalize to column entries unseen at training by learning compositional pattern encoders to parameterize the column matrix in place of embeddings. Most of these models do not generalize to unseen entity pairs and none of them generalize to unseen entities. Recently, Neelakantan et al. (2015) introduced a multi-hop relation extraction model that is ‘row-less’ having no explicit parameters for entity pairs and entities.

Entity type prediction at the individual sentence level has been studied extensively (Pantel et al., 2012; Ling

<sup>1</sup>Many past papers restrict negative samples to be of the same type as the positive example. We simply sample uniformly from the entire set of row entries

<sup>2</sup>data and code available at <https://github.com/patverga/torch-relation-extraction/tree/rowless-updates>

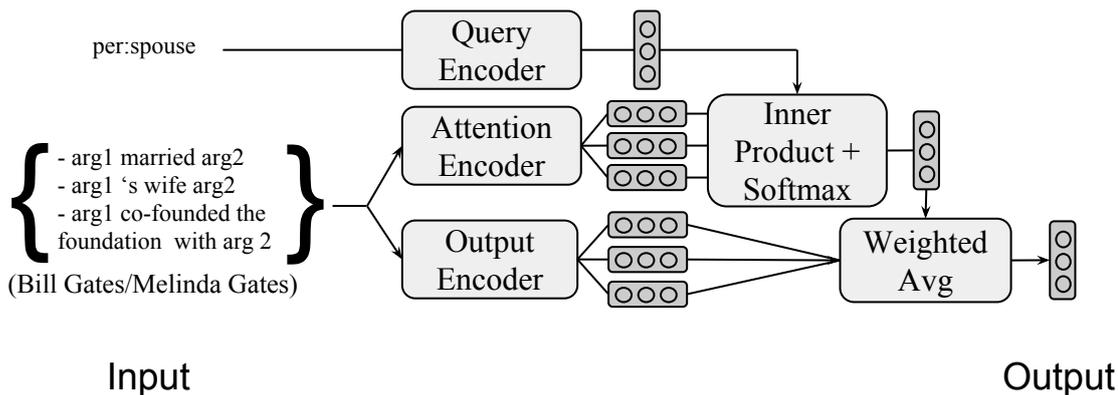

Figure 3: Example attention model in a row-less universal schema relation extractor. In the attention model, we compute the dot product between the representation of the query relation and the representation of an entity pair’s observed relation type followed by a softmax, giving a weighting over the observed relation types. This output is then used to get a weighted sum over the set of representations of the observed relation types. The result is a query-specific vector representation of the entity pair. The Max Relation model takes the most similar observed relation’s representation.

and Weld, 2012; Shimaoka et al., 2016). More recently, embedding-based methods for knowledge base entity type prediction have been proposed (Yao et al., 2013; Neelakantan and Chang, 2015). These methods have explicit entity representations, hence cannot generalize to unseen entities.

The task of generalizing to unseen row and column entries is referred to as the *cold-start* problem in recommendation systems. Methods proposed to tackle this problem commonly use user and item content and attributes (Schein et al., 2002; Park and Chu, 2009).

Multi-instance learning can be viewed as the relation classifier analogy of rowless universal schema. Riedel et al. (2010) used a relaxation of distant supervision training where all sentences for an entity pair (bag) are considered jointly and only the most relevant sentence is treated as the single training example for the bag’s label. Surdeanu et al. (2012) extended this idea with multi-instance multi-label learning (MIML) where each entity pair / bag can hold multiple relations / labels. Recently Lin et al. (2016) used a selective attention over sentences in MIML.

Concurrent to our work, Weissenborn (2016) proposes a row-less method for relation extraction considering both a uniform and weighted average aggregation function over columns. However, Weissenborn (2016) did not experiment with max and max-pool aggregation functions or evaluate on entity-type prediction. They also did not combine the rowless model with an LSTM column-less parameterization and did not compare to a model with explicit entity-pair representations.

## 5 Experimental Results

In this section, we compare our models that have aggregate row representations with models that have explicit row representations on entity type prediction and relation extraction tasks. Finally, we perform experiments on a column-less universal schema model. Table 1 shows that the row-less models require far fewer parameters since they do not explicitly store the row representations.

### 5.1 Entity Type Prediction

We first evaluate our models on an entity type prediction task. We collect all entities along with their types from a dump of Freebase<sup>3</sup>. We then filter all entities with less than five Freebase types leaving a set of 844780 (entity, type) pairs. Additionally, we collect 712072 textual (entity, type) pairs from Clueweb. The textual types are the 5000 most common appositives extracted from sentences mentioning entities. This results in 140513 unique entities, 1120 Freebase types, and 5000 free text types.

All embeddings are 25 dimensions, randomly initialized. We tune learning rates from  $\{.01, .001\}$ ,  $\ell_2$  from  $\{1e-8, 0\}$ , batch size  $\{512, 1024, 2048\}$  and negative samples from  $\{2, 200\}$ .

For evaluation, we split the Freebase (entity, type) pairs into 60% train, 20% validation, and 20% test. We randomly generate 100 negative (entity, type) pairs for each positive pair in our test set by selecting random entity and type combinations. We filter out false negatives that were observed true (entity, type) pairs in our complete data set. Each model produces a score for each positive and negative (entity, type) pair where the

type is the query. We then rank these predictions, calculate average precision for each of the types in our test set, and then use those scores to calculate mean average precision (MAP).

Table 2a shows the results of this experiment. We can see that the query dependent aggregation functions (Attention and Max Relation) performs better than the query independent functions (Mean Pool and Max Pool). The performance of models with query dependent aggregation functions which have far fewer parameters match the performance of the model with explicit entity representations.

We additionally evaluate our model’s ability to predict types for entities unseen during training. For this experiment, we randomly select 14000 entities and take all (entity, type) pairs containing those entities. We remove these pairs from our training set and use them as positive samples in our test set. We then select 100 negatives (entity, type) pairs per positive as above.

Table 2b shows the results of the experiment with unseen entities. There is very little performance drop for models trained with query dependent aggregation functions. The performance of the model with explicit entity representations is close to random.

### 5.1.1 Qualitative Results

A query specific aggregation function is able to pick out relevant columns to form a prediction. This is particularly important for rows that are not described easily by a single centroid such as an entity with several very different careers or an entity pair with multiple

highly varied relations. For example, in the first row in Table 3, for the query */baseball/baseball\_player* the model needs to correctly focus on aspects like */sports/pro\_athlete* and ignore evidence information like */tv/tv\_actor*. A model that creates a single query-independent centroid will be forced to try and merge these disparate pieces of information together.

## 5.2 Relation Extraction

We evaluate our models on a relation extraction task using the FB15k-237 dataset from Toutanova et al. (2015). The data is composed of a small set of 237 Freebase relations and approximately 4 million textual patterns from Clueweb with entities linked to Freebase (Gabrilovich et al., 2013). In past studies, for each (subject, relation, object) test triple, negative examples are generated by replacing the object with all other entities, filtering out triples that are positive in the data set. The positive triple is then ranked among the negatives. In our experiments we limit the possible generated negatives to those entity pairs that have textual mentions in our training set. This way we can evaluate how well the model classifies textual mentions as Freebase relations. We also filter textual patterns with length greater than 35. Our filtered data set contains 2740237 relation types, 2014429 entity pairs, and 176476 tokens. We report the percentage of positive triples ranked in the top 10 amongst their negatives as well as the MRR scaled by 100.

Models are tuned to maximize mean reciprocal rank (MRR) on the validation set with early stopping. The entity pair model used a batch size 1024,  $\ell_2 = 1e-8$ ,  $\epsilon = 1e-4$ , and learning rate 0.01. The aggregation models all used batch size 4096,  $\ell_2 = 0$ ,  $\epsilon = 1e-8$ , and learning rate 0.01. Each use 200 negative samples except for max pool which performed better with two negative samples. The column vectors are initialized with the columns learned by the entity pair model. Randomly initializing the query encoders and tying the output and attention encoders performed better and all results use this method. All models are trained with embedding dimension 25.

Our results are shown in Table 4a. We can see that the models with query specific aggregation functions give the same results as models with explicit entity pair representations. The Max Relation model performs competitively with the Attention model which is not entirely surprising as it is a simplified version of the Attention model. Further, the Attention model reduces to the Max Relation model for entity pairs with only a single observed relation type. In our data, 64.8% of entity pairs have only a single observed relation type and 80.9% have 1 or 2 observed relation types.

We also explore the models’ abilities to predict on unseen entity pairs (Table 4b). We remove all training examples that contain a positive entity pair in either our validation or test set. We use the same validation and test set as in Table 4a. The entity pair model predicts

random relations as it is unable to make predictions on unseen entity pairs. The query-independent aggregation functions, mean pool and max pool, perform better than models with explicit entity pair representations. Again, query specific aggregation functions get the best results, with the Attention model performing slightly better than the Max Relation model.

The two experiments indicate that we can train relation extraction models without explicit entity pair representations that perform as well as models with explicit representations. We also find that models with query specific aggregation functions accurately predict relations for unseen entity pairs.

### 5.3 ‘Column-less’ universal schema

The original universal schema approach has two main drawbacks: similar textual patterns do not share statistics, and the model is unable to make predictions about

entities and textual patterns not explicitly seen at train time.

Recently, ‘column-less’ versions of universal schema to address some of these issues (Toutanova et al., 2015; Verga et al., 2016). These models learn compositional pattern encoders to parameterize the column matrix in place of direct embeddings. Compositional universal schema facilitates more compact sharing of statistics by composing similar patterns from the same sequence of word embeddings – the text patterns ‘lives in the city’ and ‘lives in the city of’ no longer exist as distinct atomic units. More importantly, compositional universal schema can thus generalize to all possible textual patterns, facilitating reasoning over arbitrary text at test time.

The column-less universal schema model generalizes to all possible input textual relations and the row-less model generalizes to all entities and entity pairs, whether seen at train time or not. We can combine these two approaches together to make an universal schema model that generalizes to unseen rows and columns.

The parse path between the two entities in the sentence is encoded with an LSTM model. We use a single layer model with 100 dimensional token embeddings initialized randomly. To prevent exploding gradients, we clip them to norm 10 while all the other hyperparameters are tuned the same way as before. We follow the same evaluation protocol from 5.2.

The results of this experiment with observed rows are shown in Table 5a. While both the MRR and Hits@10 metrics increase for models with explicit row representations, the row-less models show an improvement only on the Hits@10 metric. The MRR of the query dependent row-less models is still competitive with the model with explicit row representation even though they have far fewer parameters to fit the data.

## 6 Conclusion

In this paper we explore a row-less extension of universal schema that forgoes explicit row representations for an aggregation function over its observed columns. This extension allows prediction between all rows in new textual mentions – whether seen at train time or not – and also provides a natural connection to the provenance supporting the prediction. Our models also have

Table 5: The percentage of positive triples ranked in the top 10 amongst their negatives as well as the mean reciprocal rank (MRR) scaled by 100 on a subset of the FB15K-237 dataset. Negative examples are restricted to entity pairs that occurred in the KB or text portion of the training set. Models with the suffix “-LSTM” are column-less. Entity-pair embeddings refers to the model with explicit row representations. b: Predicting entity pairs that are not seen at train time.

a smaller memory footprint.

In this work we show that an aggregation function based on query-specific attention over relation types outperforms query independent aggregations. We show that aggregation models are able to predict on par with models with explicit row representations on seen row entries with far fewer parameters. More importantly, aggregation models predict on unseen row entries without much loss in accuracy. Finally, we show that in relation extraction, we can combine row-less and column-less models to train models that generalize to both unseen rows and columns.

## Abstract

Automatically generating product reviews is a meaningful, yet not well-studied task in sentiment analysis. Traditional natural language generation methods rely extensively on hand-crafted rules and predefined templates. This paper presents an attention-enhanced attribute-to-sequence model to generate product reviews for given attribute information, such as user, product, and rating. The attribute encoder learns to represent input attributes as vectors. Then, the sequence decoder generates reviews by conditioning its output on these vectors. We also introduce an attention mechanism to jointly generate reviews and align words with input attributes. The proposed model is trained end-to-end to maximize the likelihood of target product reviews given the attributes. We build a publicly available dataset for the review generation task by leveraging the Amazon book reviews and their metadata. Experiments on the dataset show that our approach outperforms baseline methods and the attention mechanism significantly improves the performance of our model.

## 1 Introduction

Nowadays, there are many popular online review sites (such as Amazon, and Yelp) that allow users to read and post reviews about books, electronics, restaurants, etc. The reviews are used to express opinions for different aspects of products, and have a wide variety of writing styles and different polarity strengths. As a result, much previous work has focused on how opinions are expressed in review data. For example, previous studies on

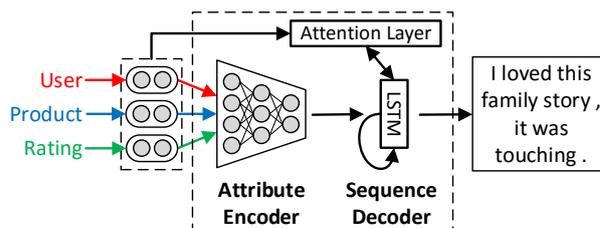

Figure 1: Our model learns to encode attributes into vectors, and then uses recurrent neural networks based on long short-term memory (LSTM) units to generate reviews by conditioning on the encoding vectors. An attention layer is used to learn soft alignments between attributes and generated words.

sentiment analysis identify and extract subjective content in review data (Liu, 2015). However, few studies have explored building data-driven models that can generate product reviews for the given products and ratings, which is helpful to understand how a specific user comments for products. As shown in Figure 1, the input to our model is a set of attributes (such as user, product, and rating information), and our goal is to generate user- and product-specific reviews that agree with the input rating. These automatically generated reviews are useful for companies. For example, we could promote a product to users who have not bought it, by generating novel and personalized recommendations. We could also build a review writing assistant for E-commerce websites. After the website generates some candidate reviews according to the user's rating score, users could select one and refine it, which makes the procedure more user-friendly. Moreover, we can generate novel and personalized recommendations for every user, which makes the recommendation system more interpretable.

This attribute-conditioned review generation

problem is very challenging due to the variety of candidate reviews that satisfy the input attributes. In other words, apart from the given attributes, there are other unknown or latent factors that influence the generated reviews, which renders the generation process non-deterministic. Moreover, although some attributes (such as rating) explicitly determine the usage of sentiment words, others (e.g., user information) implicitly influence word usage. So the model needs to handle both explicit and implicit clues. Additionally, the interactions between attributes are important to obtain the hidden factors used for generation. For example, different users tend to describe different aspects of a product and use different sentiment words to express a rating score.

In this paper, we propose a neural network based attribute-to-sequence model. As shown in Figure 1, our model contains three parts: attribute encoder, sequence decoder, and an attention mechanism. Specifically, we first use multilayer perceptrons to encode input attributes into vector representations that are used as latent factors for generating reviews. Next, the encoding vectors are fed into a coarse-to-fine sequence decoder. The decoder is built by stacking multiple layers of recurrent neural networks, which can generate words one by one conditioning on the encoding vectors. Besides, we introduce an attention layer into the proposed attribute-to-sequence model. The attention mechanism learns soft alignments between generated words and attributes, and adaptively computes encoder-side context vectors used to predict the next tokens. In order to evaluate our method, we build a dataset based on Amazon reviews and performed experiments on it. The experimental results show that the proposed model achieves superior performance against baseline methods. Moreover, we demonstrate that the attention mechanism significantly improves the performance of our model.

The contributions of this work are three-fold:

- We introduce the task of attribute-conditioned review generation, which is valuable for sentiment analysis, but not well studied previously.
- We propose an attention-enhanced attribute-to-sequence model in order to generate reviews conditioned on input attributes.
- We create a dataset based on Amazon book

reviews and present empirical studies to show the proposed model outperforms several baseline methods.

## 2 Related Work

Sentiment analysis and opinion mining aim to identify and extract subjective content in text (Liu, 2015). Most previous work focuses on using rule-based methods or machine learning techniques for sentiment classification, which classifies reviews into different sentiment categories. Recently, deep learning has achieved promising results on sentiment analysis (Socher et al., 2011; Dong et al., 2014; Kim, 2014). Lipton et al. (2015) use character-level concatenated input recurrent neural networks as a generative model to predict rating and category for reviews. In contrast, our model is mainly evaluated on the review generation task rather than classification. Moreover, we use an attention mechanism in our encoder-decoder model, which has been proved very helpful in various tasks (Bahdanau et al., 2015; Xu et al., 2015), to generate user- and product-specific reviews. Maqsd (2015) compare latent Dirichlet allocation, Markov chains, and hidden Markov models for text generation on review data. However, we focus on generating product reviews conditioned on input attributes. Park et al. (2015) propose to retrieve relevant opinion sentences using product specifications as queries, while we work on generation instead of retrieval.

Our task definition is also related to concept-to-text generation (Konstas and Lapata, 2012; Konstas and Lapata, 2013), such as generating weather forecast or sportscasting from database records. A typical system contains three main stages: content planning, sentence planning, and surface realization. Mei et al. (2016) treat database records and output texts as sequences, and use recurrent neural networks to encode and decode them. In contrast, our input is a set of discrete attributes instead of database records or sequences. In addition, the contents of database records are strong constraints on results in concept-to-text generation. However, in our setting, user and product information implicitly indicates the style of generated reviews, which makes the results extremely diverse.

Another line of related work is the encoder-decoder model with neural networks. Specifically, an encoder is employed to encode input information into vectors, and then a decoder learns to

predict results by conditioning outputs on the encoding vectors. This general framework is flexible because different neural networks can be used for encoders and decoders depending on the nature of inputs and outputs, which has been used to address various tasks. For example, recurrent neural networks are used to model sequences, such as machine translation (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014), syntactic parsing (Vinyals et al., 2015b), and semantic parsing (Dong and Lapata, 2016). Additionally, convolutional neural networks are employed for image data, such as image caption generation (Vinyals et al., 2015a), and video description generation (Donahue et al., 2015; Venugopalan et al., 2015). Our model employs multilayer perceptron to encode attribute information, and uses recurrent neural networks to decode product reviews. In order to better handle alignments between inputs and outputs, the attention mechanism is introduced for the encoder-decoder model. The attention model boosts performance for various tasks (Bahdanau et al., 2015; Luong et al., 2015; Xu et al., 2015). In our work, we use the attention mechanism to learn soft alignments between input attributes and output sequences, which has not, to our knowledge, been studied in previous work. Dosovitskiy et al. (2015) propose to use generative convolutional neural networks to generate images of chairs given chair type, viewpoint and color. Similarly, Yan et al. (2016) use variational auto-encoders to generate face images conditioned on visual attributes. However, our goal is to generate texts instead of images. Moreover, we learn a neural attention model to attend over input attributes during generation.

### 3 Modelling Approach

To begin with, we state the product review generation problem as follows. Given input attributes  $a = (a_1, \dots, a_{|a|})$ , our goal is to generate a product review  $r = (y_1, \dots, y_{|r|})$  maximizing the conditional probability  $p(r|a)$ . Notice that number of attributes  $|a|$  is fixed, while the review  $r$  is considered a word sequence of variable length. We use the user ID, product ID, and rating as attributes, so  $|a|$  is set to 3 in our task. The training data are attributes paired with corresponding reviews. The model learns to compute the likelihood of generated reviews given input attributes. This condi-

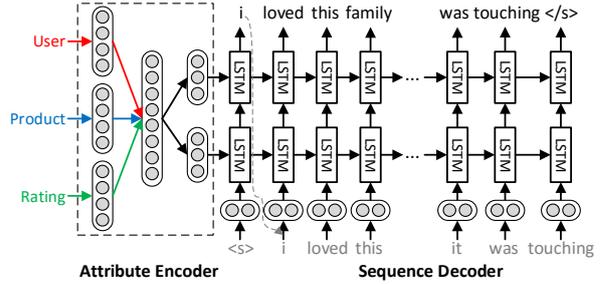

Figure 2: Attribute-to-sequence model without attention mechanism.

tional probability  $p(r|a)$  is decomposed to:

$$p(r|a) = \prod_{t=1}^{|r|} p(y_t|y_{<t}, a) \quad (1)$$

where  $y_{<t} = (y_1, \dots, y_{t-1})$ .

Our method consists of three parts, i.e., an attribute encoder, a sequence decoder, and an attention layer. The attribute encoder employs multilayer perceptrons to encode attributes  $a$  to vectors. To be specific, we represent the attributes as vectors. Next, the concatenation of these vectors is fed into a hidden layer to obtain the encoding vectors. After we obtain the encoding vectors, the sequence decoder stacks  $L$ -layer recurrent neural networks (RNNs) to generate reviews conditioning on these vectors. During decoding, RNNs recurrently compute  $n$ -dimensional hidden vectors which are used to predict output words for different time steps. In order to better utilize encoder-side information, an attention layer is introduced to learn soft alignments between attributes and output words. For every decoding time step, we use the current hidden vector to compute attention scores over attribute vectors. Then, a weighted sum of attribute vectors is used as the context vector to predict output words.

We first describe the attribute-to-sequence model without using neural attention in Section 3.1 and Section 3.2. Next, we introduce the attention mechanism in Section 3.3.

#### 3.1 Attribute Encoder

We use multilayer perceptrons with one hidden layer to encode attribute information into a vector as shown in Figure 2. At first, input attributes  $a = (a_1, \dots, a_{|a|})$  are represented by low-dimensional vectors. The attribute  $a_i$ 's vector  $\mathbf{g}(a_i)$  is computed via:

$$\mathbf{g}(a_i) = W_i^a \mathbf{e}(a_i) \quad (2)$$

where  $W_i^a \in \mathbb{R}^{m \times |a_i|}$  is a parameter matrix,  $m$  is the dimension of embedding, and  $\mathbf{e}(a_i) \in \{0, 1\}^{|a_i|}$  is a one-hot vector representing the presence or absence of  $a_i$ . Then, these attribute vectors are concatenated and fed into a hidden layer which outputs the encoding vector. The output of the hidden layer is computed as:

$$\mathbf{a} = \tanh(H[\mathbf{g}(a_1), \dots, \mathbf{g}(a_{|a|})] + \mathbf{b}_a) \quad (3)$$

where  $[\mathbf{g}(a_1), \dots, \mathbf{g}(a_{|a|})]$  are concatenated attribute vectors,  $\tanh$  is a nonlinearity function,  $H \in \mathbb{R}^{Ln \times |a|m}$  is a weight matrix, and  $\mathbf{b}_a \in \mathbb{R}^{Ln}$  is the bias. Next, the vector  $\mathbf{a}$  is used to initialize the  $n$ -dimensional hidden vectors of the  $L$ -layer recurrent neural networks in the decoder.

### 3.2 Sequence Decoder

As shown in Figure 2, the decoder is built upon multilayer recurrent neural networks (RNNs) with long short-term memory (LSTM) units. RNNs use vectors to represent information for the current time step and recurrently compute the next hidden states. In our work, we stack multiple layers of RNNs in our architecture. Additionally, a long short-term memory (Hochreiter and Schmidhuber, 1997) unit is employed to better handle long sequences. The LSTM introduces several gates and explicit memory cells to memorize or forget information, which enables networks learn more complicated patterns. Let  $\mathbf{h}_t^l \in \mathbb{R}^n$  denote an  $n$ -dimensional hidden vector in layer  $l$  and time step  $t$ .  $\mathbf{h}_t^l$  is computed via:

$$\mathbf{h}_t^l = f(\mathbf{h}_{t-1}^l, \mathbf{h}_t^{l-1}) \quad (4)$$

where  $\mathbf{h}_t^0 = W^r \mathbf{e}(y_{t-1})$  is the word embedding of the previous predicted word,  $W^r \in \mathbb{R}^{n \times |V_r|}$  is a parameter matrix,  $|V_r|$  is the vocabulary size, and  $\mathbf{e}(y_{t-1})$  is a one-hot vector used to extract word vector for  $y_{t-1}$ . We follow the architecture of LSTM unit described in Zaremba et al. (2015). To be specific, the unit is given by:

$$\begin{pmatrix} \mathbf{i} \\ \mathbf{f} \\ \mathbf{o} \\ \mathbf{g} \end{pmatrix} = \begin{pmatrix} \text{sigm} \\ \text{sigm} \\ \text{sigm} \\ \text{tanh} \end{pmatrix} W^l \begin{pmatrix} \mathbf{h}_t^{l-1} \\ \mathbf{h}_{t-1}^l \end{pmatrix} \quad (5)$$

$$\mathbf{p}_t^l = \mathbf{f} \odot \mathbf{p}_{t-1}^l + \mathbf{i} \odot \mathbf{g}$$

$$\mathbf{h}_t^l = \mathbf{o} \odot \tanh(\mathbf{p}_t^l)$$

where  $\tanh$ ,  $\text{sigm}$ , and  $\odot$  are element-wise operators, and  $W^l \in \mathbb{R}^{4n \times 2n}$  is a weight matrix for the  $l$ -th layer.

Once the input attributes are encoded to the vector  $\mathbf{a} \in \mathbb{R}^{Ln}$  by Equation (3), the encoding vector is split into  $L$  vectors to initialize the hidden vectors of the first time step in decoder. Then, RNNs compute hidden vectors recurrently and predict output words using the hidden vectors of the top-most layer  $\mathbf{h}_t^L$ . For the vanilla model without using an attention mechanism, the predicted distribution of the  $t$ -th output word is:

$$p(y_t | y_{<t}, a) = \text{softmax}_{y_t}(W^p \mathbf{h}_t^L) \quad (6)$$

where  $W^p \in \mathbb{R}^{|V_r| \times n}$  is a parameter matrix.

### 3.3 Attention Mechanism

The attention mechanism is introduced to better utilize encoder-side information. As indicated in Equation (6), the vanilla model does not directly use attribute vectors to generate sequences. Intuitively, the model can concentrate on different parts of encoding information to predict the next word. Previous work has proved this idea significantly improves performance especially for long sequences (Bahdanau et al., 2015; Vinyals et al., 2015b; Luong et al., 2015).

Figure 3 demonstrates how to compute the encoder-side context vector and use it to predict output words. For the  $t$ -th time step of the decoder, we compute the attention score of attribute  $a_i$  via:

$$s_i^t = \exp(\tanh(W^s[\mathbf{h}_t^L, \mathbf{g}(a_i)])) / Z \quad (7)$$

where the brackets  $[\cdot, \cdot]$  denote concatenation,  $Z$  is a normalization term that ensures  $\sum_{i=1}^{|a|} s_i^t = 1$ , and  $W^s \in \mathbb{R}^{1 \times (n+m)}$  is a parameter matrix. Next, the attention context vector  $\mathbf{c}^t$  is obtained by:

$$\mathbf{c}^t = \sum_{i=1}^{|a|} s_i^t \mathbf{g}(a_i) \quad (8)$$

which is a weighted sum of attribute vectors. We further employ the vector  $\mathbf{c}^t$  to predict the  $t$ -th output token as:

$$\mathbf{h}_t^{\text{att}} = \tanh(W_1 \mathbf{c}^t + W_2 \mathbf{h}_t^L) \quad (9)$$

$$p(y_t | y_{<t}, a) = \text{softmax}_{y_t}(W^p \mathbf{h}_t^{\text{att}}) \quad (10)$$

where  $W^p \in \mathbb{R}^{|V_r| \times n}$ ,  $W_1 \in \mathbb{R}^{n \times m}$  and  $W_2 \in \mathbb{R}^{n \times n}$  are three parameter matrices.

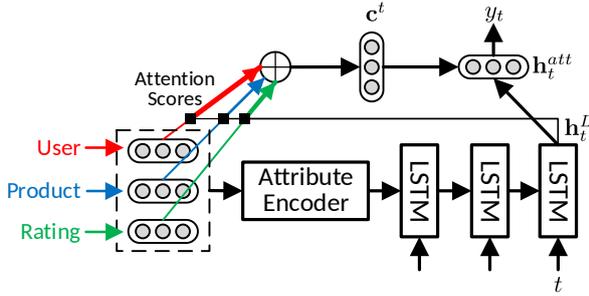

Figure 3: Attention scores are computed by attribute vectors and the current hidden vector of the decoder. Then, the encoder-side context vector is obtained in the form of a weighted sum, which is further used to predict the word distribution.

### 3.4 Model Training

We aim at maximizing the likelihood of generated reviews given input attributes for the training data. So we define the optimization problem as:

$$\text{maximize } \sum_{(a,r) \in \mathcal{D}} \log p(r|a) \quad (11)$$

where  $\mathcal{D}$  is the dataset of all attribute-review training pairs, and  $p(r|a)$  is defined as shown in Equation (1). In order to avoid overfitting, we insert dropout layers between different LSTM layers as suggested in Zaremba et al. (2015). The mini-batched RMSProp (Tieleman and Hinton, 2012) algorithm is used to optimize the objective function.

### 3.5 Inference

At test time, we first use the encoder to encode input attributes into vectors, and use them to initialize the LSTM units of the decoder. Then, the decoder predicts a review  $\hat{r}$  that maximizes the conditional probability defined in Equation (1):

$$\hat{r} = \arg \max_{r'} p(r'|a) \quad (12)$$

where  $r'$  is a candidate review. Because we decompose this probability as shown in Equation (1), we can use beam search or greedy search to generate words, which avoids iterating over all candidate reviews. In order to determine the termination of the generation process, we add a special token  $\langle /s \rangle$  to the end of every output review. The generation terminates once this token is emitted.

## 4 Experiments

We first introduce a new dataset for this task and compare our method with several baseline ap-

proaches. Then we conduct some ablation experiments and present model analysis to help us understand what the model learns.

### 4.1 Dataset Description

Our dataset is built upon Amazon product data (McAuley et al., 2015) that includes reviews and metadata spanning from May 1996 to July 2014 with duplicates removed. The products of the book domain are used in our experiments. Every review is paired with three attributes, i.e., user ID, product ID and rating. We filter books and users which do not occur at least 6 and 15 times, respectively. The reviews whose lengths are greater than 60 words are filtered. Because we observe that long reviews mainly describe the plots of books, while our goal is to generate reviews expressing opinions. The average review length is about 35 words, and the average number of sentences is 3. The dataset contains 937,033 reviews paired with attributes. Specifically, we have 80,256 books, 19,675 users, and 5 rating levels. The word vocabulary size is 161K. Then, the whole dataset is randomly split into TRAIN, DEV, and TEST (70%/10%/20%). The dataset is available at <https://goo.gl/TFjEH4>.

### 4.2 Settings

We used NLTK (Bird et al., 2009) to tokenize the reviews, and employed the Wikipedia list of common misspellings to correct misspelled words. We kept words that appeared more than 10 times in our vocabulary. The training hyperparameters are selected based on the results of the DEV set. The dimension of attribute vectors is set to 64. The dimensions of word embeddings and hidden vectors are set to 512 in the sequence decoder. Moreover, we stack two layers of recurrent neural networks with LSTM units to generate reviews. All the parameters are randomly initialized by sampling from a uniform distribution  $[-0.08, 0.08]$ . The batch size, smoothing constant and base learning rate of RMSProp are set to 50, 0.95 and 0.002, respectively. After 10 epochs, the learning rate is decreased by a factor of 0.97 at the end of every epoch as suggested in Karpathy et al. (2016). The dropout rate is set to 0.2 for regularization. We also clamp gradient values into the range  $[-5, 5]$  to avoid the exploding gradient problem (Pascanu et al., 2013). The number of epochs is determined by early stopping on the DEV set. At test time,

Method	BLEU-4 (%)	BLEU-1 (%)
Rand	0.86	20.36
MELM	1.28	21.59
NN-pr	1.53	22.44
NN-ur	3.61	26.37
Att2Seq	4.51	30.24
Att2Seq+A	<b>5.03*</b>	<b>30.48*</b>

Table 1: Evaluation results on the TEST set of Amazon data. \*: significantly better than the second best score ( $p < 0.05$ ).

we use the greedy search algorithm to generate reviews.

### 4.3 Evaluation Results

The BLEU (Papineni et al., 2002) score is used for automatic evaluation, which has been shown to correlate well with human judgment on many generation tasks. The BLEU score measures the precision of n-gram matching by comparing the generated results with references, and penalizes length using a brevity penalty term. We compute BLEU-1 (unigram) and BLEU-4 (up to 4 grams) in experiments.

#### 4.3.1 Comparison with Baseline Methods

We describe the comparison methods as follows:

**Rand.** The predicted results are randomly sampled from all the reviews in the TRAIN set. This baseline method suggests the expected lower bound for this task.

**MELM.** Maximum Entropy Language Model uses n-gram (up to trigram) features, and the feature template attribute&n-gram (up to bigram). The feature hashing technique is employed to reduce memory usage in each feature group. Noise contrastive estimation (Gutmann and Hyvrinen, 2010) is used to accelerate the training by dropping the normalization term, with 20 contrastive samples in training.

**NN-pr.** This Nearest Neighbor based method retrieves the reviews that have the same product ID and rating as the input attributes in the TRAIN set. Then we randomly choose a review from them, and use it as the prediction.

**NN-ur.** The same method as NN-pr but uses both user ID and rating to retrieve candidate reviews.

**Att2Seq.** Our attribute-to-sequence method described in Section 3. Notice that the attention model is not used.

Method	MELM	Att2Seq	Att2Seq+A
<b>Accuracy (%)</b>	59.00	88.67	<b>93.33*</b>

Table 2: We manually annotate some polarity labels (positive or negative) for generated reviews and compute accuracy by comparing them with the input ratings. \*: significantly better than the second best accuracy ( $p < 0.05$ ).

**Att2Seq+A.** Our method with an attention mechanism.

As shown in Table 1, we compute BLEU scores for these methods. The results of random guess indicate that this task is non-trivial to obtain reasonable performance. MELM performs worse than nearest neighbor search due to the sparsity of lexicalized features, while our model employs distributed representations to avoid using sparse indicator features. Then, we evaluate the NN methods that use different attributes to retrieve reviews, which is a strong baseline for the generation task. The results show that our method outperforms the baseline methods. Moreover, the improvements of the attention mechanism are significant with  $p < 0.05$  according to the bootstrap resampling test (KoeHN, 2004). We further show some examples to analyze the attention model in Section 4.4.

#### 4.3.2 Polarity of Generated Reviews

In order to evaluate whether the polarities of generated reviews correspond to their input ratings, we randomly sample some generated reviews and manually annotate their polarity labels. Specifically, we regard the rating 1-2 as negative and 4-5 as positive, and then evaluate performance by computing their classification accuracy. We randomly sample 150 negative examples and 150 positive examples for each method. Next, we ask two graduate students to classify the generated reviews to positive, negative, and indeterminable/neutral. About 93% of examples are annotated with the same labels by two annotators. Table 2 shows our method significantly outperforms others ( $p < 0.05$ ). For Att2Seq+A, some generated reviews are classified to indeterminable/neutral because they contain mixed opinions towards different aspects of books.

#### 4.3.3 Ablation Experiments

In order to evaluate the contributions of model components in our method, we compare to the variants of our model. These models are described

Method	BLEU-4 (%)	BLEU-1 (%)
Att2Seq+A	5.01	30.23
AvgEnc	4.07	28.13
NoStack	4.73	29.58
w/o user	4.10	26.87
w/o product	4.13	27.15
w/o rating	4.12	27.98

Table 3: Model ablation results on the DEV set.

as follows:

**AvgEnc.** This model uses the average of attribute vectors as the encoding vector, rather than multilayer perceptrons.

**NoStack.** The method only uses one-layer recurrent neural networks for the sequence decoder.

**w/o user/product/rating.** This variant does not use the corresponding attribute as input. These results indicate the importance of different information for our model.

As shown in Table 3, we compute BLEU-4 and BLEU-1 scores for our full model and the different variants on the DEV set. The ablation model AvgEnc performs worse than Att2Seq+A. This indicates that multilayer perceptrons can better handle interactions between attributes, outperforming simple averaging of input vectors. Next, we compare to the model without stacking multiple layers of recurrent neural networks as described in Section 3.2. The results demonstrate that deep architectures can improve generation performance. For the next group of variants, we find that removing user, product and rating information harms performance, which indicates that all three attributes contribute to generating relevant reviews.

#### 4.4 The Attention Mechanism

As described in Section 3.3, the attention mechanism learns soft alignment scores between generated words and input attributes. These scores are used to obtain encoder-side context vectors that can better utilize attribute information to predict the next word.

Figure 4 shows three generated examples with different input ratings. The attention scores are represented by gray scales and are column-wisely normalized as described in Equation (7). Firstly, we explain the attention scores over rating information. The input rating of the first example is 1. We find that the phrases “*n’t expecting much*”, “*n’t like*” and “*a little too much*” have larger attention scores on the rating attribute. This demon-

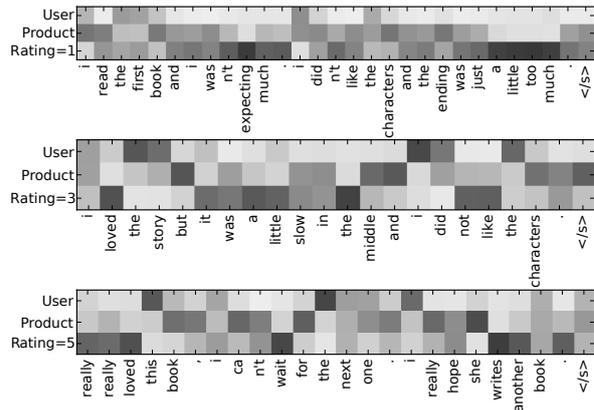

Figure 4: Examples of attention scores (Equation (7)) over three attributes. Darker color indicates higher attention score.

strates rating information has more effect on generating these sentiment words. Next, we increase the rating score to 3 in the second example. The generated review expresses a mixed opinion for different aspects of the book. As indicated by the attention scores, we know that the sentiment words “*loved*”, “*little slow*”, and “*not like*” attend more to rating information. The last example is a positive review with a rating of 5. The attention scores demonstrate the phrases “*loved*”, “*ca n’t wait*”, and “*hope \* writes another book*” are used to express polarity. Similarly, the attention scores over user and product information indicate how the generated words are aligned with these two input attributes. For instance, the word “*characters*” has higher attention scores over the product attribute in the first and second example. This indicates that users tend to comment about the characters in this book’s reviews.

#### 4.5 Generated Examples

As shown in Table 4, we sample products and users to generate some examples with different ratings. The special unknown token is removed from the vocabulary of the decoder in the generation process. We keep two attributes fixed and change the other one in every group to show the effects of input.

In the first group, we change the rating from 1 to 5 and keep the others unchanged. The results show that the polarity of generated reviews changes with the rating. For instance, the words “*nice*” and “*liked*” are used for the rating of 3, while the words “*very good*” and “*enjoyed*” are employed for the rating of 5. Moreover, both ex-

<b>U</b>	<b>P</b>	<b>R</b>	<b>Generated Review</b>
A	V	1	i'm sorry to say this was a very boring book. i didn't finish it. i'm not a new fan of the series, but this was a disappointment.
A	V	3	this was a nice story. i liked the characters and the story line. i'm not sure i'd read another by this author.
A	V	5	this was a very good book. i enjoyed the characters and the story line. i'm looking forward to reading more in this series.
B	W	5	i couldn't put it down. it was a great love story. i can't wait to read the next one.
C	W	5	enjoyable story that keeps you turning the pages. the characters are well developed and the plot is excellent. i would recommend this book to anyone who enjoys a good love story.
D	W	5	i loved this book. i could not put it down. i loved this story and the characters. i will be reading the next book.
E	X	1	i read this book because i was looking for something to read. this book was just too much like the others. i thought the author was going to be a good writer, but i was disappointed.
E	Y	1	i was disappointed. i read the first chapter and then i was bored. i read the whole thing, but i just couldn't get into it.
E	Z	1	this book was just too much. i read the whole thing, but i didn't like the way the author ended it. i was hoping for a different ending.

Table 4: **U**: User. **P**: Product. **R**: Rating. This table shows some generated examples of the Att2Seq+A model. In every group, two attributes are kept unchanged, while the other attribute has different values. For instance, in the first group, we use different ratings ranging from 1 (the lowest score) to 5 (the highest score) with the same user and product to generate reviews. The users and products are anonymized by A-E and V-Z.

amples describe “*characters*” and “*story line*”, and are written in the similar styles. This indicates that user and product information determines the content and style of generated reviews, while rating affects the choice of sentiment words. In the next group, we use different user IDs as input attributes. This book is one of the *Fatal Series* written by *Marie Force*, which tells a romantic love story. The first and third examples mention “*next one/book*”, and both the first two reviews contain the phrase “*love story*”. This demonstrates the generated reviews agree with the input product information. In the third group, the attributes, except product ID, are kept unchanged. The examples show our model generates varied reviews for different products.

## 5 Conclusion

In this paper, we proposed a novel product review generation task, in which generated reviews are conditioned on input attributes. For this task, we formulated a neural network based attribute-to-sequence model that uses multilayer perceptrons to encode input attributes and employs recurrent neural networks to generate reviews. Moreover, we introduced an attention mechanism to better

utilize input attribute information. Additionally, we built a dataset of Amazon product reviews to conduct evaluations. The proposed model consistently outperforms the nearest neighbor search and maximum entropy language model baselines. Besides, the attention mechanism significantly improves the vanilla attribute-to-sequence model. This work suggests several interesting directions for future research. We could use more fine-grained attributes as the input of our model. For example, the generated reviews could be conditioned on device specification, brand, user’s gender, product description, or ratings of a product’s various aspects. Moreover, we could leverage review texts without attributes to improve the sequence decoder.

## Abstract

We investigate the generation of one-sentence Wikipedia biographies from facts derived from Wikidata slot-value pairs. We train a recurrent neural network sequence-to-sequence model with attention to select facts and generate textual summaries. Our model incorporates a novel secondary objective that helps ensure it generates sentences that contain the input facts. The model achieves a BLEU score of 41, improving significantly upon the vanilla sequence-to-sequence model and scoring roughly twice that of a simple template baseline. Human preference evaluation suggests the model is nearly as good as the Wikipedia reference. Manual analysis explores content selection, suggesting the model can trade the ability to infer knowledge against the risk of hallucinating incorrect information.

## 1 Introduction

Despite massive effort, Wikipedia and other collaborative knowledge bases (KBs) have coverage and quality problems. Popular topics are covered in great detail, but there is a long tail of specialist topics with little or no text. Other text can be incorrect, whether by accident or vandalism. We report on the task of generating textual summaries for people, mapping slot-value facts to one-sentence encyclopaedic biographies. In addition to initialising stub articles with only structured data, the resulting model could be used to improve consistency and accuracy of existing articles. Figure 1 shows a Wikidata entry for *Mathias Tuomi*, with fact keys and values flattened into a sequence, and the first sentence from his Wikipedia article. Some values are in the text, others are missing

---

```
TITLE mathias tuomi SEX_OR_GENDER
male DATE_OF_BIRTH 1985-09-03
OCCUPATION squash player
CITIZENSHIP finland
```

---

Figure 1: Example Wikidata facts encoded as a flat input string. The first sentence of the Wikipedia article reads: *Mathias Tuomi, (born September 30, 1985 in Espoo) is a professional squash player who represents Finland.*

(e.g. *male*) or expressed differently (e.g. *dates*).

We treat this *knowledge-to-text* task like translation, using a recurrent neural network (RNN) sequence-to-sequence model (Sutskever et al., 2014) that learns to select and realise the most salient facts as text. This includes an attention mechanism to focus generation on specific facts, a shared vocabulary over input and output, and a multi-task autoencoding objective for the complementary extraction task. We create a reference dataset comprising more than 400,000 knowledge-text pairs, handling the 15 most frequent slots. We also describe a simple template baseline for comparison on BLEU and crowd-sourced human preference judgements over a heldout TEST set.

Our model obtains a BLEU score of 41.0, compared to 33.1 without the autoencoder and 21.1 for the template baseline. In a crowdsourced preference evaluation, the model outperforms the baseline and is preferred 40% of the time to the Wikipedia reference. Manual analysis of content selection suggests that the model can infer knowledge but also makes mistakes, and that the autoencoding objective encourages the model to select more facts without increasing sentence length. The task formulation and models are a foundation for text completion and consistency in KBs.

## 2 Background

RNN sequence-to-sequence models (Sutskever et al., 2014) have driven various recent advances in natural language understanding. While initial work focused on problems that were sequences of the same units, such as translating a sequence of words from one language to another, other work has been able to use these models by *coercing* different structures into sequences, e.g., flattening trees for parsing (Vinyals et al., 2015), predicting span types and lengths over byte input (Gillick et al., 2016) or flattening logical forms for semantic parsing (Xiao et al., 2016).

RNNs have also been used successfully in *knowledge-to-text* tasks for human-facing systems, e.g., generating conversational responses (Vinyals and Le, 2015), abstractive summarisation (Rush et al., 2015). Recurrent LSTM models have been used with some success to generate text that completely expresses a set of facts: restaurant recommendation text from dialogue acts (Wen et al., 2015), weather reports from sensor data and sports commentary from on-field events (Mei et al., 2015). Similarly, we learn an end-to-end model trained over key-value facts by flattening them into a sequence.

Choosing the salient and consistent set of facts to include in generated output is also difficult. Recent work explores unsupervised autoencoding objectives in sequence-to-sequence models, improving both text classification as a pretraining step (Dai and Le, 2015) and translation as a multi-task objective (Luong et al., 2016). Our work explores an autoencoding objective which selects content as it generates by constraining the text output sequence to be predictive of the input.

Biographic summarisation has been extensively researched and is often approached as a sequence of subtasks (Schiffman et al., 2001). A version of the task was featured in the Document Understanding Conference in 2004 (Blair-Goldensohn et al., 2004) and other work learns policies for content selection without generating text (Duboue and McKeown, 2003; Zhang et al., 2012; Cheng et al., 2015). While pipeline components can be individually useful, integrating selection and generation allows the model to exploit the interaction between them.

KBs have been used to investigate the interaction between structured facts and unstructured text. Generating textual templates that are filled

by structured data is a common approach and has been used for conversational text (Han et al., 2015) and biographical text generation (Duma and Klein, 2013). Wikipedia has also been a popular resource for studying biography, including sentence harvesting and ordering (Biadys et al., 2008), unsupervised discovery of distinct sequences of life events (Bamman and Smith, 2014) and fact extraction from text (Garera and Yarowsky, 2009). There has also been substantial work in generating from other structured KBs using template induction (Kondadadi et al., 2013), semantic web techniques (Power and Third, 2010), tree adjoining grammars (Gyawali and Gardent, 2014), probabilistic context free grammars (Konstas and Lapata, 2012) and probabilistic models that jointly select and realise content (Angeli et al., 2010).

Lebret et al. (2016) present the closest work to ours with a similar task using Wikipedia infoboxes in place of Wikidata. They condition an attentional neural language model (NLM) on local and global properties of infobox tables, including *copy actions* that allow wholesale insertion of values into generated text. They use 723k sentences from Wikipedia articles with 403k lower-cased words mapping to 1,740 distinct facts. They compare to a 5-gram language-model with copy actions, and find that the NLM has higher BLEU and lower perplexity than their baseline. In contrast, we utilise a deep recurrent model for input encoding, minimal slot value templating and greedy output decoding. We also explore a novel autoencoding objective that measures whether input facts can be re-created from the generated sentence.

Evaluating generated text is challenging and no one metric seems appropriate to measure overall performance. Lebret et al. (2016) report BLEU scores (Papineni et al., 2002) which calculate the n-gram overlap between text produced by the system with respect to a human-written reference. Summarisation evaluations have concentrated on the content that is included in the summary, with semantic content typically extracted manually for comparison (Lin and Hovy, 2003; Nenkova and Passonneau, 2004). We draw from summarisation and generation to formulate a comprehensive evaluation based on automated metrics and human validation. Our final system comparison follows Kondadadi et al. (2013) in running a crowd task to collect pairwise preferences for evaluating and comparing both systems and references.

Table 1: The top fifteen slots across entities used for input, and the % of time the value is a substring in the entity’s first sentence.

### 3 Task and Data

We formulate the one-sentence biography generation task as shown in Figure 1. Input is a flat string representation of the structured data from the KB, comprising slot-value pairs (the subject being the topic of the KB record, e.g., *Mathias Tuomi*), ordered by slot frequency from most to least common. Output is a biography string describing the salient information in one sentence.

We validate the task and evaluation using a closely-aligned set of resources: Wikipedia and Wikidata. In addition to the KB maintenance issues discussed in the introduction, Wikipedia first sentences are of particular interest because they are clear and concise biographical summaries. These could be applied to entities outside Wikipedia for which one can obtain comparable parallel structured/textual data, e.g., movie summaries from IMDb, resume overviews from LinkedIn, product descriptions from Amazon.

We use snapshots of Wikidata (2015/07/13) and Wikipedia (2015/10/02) and batch process them to extract instances for learning. We select all entities that are `INSTANCE_OF human` in Wikidata. We then use `sitelinks` to identify each entity’s Wikipedia article text and NLTK (Bird et al., 2009) to tokenize and extract the lower-cased first sentence. This results in 1,268,515 raw knowledge-text pairs. The summary sentences can be long and the most frequent length is 21 tokens. We filter to

only include those between the 10th and 90th percentiles: 10 and 37 tokens. We split this collection into TRAIN, DEV and TEST collections with 80%, 10% and 10% of instances allocated respectively. Given the large variety of slots which may exist for an entity, we restrict the set of slots used to the top-15 by occurrence frequency. This criteria covers 72.8% of all facts. Table 1 shows the distribution of fact slots in the structured data and the percentage of time tokens from a fact value occur in the corresponding Wikipedia summary.

Additionally, some Wikidata entities remain underpopulated and do not contain sufficient facts to reconstruct a text summary. We control for this information mismatch by limiting our dataset to include only instances with at least 6 facts present. The final dataset includes 401,742 TRAIN, 50,017 DEV and 50,030 TEST instances. Of these instances, 95% contain 6 to 8 slot values while 0.1% contain the maximum of 10 slots. 51% of unique slot-value pairs expressed in TEST and DEV are not observed in TRAIN so generalisation of slot usage is required for the task. The KB facts give us an opportunity to measure the correctness of the generated text in a more precise way than text-to-text tasks. We use this for analysis in Section 7.3, driving insight into system characteristics and implications for use.

#### 3.1 Task complexity

Wikipedia first sentences exhibit a relatively narrow domain of language in comparison to other generation tasks such as translation. As such, it is not clear how complex the generation task is, and we first try to use perplexity to describe this.

We train both RNN models until DEV perplexity stops improving. Our basic sequence-to-sequence model (S2S) reaches perplexity of 2.82 on TRAIN and 2.92 on DEV after 15,000 batches of stochastic gradient descent. The autoencoding sequence-to-sequence model (S2S+AE) takes longer to fit, but reaches a lower minimum perplexity of 2.39 on TRAIN and 2.51 on DEV after 25,000 batches.

To help ground perplexity numbers and understand the complexity of sentence biographies we train a benchmark language model and evaluate perplexity on DEV. Following Lebre et al. (2016), we build Kneser-Ney smoothed 5-gram language models using the KenLM toolkit (Heafield, 2011).

Table 2 lists perplexity numbers for the benchmark LM models with different templating

Templates	DEV
None	29.8
Title	14.5
Full	10.1

Table 2: Language model perplexity across templated datasets.

schemes on DEV. We observe decreasing perplexity for data with greater fact value templating. TITLE indicates templating of entity names only, while FULL indicates templating of all fact values by token index as described in Lebret et al. (2016). This shows that templating is an effective way to reduce the sparsity of a task, and that titles account for a large component of this.

Although Lebret et al. (2016) evaluate on a different dataset, we are able to draw some comparisons given the similarity of our task. On their data, the benchmark LM baseline achieves a similar perplexity of 10.5 to ours when following their templating scheme on our dataset - suggesting both samples are of comparable complexity.

## 4 Model

We model the task as a sequence-to-sequence learning problem. In this setting, a variable length input sequence of entity facts is encoded by a multi-layer RNN into a fixed-length distributed representation. This input representation is then fed into a separate decoder network which estimates a distribution over tokens as output. During training, parameters for both the encoder and decoder networks are optimized to maximize the likelihood of a summary sequence given an observed fact sequence.

Our setting differs from the translation task in that the input is a sequence representation of structured data rather than natural human language. As described above in Section 3, we map Wikidata facts to a sequence of tokens that serves as input to the model as illustrated at the top of Figure 2. Experiments below demonstrate that this is sufficient for end-to-end learning in the generation task addressed here. To generate summaries, our model must both select relevant content and transform it into a well formed sentence. The decoder network includes an attention mechanism (Vinyals et al., 2015) to help facilitate accurate content selection. This allows the network to focus on different parts of the input sequence during inference.

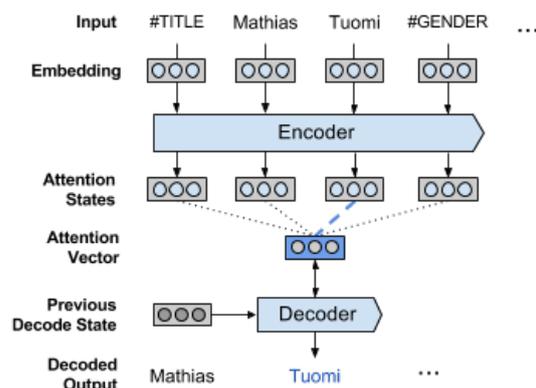

Figure 2: Sequence-to-sequence translation from linearized facts to text.

### 4.1 Sequence-to-sequence model (s2s)

To generate language, we seed the decoder network with the output of the encoder and a designated GO token. We then generate symbols greedily, taking the most likely output token from the decoder at each step given the preceding sequence until an EOS token is produced. This approach follows (Sutskever et al., 2014) who demonstrate a larger model with greedy sequence inference performs comparably to beam search. In contrast to translation, we might expect good performance on the summarization task where output summary sequences tend to be well structured and often formulaic. Additionally, we expect a partially-shared language across input and output. To exploit this, we use a tied embedding space, which allows both the encoder and decoder networks to share information about word meaning between fact values and output tokens.

Our model uses a 3-layer stacked Gated Recurrent Unit RNN for both encoding and decoding, implemented using TensorFlow.<sup>1</sup> We limit the shared vocabulary to 100,000 tokens with 256 dimensions for each token embedding and hidden layer. Less common tokens are marked as UNK, or unknown. To account for the long tail of entity names, we replace matches of title tokens with templated copy actions (e.g. TITLE0 TITLE1...). These template are then filled after generation, as well as any initial unknown tokens in the output, which we fill with the first title token. We learn using minibatch Stochastic Gradient Descent with a batch size of 64 and a fixed learning rate of 0.5.

<sup>1</sup><https://www.tensorflow.org>, v0.8.

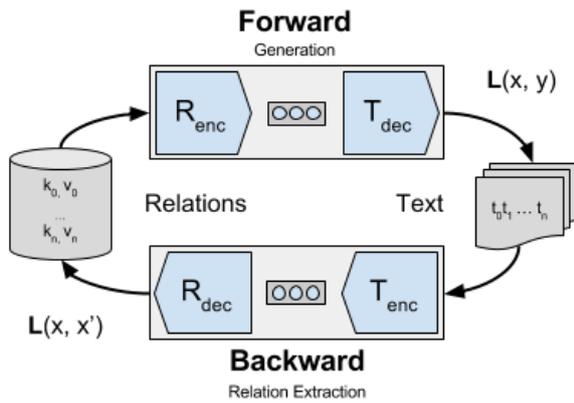

Figure 3: Sequence-to-sequence autoencoder.

#### 4.2 S2S with autoencoding (S2S+AE)

One challenge for vanilla sequence-to-sequence models in this setting is the lack of a mechanism for constraining output sequences to only express those facts present in the data. Given a fact extraction oracle, we might compare facts expressed in the output sequence with those of the input and appropriately adjust the loss for each instance. While a forward-only model is only constrained to generate text sequences predicted by the facts, an autoencoding model is additionally constrained to generate text predictive of the input facts. In place of this ideal setting, we introduce a second sequence-to-sequence model which runs in reverse - re-encoding the text output sequence of the forward model into facts.

This closed-loop model is detailed in Figure 3. The resulting network is trained end-to-end to minimize both the input-to-output sequence loss  $L(x, y)$  and output-to-input reconstruction loss  $L(x, x')$ . While gradients cannot propagate through the greedy forward decode step, shared parameters between the forward and backward network are fit to both tasks. To generate language at test time, the backward network does not need to be evaluated.

## 5 Experimental methodology

The evaluation suite here includes standard baselines for comparison, automated metrics for learning, human judgement for evaluation and detailed analysis for diagnostics. While each are individually useful, their combination gives a comprehensive analysis of a complex problem space.

### 5.1 Benchmarks

**WIKI** We use the first sentence from Wikipedia both as a gold standard reference for evaluating generated sentences, and as an upper bound in human preference evaluation.

**BASE** Template-based systems are strong baselines, especially in human evaluation. While output may be stilted, the corresponding consistency can be an asset when consistency is important. We induce common patterns from the TRAIN set, replacing full matches of values with their slot and choosing randomly on ties. Multiple non-fact tokens are collapsed to a single symbol. A small sample of the most frequent patterns were manually examined to produce templates, roughly expressed as: TITLE, known as GIVEN\_NAME, (born DATE\_OF\_BIRTH in PLACE\_OF\_BIRTH; died DATE\_OF\_DEATH in PLACE\_OF\_DEATH) is an POSITION\_HELD and OCCUPATION from CITIZENSHIP, with some sensible back-offs where slots are not present, and rules for determiner agreement and *is* versus *was* where a death date is present. For example, *ollie freckingham (born 12 november 1988) is a cricketer from the united kingdom.* In total, there are 48 possible template variations.

### 5.2 Metrics

**BLEU** We also report BLEU n-gram overlap with respect to the reference Wikipedia summary. With a large dev/test sets (10,000 sentences here), BLEU is a reasonable evaluation of generated content. However, it does not give an indication of well-formedness or readability. Thus we complement BLEU with a human preference evaluation.

**Human preference** We use crowd-sourced judgements to evaluate the relative quality of generated sentences and the reference Wikipedia first sentence. We obtain pairwise judgements, showing output from two different systems to crowd workers and asking each to give their binary preference. The system name mappings are anonymized and ordered pseudo-randomly. We request 3 judgements and dynamically increase this until we reach at least 70% agreement or a maximum of 5 judgements. We use Crowd-Flower<sup>2</sup> to collect judgements at the cost of 31 USD for all 6 pairwise combinations over 82

S2S+AE	40.5	41.0

Table 3: BLEU scores for each hypothesis against the Wikipedia reference

randomly selected entities. 67 workers contributed judgements to the test data task, each providing no more than 50 responses. We use the majority preference for each comparison. The CrowdFlower agreement is 80.7%, indicating that roughly 4 of 5 votes agree on average.

### 5.3 Analysis of content selection

Finally, no system is perfect, and it can be challenging to understand the inherent difficulty of the problem space and the limitations of a system. Due to the limitations of the evaluation metrics mentioned above, we propose that manual annotation is important and still required for qualitative analysis to guide system improvement. The structured data in knowledge-to-text tasks allows us, if we can identify expressions of facts in text, cases where facts have been omitted, incorrectly mentioned, or expressed differently.

## 6 Results

### 6.1 Comparison against Wikipedia reference

Table 3 shows BLEU scores calculated over 10,000 entities sampled from DEV and TEST using the Wikipedia sentence as a single reference, using uniform weights for 1- to 4-grams, and padding sentences with fewer than 4 tokens. Scores are similar across DEV and TEST, indicating that the samples are of comparable difficulty. We evaluate significance using bootstrapped resampling with 1,000 samples. Each system result lies outside the 95% confidence intervals of other systems. BASE has reasonable scores at 21, with S2S higher at around 32, indicating that the model is at least able to generate closer text than the baseline. S2S+AE scores higher still at around 41, roughly double the baseline scores, indicating that the autoencoder is indeed able to constrain the model to generate better text.

### 6.2 Human preference evaluation

Table 4 shows the results of our human evaluation over 82 entities sampled from TEST. For each

S2S+AE	BASE	S2S	
60%	61%*	87%**	WIKI
	62%*	77%**	S2S+AE
		65%**	BASE

Table 4: Percentage of entities for which human judges preferred the row system to the column system. E.g., S2S+AE summaries are preferred to BASE for 62% of sample entities.

pair of systems, we show the percentage of entities where the crowd preferred A over B. Significant differences are annotated with \* and \*\* for  $p$  values  $< 0.05$  and  $0.01$  using a one-way  $\chi^2$  test. WIKI is uniformly preferred to any system, as is appropriate for an upper bound. The S2S model is the least-preferred with respect to WIKI. The S2S+AE model is more-preferred than the BASE and S2S models, by a larger margin for the latter. These results show that without autoencoding, the sequence-to-sequence model is less effective than a template-based system. Finally, although WIKI is more preferred than S2S+AE, the distributions are not significantly different, which we interpret as evidence that the model is able to generate good text from the human point-of-view, but autoencoding is required to do so.

## 7 Analysis

While results presented above are encouraging and suggest that the model is performing well, they are not diagnostic in the sense that they can drive deeper insights into model strengths and weaknesses. While inspection and manual analysis is still required, we also leverage the structured factual data inherent to our task to perform quantitative as well as qualitative analysis.

### 7.1 Fact Count

Figure 4 shows the effects of input fact count on generation performance. While more input facts give more information for the model to work with, longer inputs are also both rarer and more complex to encode. Interestingly, we observe the S2S+AE model maintains performance for more complex inputs while S2S performance declines.

### 7.2 Example generated text

Table 5 shows some DEV entities and their summaries. The model learns interesting mappings: between numeric and string dates, and country de-

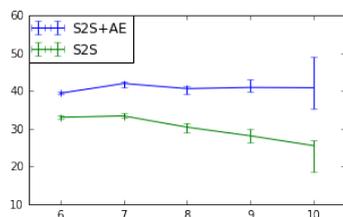

Figure 4: BLEU vs Fact Count on instances from DEV. Error bars indicate the 95% confidence interval for BLEU.

monyms. The model also demonstrates the ability to work around edge cases where templates fail, i.e. stripping parenthetical disambiguations (e.g. (actor)) and emitting the name Robert when the input is Bob. Output also suggests the model may perform inference across multiple facts to improve generation precision, e.g. describing an entity as english rather than british given information about both citizenship and place of birth. Unfortunately, the model can also infer unsubstantiated facts into the text (i.e. jazz drummer).

### 7.3 Content selection and hallucination

We randomly sample 50 entities from DEV and manually annotate the Wikipedia and system text. We note which fact slots are expressed as well as whether the expressed values are correct with respect to Wikidata. Given two sets of correctly extracted facts, we can consider one *gold*, one *system* and calculate set-based precision, recall and F1.

**What percentage of facts are used in the reference summaries?** Firstly, to understand how Wikipedia editors select content for the first sentence of articles, we measure recall with the real facts as gold, and Wikipedia as system. Overall, the recall is 0.61 indicating that 61% of input facts are expressed in the reference summary from Wikipedia. The entity name (TITLE) is always expressed. Four slots are nearly always expressed when available: OCCUPATION (90%), DATE\_OF\_BIRTH (84%), CITIZENSHIP (81%), DATE\_OF\_DEATH (80%). Six slots are infrequently expressed in the analysis sample: PLACE\_OF\_BIRTH (33%), POSITION\_HELD (25%), PARTICIPANT\_OF (20%), POLITICAL\_PARTY (20%), EDUCATED\_AT (14%), SPORTS\_TEAM (9%). Two are never expressed explicitly: PLACE\_OF\_DEATH (0%), SEX\_OR\_GENDER (0%). AWARD\_RECEIVED and SPORT are not in the analysis sample.

**Do systems select the same facts found in the reference summaries?** Table 6 shows content selection scores for systems with respect to the Wikipedia text as reference. This suggests that the autoencoding in S2S+AE helps increase fact recall without sacrificing precision. The template baseline also attains this higher recall, but at the cost of precision. For commonly expressed facts found in most person biographies, recall is over 0.95 (e.g., CITIZENSHIP, BIRTH\_DATE, DEATH\_DATE and OCCUPATION). Facts that are infrequently expressed are more difficult to select, with system F1 ranging from 0.00 to 0.50. Interestingly, macro-averaged F1 across infrequently expressed facts mirror human preference rather than BLEU results, with S2S+AE (0.26) > BASE (0.17) > S2S (0.07). However, all systems perform poorly on these facts and no reliable differences are observed.

**How does autoencoding effect fact density?** Interestingly, we observe that the autoencoding objective encourages the model to select more

	P	R	F

S2S	0.89	0.67	0.77
S2S+AE	0.89	0.78	0.83

Table 6: Fact-set content selection results phrased as precision, recall and F1 of systems with respect to the Wikipedia reference on DEV.

	P	R	F
BASE	1.00	0.74	0.85
S2S	0.96	0.55	0.70
S2S+AE	0.93	0.62	0.74
WIKI	0.81	0.61	0.69

Table 7: Hallucination results phrased as precision, recall and F1 of systems with respect to the Wikidata input on DEV.

facts (5.2 for S2S+AE vs. 4.5 for S2S), without increasing sentence length (19.1 vs. 19.7 tokens). BASE is similarly productive (5.1 facts) but wordier (21.2 tokens), while the WIKI reference produces both more facts (6.1) and longer sentences (23.7).

**Do systems hallucinate facts?** To quantify the effect of hallucinated facts, we assess content selection scores of systems with respect to the input Wikidata relations (Table 7). Our best model achieves a precision of 0.93 with respect to Wikidata input. Notably, the template-driven baseline maintains a precision of 1.0 as it is constrained to emit Wikidata facts verbatim.

## 8 Discussion and future work

Our experiments show that RNNs can generate biographic summaries from structured data, and that a secondary autoencoding objective is able to account for some of the information mismatch between input facts and target output sentences. In the future, we will explore whether results improve with explicit modelling of facts and conditioning of generation and autoencoding losses on slots. We expect this could benefit generation for diverse and noisy slot schemas like Wikipedia Infoboxes.

Another natural extension is to investigate the performance of the network running in reverse, from summary text back to facts. We plan to isolate the performance of the S2S+AE backward model when inferring facts and compare it to stan-

standard relation extraction systems. Finally, similar RNN models have been applied extensively to language translation tasks. We plan to explore whether a joint model of machine translation and fact-driven generation can help populate KB entries for low-coverage languages by leveraging a shared set of facts.

## 9 Conclusion

We present a neural model for mapping between structured and unstructured data, focusing on creating Wikipedia biographic summary sentences from Wikidata slot-value pairs. We introduce a sequence-to-sequence autoencoding RNN which improves upon base models by jointly learning to generate text and reconstruct facts. Our analysis of the task suggests evaluation in this domain is challenging. In place of a single score, we analyse statistical measures, human preference judgements and manual annotation to help characterise the task and understand system performance. In the human preference evaluation, our best model outperforms template baselines and is preferred 40% of the time to the gold standard Wikipedia reference.

## Abstract

Traditional methods for deep NLG adopt pipeline approaches comprising stages such as constructing syntactic input, predicting function words, linearizing the syntactic input and generating the surface forms. Though easier to visualize, pipeline approaches suffer from error propagation. In addition, information available across modules cannot be leveraged by all modules. We construct a transition-based model to jointly perform linearization, function word prediction and morphological generation, which considerably improves upon the accuracy compared to a pipelined baseline system. On a standard deep input linearization shared task, our system achieves the best results reported so far.

## 1 Introduction

Natural language generation (NLG) (Reiter and Dale, 1997; White, 2004) aims to synthesize natural language text given input syntactic, semantic or logical representations. It has been shown useful in various tasks in NLP, including machine translation (Chang and Toutanova, 2007; Zhang et al., 2014), abstractive summarization (Barzilay and McKeown, 2005) and grammatical error correction (Lee and Seneff, 2006).

A line of traditional methods treat the problem as a pipeline of several independent steps (Bohnet et al., 2010; Wan et al., 2009; Bangalore et al., 2000; H. Oh and I. Rudnicky, 2000; Langkilde and Knight, 1998). For example, shown in Figure 1b, a pipeline based on the meaning text theory (MTT) (Melčuk, 1988) splits NLG into three

\*Part of the work was done when the author was a visiting student at Singapore University of Technology and Design.

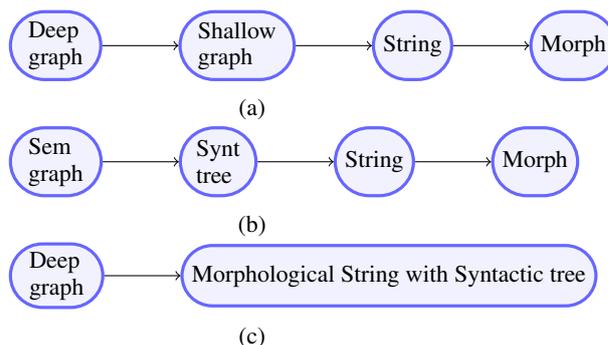

Figure 1: Linearization pipelines (a) NLG pipeline with deep input graph, (b) pipeline based on the meaning text theory, (c) this paper.

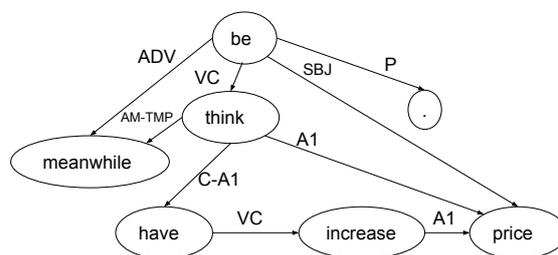

Figure 2: Sample deep graph for the sentence: *meanwhile, prices are thought to have increased.* Note that words are replaced by their lemmas. The function word *to* and comma are absent in graph.

independent steps 1. syntactic generation: generating an unordered and lemma-formed syntactic tree from a semantic graph, introducing function words; 2. syntactic linearization: linearizing the unordered syntactic tree; 3. morphological generation: generating the inflection for each lemma in the string.

In this paper we focus on deep graph as input. Exemplified in Figure 2, the deep input type is intended to be an abstract representation of the meaning of a sentence. Unlike semantic input, where the nodes are semantic representations of input, deep input is more surface centric, with lem-

mas for each word being connected by semantic labels (Banarescu et al., 2013; Melčuk, 2015). In contrast to shallow syntactic trees, function words in surface forms are not included in deep graphs (Belz et al., 2011). Deep inputs can more commonly occur as input of NLG systems where entities and content words are available, and one has to generate a grammatical sentence using them with only provision for inflections of words and introduction of function words. Such usecases include summarization, dialog generation etc.

A pipeline of deep input linearization is shown in Figure 1a. Generation involves predicting the correct word order, deciding inflections and also filling in function words at the appropriate positions. The worst-case complexity is  $n!$  for permuting  $n$  words,  $2^n$  for function word prediction (assuming that a function word can be inserted after each content word), and  $2^n$  for inflection generation (assuming two morphological forms for each lemma). On the dataset from the First Surface Realisation Shared Task, Bohnet et al. (2011) achieved the best reported results on linearizing deep input representation, following the pipeline of Figure 1b (with input as deep graph instead of semantic graph). They construct a syntactic tree from deep input graph followed by function word prediction, linearization and morphological generation. A rich set of features are used at each stage of the pipeline and for each adjacent pair of stages, an SVM decoder is defined.

Pipelined systems suffer from the problem of error propagation. In addition, because the steps are independent of each other, information available in a later stage is not made use of in the earlier stages. We introduce a transition-based (Nivre, 2008) method for *joint* deep input surface realisation integrating linearization, function word prediction and morphological generation. The model is shown in Fig 1c, as compared with the pipelined baseline in Fig 1a. For a directly comparable baseline, we construct a pipeline system of function words prediction, linearization and morphological generation similar to the pipeline of Bohnet et al. (2011), but with the following difference. Our baseline pipeline system makes function word prediction for a deep input graph, whereas Bohnet et al. (2011) have a preprocessing step to construct a syntactic tree from the deep input graph, which is given as input to the function word prediction module. Our pipeline is directly comparable to the

joint system with regard to the use of information.

Standard evaluations show that: 1. Our joint model for deep input surface realisation achieves significantly better scores over its pipeline counterpart. 2. We achieve the best results reported on the task. Our system scores 1 BLEU point better over Bohnet et al. (2011) without using any external resources. We make the source code available at <https://github.com/SUTDNLP/ZGen/releases/tag/v0.3>.

## 2 Related Work

Related work can be broadly summarized into three areas: abstract word ordering, applications of meaning-text theory and joint modelling of NLP tasks. In abstract word ordering (Wan et al., 2009; Zhang, 2013; Zhang and Clark, 2015), De Gispert et al. (2014) compose phrases over individual words and permute the phrases to achieve linearization. Schmaltz et al. (2016) show that strong surface-level language models are more effective than models trained with syntactic information for the task of linearization. Transition-based techniques have also been explored (Liu et al., 2015; Liu and Zhang, 2015; Puduppully et al., 2016). To our knowledge, we are the first to use transition-based techniques for *deep* input linearization.

There has been work done in the area of sentence linearization using meaning-text theory (Melčuk, 1988). Belz et al. (2011) organized a shared task on both shallow and deep linearization according to meaning-text theory, which provides a standard benchmark for system comparison. Song et al. (2014) achieved the best results for the task of *shallow*-syntactic linearization. Using SVM models with rich features, Bohnet et al. (2011) achieved state-of-art results on the task of *deep* realization. While they built a pipeline system, we show that joint models can be used to overcome limitations of the pipeline approach giving the best results.

Joint models for NLP have shown effectiveness in recent years. Though having to tackle increased search space, they overcome issues with error propagation in pipelined models. Joint models have been explored for grammar-based approaches to surface realisation using HPSG and CCG (Carroll and Oepen, 2005; Velldal and Oepen, 2006; Espinosa et al., 2008; White and Rajkumar, 2009; White, 2006; Carroll et al., 1999).

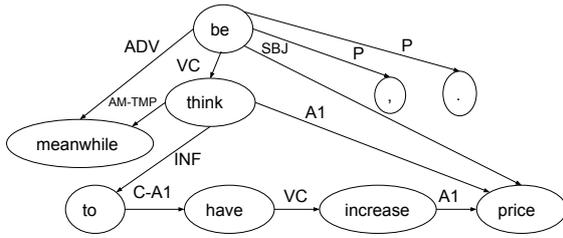

Figure 3: Equivalent shallow graph for Figure 2.

Joint models have been proposed for word segmentation and POS-tagging (Zhang and Clark, 2010), POS-tagging and syntactic chunking (Sutton et al., 2007), segmentation and normalization (Qian et al., 2015), syntactic linearization and morphologization (Song et al., 2014), parsing and NER (Finkel and Manning, 2009), entity and relation extraction (Li and Ji, 2014) and so on. We propose a first joint model for deep realization, integrating linearization, function word prediction and morphological generation.

### 3 Baseline

We build a baseline following the pipeline in Figure 1a. Three stages are involved: 1. prediction of function words, inserting the predicted function words in the deep graph, resulting in a *shallow* graph; 2. linearizing the shallow graph; 3. generating the inflection for each lemma in the string.

#### 3.1 Function Word Prediction

In the First Surface Realisation Shared Task dataset (Belz et al., 2011), there are three classes of function words to predict: *to* infinitive, *that* complementizer and *comma*. We implement classifiers to predict these classes of function words locally at respective positions in the deep graph resulting in a shallow graph (Figure 3). At each location the input is a node and output is a class indicating if *to* or *that* need to be inserted under the node or the count of *comma* to be introduced under the node.

Table 1 shows the feature templates for classification of *to* infinitives and *that* complementizers and Table 2 shows the feature templates for predicting the count of *comma* child nodes for each non-leaf node in the graph. These feature templates are a subset of features used in the joint model (Section 4) with the exceptions being word order features, which are not available here for the pipeline system, since earlier stages cannot leverage features in subsequent outcomes. We use av-

Features for predicting function words including <i>to</i> infinitive, <i>that</i> complementizer
WORD( $n$ ); POS( $n$ ); WORD( $c$ )

Table 1: Feature templates for the prediction of function words- *to* infinitive and *that* complementizer. Indices on the surface string:  $n$  – word index;  $c$  – child of  $n$ ; Functions: WORD – word at index; POS – part-of-speech at index.

Features for predicting count of <i>comma</i>
WORD( $n$ ); POS( $n$ )
BAG(WORD-MOD( $n$ ))
BAG(LABEL-MOD( $n$ ))

Table 2: Feature templates for the comma prediction system. Indices on the surface string:  $n$  – word index; Functions: WORD – word at index; POS – part-of-speech at index; WORD-MOD – modifiers of index; LABEL-MOD – dependency labels of modifiers; BAG – set.

eraged perceptron classifier (Collins, 2002) to predict function words, which is consistent with the joint model.

#### 3.2 Linearization

The next step is linearizing the graph, which we solve using a novel transition-based algorithm.

##### 3.2.1 Transition-Based Tree Linearization

Liu et al. (2015) introduce a transition-based model for tree linearization. The approach extends from transition-based parsers (Nivre and Scholz, 2004; Chen and Manning, 2014), where *state* consists of *stack* to hold partially built outputs and a *queue* to hold input sequence of words. In case of linearization, the input is a set of words. Liu et al. therefore use a set to hold the input instead of a queue. State is represented by a tuple  $(\sigma, \rho, A)$ , where  $\sigma$  is stack to store partial derivations,  $\rho$  is set of input words and  $A$  is the set of dependency relations that have been built. There are three transition actions:

- SHIFT-Word-POS – shifts *Word* from  $\rho$ , assigns POS to it and pushes it to top of stack as  $S_0$ ;
- LEFTARC-LABEL – constructs dependency arc  $S_1 \xleftarrow{LABEL} S_0$  and pops out second element from top of stack  $S_1$ ;
- RIGHTARC-LABEL – constructs dependency arc  $S_1 \xrightarrow{LABEL} S_0$  and pops out top of stack  $S_0$ .

**Input lemmas:** {think<sub>1</sub>, price<sub>2</sub>, .<sub>3</sub>, increase<sub>4</sub>, be<sub>5</sub>, have<sub>6</sub>, meanwhile<sub>7</sub>, .<sub>8</sub>, to<sub>9</sub>}

Table 3: Transition action sequence for linearizing the graph in Figure 3. SH - SHIFT, RA - RIGHTARC, LA - LEFTARC. POS is not shown in SHIFT actions.

The sequence of actions to linearize the set {*he*, *goes*, *home*} is SHIFT-*he*, SHIFT-*goes*, SHIFT-*home*, RIGHTARC-OBJ, LEFTARC-SBJ.

The full set of feature templates are shown in Table 2 of Liu et al. (2015), partly shown in Table 4. The features include word(*w*), POS(*p*) and dependency label (*l*) of elements on stack and their descendants  $S_0$ ,  $S_1$ ,  $S_{0,l}$ ,  $S_{0,r}$  etc. For example, word on top of stack is  $S_0w$  and word on first left child of  $S_0$  is  $S_{0,l}w$ . These are called configuration features. They are combined with all possible actions to score the action. Puduppully et al. (2016) extend Liu et al. (2015) by redefining features to address feature sparsity and introduce lookahead features, thereby achieving highest accuracies on task of abstract word ordering.

### 3.2.2 Shallow Graph Linearization

Our transition based graph linearization system extends from Puduppully et al. (2016). In our case, the input is a shallow graph instead of a syntactic tree, and hence the search space is larger. On the other hand, the same set of actions can still be applied, with additional constraints on valid actions given each configuration (Section 3.2.3). Table 3 shows the sequence of transition actions to linearize shallow graph in Figure 3.

### 3.2.3 Obtaining Possible Transition Actions Given a Configuration

The purpose of a GETPOSSIBLEACTIONS function is to find out the set of transition actions that can lead to a valid output given a certain state.

---

### Algorithm 1: GETPOSSIBLEACTIONS for shallow graph linearization

---

**Input:** A state  $s = ([\sigma|j\ i], \rho, A)$  and input graph  $C$   
**Output:** A set of possible transition actions  $T$

```

1  $T \leftarrow \emptyset$ 
2 if  $s.\sigma == \emptyset$  then
3   for  $k \in s.\rho$  do
4      $T \leftarrow T \cup (\text{SHIFT}, \text{POS}, k)$ 
5 else
6   if  $\exists k, k \in (\text{DIRECTCHILDREN}(i) \cap s.\rho)$  then
7      $\text{SHIFTSUBTREE}(i, \rho)$ 
8   else
9     if  $A.\text{LEFTCHILD}(i)$  is NIL then
10       $\text{SHIFTSUBTREE}(i, \rho)$ 
11     if  $\{j \rightarrow i\} \in C \wedge A.\text{LEFTCHILD}(j)$  is NIL then
12       then
13          $T \leftarrow T \cup (\text{RIGHTARC})$ 
14         if  $i \in \text{DESCENDANT}(j)$  then
15            $\text{PROCESSDESCENDANT}(i, j)$ 
16         if  $i \in \text{SIBLING}(j)$  then
17            $\text{PROCESSSIBLING}(i, j)$ 
18       else if  $\{j \leftarrow i\} \in C$  then
19          $T \leftarrow T \cup (\text{LEFTARC})$ 
20         if  $i \in \text{SIBLING}(j)$  then
21            $\text{PROCESSSIBLING}(i, j)$ 
22       else
23         if  $\text{size}(s.\sigma) == 1$  then
24            $\text{SHIFTPARENTANDSIBLINGS}(i)$ 
25         else
26           if  $i \in \text{DESCENDANT}(j)$  then
27              $\text{PROCESSDESCENDANT}(i, j)$ 
28           if  $i \in \text{SIBLING}(j)$  then
29              $\text{PROCESSSIBLING}(i, j)$ 
29 return  $T$ 

```

---

---

### Algorithm 2: DIRECTCHILDREN

---

**Input:** A state  $s = ([\sigma|j\ i], \rho, A)$ , *input\_node* and graph  $C$ .

**Output:** DC direct child nodes of input node

```

1  $DC \leftarrow \emptyset$ 
2 for  $k \in (C.\text{CHILDREN}(\text{input\_node}))$  do
3    $\text{Parents} \leftarrow C.\text{PARENTS}(k)$ 
4   if  $\text{Parents.size} == 1$  then
5      $DC \leftarrow DC \cup k$ 
6   else
7     for  $m \in \text{Parents}$  do
8       if  $A.\text{LEFTCHILD}(m)$  is not NIL  $\vee m == \text{input\_node}$  then
9         continue
10      if  $m \cap s.\rho$  then
11        goto OutsideLoop
12      if  $m \in \sigma \wedge \sigma.\text{ISANCESTOR}(m, C)$  then
13        goto OutsideLoop
14       $DC \leftarrow DC \cup k$ 
15   OutsideLoop:
16 return  $DC$ 

```

---

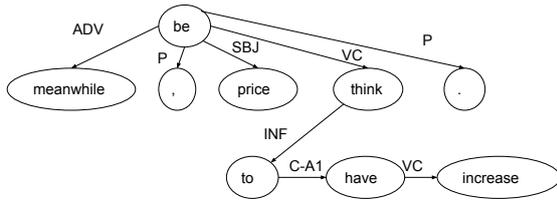

Figure 4: Equivalent syntactic tree for Figure 2.

---

### Algorithm 3: SHIFTSUBTREE

---

**Input:** A state  $s = ([\sigma|j\ i], \rho, A)$ , graph  $C$ , head  $k$

**Output:** a set of possible Transition actions  $T$

```

1  $T \leftarrow \emptyset$ 
2  $T \leftarrow T \cup (\text{SHIFT}, \text{POS}, k)$ 
3  $queue\ q$ 
4  $q.push(k)$ 
5 while  $q$  is not empty do
6    $front = q.pop()$ 
7   for  $m \in (C.CHILDREN(front) \cap s.\rho)$  do
8      $q.push(m)$ 
9      $T \leftarrow T \cup (\text{SHIFT}, \text{POS}, m)$ 

```

---

This is because not all sequences of actions correspond to a well-formed output. Essentially, given a state  $s = ([\sigma|j\ i], \rho, A)$  and an input graph  $C$ , the Decoder extracts syntactic tree from the graph (cf. Figure 4 extracted from Figure 3), outputting RIGHTARC, LEFTARC only if the corresponding arc exists in  $C$ . The corresponding pseudocode is shown in Algorithm 1.

In particular, if node  $i$  has *direct child nodes* in  $C$ , the descendants of  $i$  are shifted (line 6-7) (see Algorithm 3). Here *direct child nodes* (see Algorithm 2) include those child nodes of  $i$  for which  $i$  is the only parent or if there is more than one parent then every other parent is shifted on to the stack without possibility to reduce the child node. If no *direct child node* is in the buffer, then all graph descendants of  $i$  are shifted. Now, there are three configurations possible between  $i$  and  $j$ : 1.  $i$  and  $j$  are directly connected in  $C$ . This results in RIGHTARC or LEFTARC action; 2.  $i$  is descendant of  $j$ . In this case the parents of  $i$  (such that they are descendants of  $j$ ) and siblings of  $i$  through such parents are shifted. 3.  $i$  is sibling of  $j$ . In this case, parents of  $i$  and their descendants are shifted such that  $A$  remains consistent. Because the input is a graph, more than one of the above configuration can occur simultaneously. More detailed discussion related to GETPOSSIBLEACTIONS is given in Appendix A.

Table 4: Baseline linearization feature templates. A subset is shown here. For the full feature set, refer to Table 2 of Liu et al. (2015).

### 3.2.4 Feature Templates

There are three sets of features. The first is the set of baseline linearization feature templates from Table 2 in Liu et al. (2015), partly shown in Table 4. The second is a set of *lookahead features* similar to that of Puduppully et al. (2016), shown in Table 5.<sup>1</sup> Parent lookahead feature in Puduppully et al. (2016) is defined for the only parent. For graph linearization, however, the parent lookahead feature need to be defined for set of parents. The third set of features in Table 6 are newly introduced for Graph Linearization.  $Arc_{left}$  is a binary feature indicating if there is left arc between  $S_0$  and  $S_1$ , whereas  $Arc_{right}$  indicates if there is a right arc.  $L_{is\_descendant}$  is a binary feature indicating if  $L$  is descendant of  $S_0$ , and  $L_{is\_parent\_or\_sibling}$  indicates if it is a parent or sibling of  $S_0$ .  $S_{0descendants\_shifted}$  is binary feature indicating if all the descendants of  $S_0$  are shifted.

Not having POS in the input dataset, we compute the feature templates for POS making use of the most frequent POS of the lemma in the gold training data. For the features with dependency labels, we use the input graph labels.

### 3.2.5 Search and Learning

We follow Puduppully et al. (2016) and Liu et al. (2015), applying the learning and search framework of Zhang and Clark (2011). Pseudocode is shown in Algorithm 4. It performs beam search holding  $k$  best states in an agenda at each incremental step. At the start of decoding, agenda holds the initial state. At a step, for each state in the

Table 6: Graph linearization feature templates

agenda, each of transition actions in GETPOSSIBLEACTIONS is applied. The top- $k$  states are updated in the agenda for the next step. The process repeats for  $2n$  steps as each word needs to be shifted once on to the stack and reduced once. After  $2n$  steps, the highest scoring state in agenda is taken as the output. The complexity of algorithm is  $n^2$ , as it takes  $2n$  steps to complete and during each step, the number of transition actions is proportional to  $\rho$ . Given a configuration  $C$ , the score of a possible action  $a$  is calculated as:

$$Score(a) = \vec{\theta} \cdot \Phi(\vec{C}, a),$$

where  $\vec{\theta}$  is the model parameter vector and  $\Phi(\vec{C}, a)$  denotes a feature vector consisting of *configuration* and *action* components. Given a set of labeled training examples, the averaged perceptron with early update (Collins and Roark, 2004) is used.

### 3.3 Morphological Generation

The last step is to inflate the lemmas in the sentence. There are three POS categories, including nouns, verbs and articles, for which we need to generate morphological forms. We use Wiktionary<sup>2</sup> as a basis and write a small set of rules

<sup>2</sup><https://en.wiktionary.org/>

### Algorithm 4: transition-based linearization

Table 7: Lemma rules. All rules are in the format: conditions  $\rightarrow$  candidate inflections. Nested conditions are listed in multi-lines with indentation. *wik* denotes english wiktionary.

similar to that used in Song et al. (2014), listed in Table 7, to generate a candidate set of inflections. An averaged perceptron classifier (Collins, 2002) is trained for each lemma. For distinguishing between singular and plural candidate verb forms, the feature templates in Table 8 are used.

## 4 Joint Method

We design a joint method for function word prediction (Section 3.1), linearization (Section 3.2) and morphological generation (Section 3.3) by further extending the transition-based system of Section 3.2, integrating actions for function word prediction and morphological generation.

Features for predicting singular/ plural verb forms
WORD( $n-1$ )WORD( $n-2$ )WORD( $n-3$ ); COUNT.SUBJ( $n$ );
COUNT( $n-1$ )COUNT( $n-2$ )COUNT( $n-3$ ); SUBJ( $n$ );
WORD( $n-1$ )WORD( $n-2$ ); COUNT( $n-1$ )COUNT( $n-2$ );
WORD( $n-1$ ); COUNT( $n-1$ ); WORD( $n+1$ ); COUNT( $n+1$ );

Table 8: Feature templates for predicting singular/ plural verb forms. Indices on the surface string:  $n$  – word index; Functions: WORD – word at index  $n$ ; COUNT – word at  $n$  is singular or plural form; SUBJ – word at subject of  $n$ ; COUNT.SUBJ – word at subject of  $n$  is singular or plural form.

Figure 5: Example for SPLITARC-*to*.

## 4.1 Transition Actions

In addition to SHIFT, LEFTARC and RIGHTARC in Section 3.2.1, we use the following new transition actions for inserting function words:

- INSERT, inserts comma at the present position;
- SPLITARC-*Word*, splits an arc in the input graph  $C$ , inserting a function word between the words connected by the arc. Here *Word* specifies the function word being inserted (Figure 5).

We generate a candidate set of inflections for each lemma following the approach in Section 3.3. For each candidate inflection, we generate a corresponding SHIFT transition action. The rules in Table 7 are used to prune impossible inflections.<sup>3</sup>

Table 9 shows the transition actions to linearize the graph in Figure 2. These newly introduced transition actions result in variability in the number of transition actions. With function word prediction, the number of transition actions for a bag of  $n$  words is not necessarily  $2n-1$ . For example, considering an INSERT, SPLITARC-*to* or SPLITARC-*that* action post each SHIFT action, the maximum number of possible actions is  $5n-1$ . This variance in the number of actions can impact the linear separability of state items. Following Zhu et al. (2013), we use IDLE actions as a form of padding method, which results in completed state items being further expanded up to  $5n-1$  steps. The joint model uses the same perceptron training al-

<sup>3</sup>For example in Figure 2, *price* is the subject of *be* and if *be* is in present tense and *price* is in plural form, the inflections {*am*, *is*, *was*, *were*} are impossible and *are* is the correct inflection for *be*. We therefore generate transition action as SHIFT-*are*.

gorithm and similar features compared to the baseline model.

## 4.2 Obtaining Possible Transition Actions Given a Configuration

Given a state  $s = ([\sigma | j \ i], \rho, A)$  and an input graph  $C$ , the possible transition actions include as a subset the transition actions in Algorithm 1 for shallow graph linearization. In addition, for each lemma being shifted, we enumerate its inflections and create SHIFT transition actions for each inflection. Further, we predict SPLITARC, INSERT and IDLE actions to handle function words. If node  $i$  has a child node in  $C$ , which is not shifted, we predict SPLITARC and INSERT. If  $i$  is sibling to  $j$ , we predict INSERT. If both the stack and buffer are empty, we predict IDLE. Pseudocode for GET-POSSIBLEACTIONS for the joint method is shown in Algorithm 5.

## 5 Experiments

### 5.1 Dataset

We work on the deep dataset from the Surface Realisation Shared Task (Belz et al., 2011)<sup>4</sup>. Sentences are represented as sets of unordered nodes with labeled semantic edges between them. Semantic representation is obtained by merging Nombank (Meyers et al., 2004), Propbank (Palmer et al., 2005) and syntactic dependencies. Edge labeling follows PropBank annotation scheme such as  $\{A0, A1, \dots, An\}$ . The nodes are annotated with lemma and where appropriate number, tense and participle features. Function words including

Table 10: Deep type training instance from Surface Realisation Shared Task 2011. *Sem* – semantic label, *ID* – unique ID of node within graph, *PID* – the ID of the parent, *Attr* – Attributes such as partic (participle), tense or number, *Lexeme* – lexeme which is resolved using wiktionary and rules in Table 7.

tween edges in the input deep graph and *gold output tree*. The gold output tree is the corresponding shallow tree from the shared task. We approach the task of linearization as extracting a linearized tree from the input semantic graph. So we exclude those instances which do not have edges corresponding to gold tree i.e mismatch between edges of gold tree and input graph. After excluding these instances, we have 34.3k training instances. We also exclude 800 training instances where the function words *to* and *that* have more than one child, and around 100 training instances where function words’ parent and child nodes are not connected by an arc in the deep graph. The above cases are deemed annotation mistakes. We thus train on a final subset of 33.4k training instances. The development set comprises 1034 instances and the test set comprises 2398 instances. Evaluation is done using the BLEU metric (Papineni et al., 2002).

## 6 Development Results

### 6.1 Influence of Beam Size

We study the effect of beam size on the accuracies of joint model in Figure 6, by varying the beam size and comparing the accuracies on development dataset over training iterations. Beam sizes of 64 and 128 perform the best. However, beam size 128 does not improve the performance significantly, yet is twice as slow compared to a beam size 64. So we retain a 64 beam for further experiments.

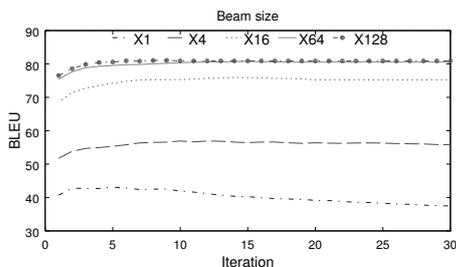

Figure 6: Influence of beam sizes.

	Pipeline	Joint
<i>to</i> infinitive	92.7	94.1
<i>that</i> complementizer	70.6	76.5
count of <i>comma</i>	60.2	63.3

Table 11: Average F-measure for function word prediction for development set.

## 6.2 Pipeline vs Joint Model

We compare the results of the joint model with the pipeline baseline system. Table 11 shows the development results of function word prediction, and Table 12 shows the overall development results. Our joint model of Transition-Based Deep Input Linearization (TBDIL) achieves an improvement of 5 BLEU points over the pipeline using the same feature source and training algorithm. Thanks to the sharing of word order information, the joint model improves function word prediction compared to the pipeline, which forbids such feature integration because function word prediction is the first step, taken before order becomes available.

## 7 Final Results

Table 13 shows the final results. The best performing system for the Shared Task was STUMABA-D by Bohnet et al. (2011), which leverages a large-scale n-gram language model. The joint model TBDIL significantly outperforms the pipeline system and achieves an improvement of 1 BLEU point over STUMABA-D, obtaining 80.49 BLEU without making use of external resources.

## 8 Analysis

Table 14 shows sample outputs from the Pipeline system and the corresponding output from TBDIL. In the first instance, the function word *to* is incorrectly predicted in the arc between nodes *does* and *yield* in the pipeline system. In case of TBDIL, the n-gram feature helps avoid incorrect insertion of *to* which demonstrates the advantage of integrating information across stages. In the second

System	BLEU Score
Pipeline	75.86
TBDIL	<b>80.77</b>

Table 12: Development results.

System	BLEU Score
STUMABA-D	79.43
Pipeline	70.99
TBDIL	<b>80.49</b>

TBDIL	economists who read september 's low level of factory job growth as a sign of a slowdown

Table 14: Example outputs.

instance, because of incorrect linearization, there is error propagation to morphological generation in the pipeline system. In particular, *economists* is linearized to the object part of the sentence and the subject is singular. This, in turn, results in the incorrect prediction of morphological form of verb *read* as its singular variant. In TBDIL, in contrast, the joint modelling of linearization and morphology helps ordering the sentence correctly.

## 9 Conclusion

We showed the usefulness of a joint model for the task of Deep Linearization, by taking (Puduppully et al., 2016) as the baseline and extending it to perform joint graph linearization, function word prediction and morphological generation. To our knowledge, this is the first work to use Transition-Based method for joint NLG from semantic structure. Our system gave the highest scores reported for the NLG 2011 shared task on Deep Input Linearization (Belz et al., 2011).

## A Obtaining possible transition actions given a configuration for Shallow Graph

During shallow linearization, a state is represented by  $s = ([\sigma|j \ i], \rho, A)$  and  $C$  is the input graph. Given  $C$ , the Decoder outputs actions which extract syntactic tree from the graph. Thus the Decoder outputs RIGHTARC or LEFTARC only if corresponding arc exists in  $C$ . The detailed pseudocode is given in Algorithm 1. If  $i$  has *direct child nodes* in  $C$ , the descendants of  $i$  are shifted (line 6-7) (see Algorithm 3). Here, *direct child nodes* (see Algorithm 2) include those child nodes of  $i$  for which  $i$  is the only parent or if there is more than one parent then every other parent is shifted on to the stack without possibility to reduce the child node. If no *direct child node* is in buffer, then descendants of  $i$  are shifted (line 9-10). Now, there are three configurations possible between  $i$  and  $j$ : 1.  $i$  and  $j$  are connected by arc in  $C$ . This results in RIGHTARC or LEFTARC action; 2.  $i$  is descendant of  $j$ . In this case the parents of  $i$  (such that they are descendants of  $j$ ) and siblings of  $i$  through such parents are shifted. 3.  $i$  is sibling of  $j$ . In this case, the parents of  $i$  and their descendants are shifted such that  $A$  remains consistent. Additionally, because the input is a graph structure, more than one of the above configuration can occur simultaneously. We analyse the three configurations in detail below.

Since the *direct child nodes* of  $i$  are shifted,  $\{j \leftarrow i\}$  results in a LEFTARC action (line 18). Also because the input is a graph,  $i$  can be a sibling node of  $j$ . In this case, the valid parents and siblings of  $i$  are shifted. We iterate through the other elements in stack to identify the valid parents and siblings. These conditions are encapsulated in PROCESSSIBLING (line 20). Conditions for RIGHTARC are similar to that of LEFTARC with the following differences. We ensure that there is no left arc relationship for  $j$  in  $A$  (line 11). If there is a left arc relationship for  $j$  in  $A$ , it means that in an arc-standard setting, the RIGHTARC actions for  $j$  have already been made. If  $i$  is a descendant of  $j$ , valid parents and siblings of  $i$  are shifted. We iterate through the parents of  $i$  and those parents which are in turn descendants of  $j$  and not shifted on to the stack are valid parents. We shift the parent and the subtree through each such parent. These conditions are denoted by PROCESSDESCENDANT (line 14).

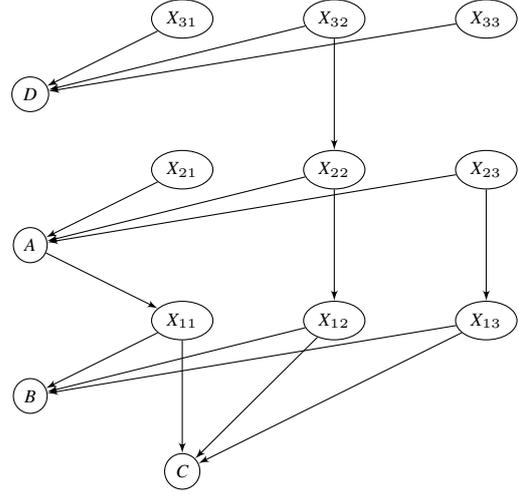

Figure 7: Sample graph to illustrate PROCESSSIBLING

If there is no arc between  $j$  and  $i$  and there is only one element on the stack, then the parents and siblings of  $i$  are shifted (line 22-23). If there is more than one element on the stack, and if  $i$  is descendant of  $j$ , then we use PROCESSDESCENDANT (line 25-26). If  $i$  is sibling to  $j$  we use PROCESSSIBLING (line 27-28).

Consider an example to see the working of PROCESSSIBLING in detail. In PROCESSSIBLING, we need to ensure that  $i$  is in stack because of sibling relation with  $j$  and we need to shift the valid parent nodes of  $i$  and their descendants. We call these valid nodes *inflection points*. Consider the following stack entries  $[D, A, B, C]$  with  $C$  as stack top. Assume that the input graph is as in Figure 7.  $C$  is sibling of  $B$  through  $B$ 's parents  $X_{11}, X_{12}, X_{13}$ . Out of these, only  $X_{11}$  and  $X_{12}$  are valid parents.  $X_{13}$  is sibling to  $A$  through  $A$ 's parent  $X_{23}$ . But  $X_{23}$  is in turn neither descendant of  $D$  nor sibling of  $D$ . Thus  $X_{13}$  is not a valid inflection point for  $C$ . Now,  $X_{12}$  is sibling of  $A$  through  $A$ 's parent  $X_{22}$ .  $X_{22}$  is in turn sibling of  $D$  through  $X_{32}$ . Thus there is a path to the stack bottom through a path of siblings/ descendant. In case of  $X_{11}$ ,  $X_{11}$  is descendant of stack element  $A$  and is thus valid.  $X_{11}$  and  $X_{12}$  are called valid inflection points. If inflection point is a common parent to both  $S_0$  and  $S_1$  then inflection point and its descendants are shifted. Instead, if inflection point is ancestor to  $S_0$ , then parents of  $S_0$  (say  $P_0$ ) which are descendants of inflection point are shifted. Additionally, descendants of  $P_0$  are shifted.

# Generating flexible proper name references in text: Data, models and evaluation

Thiago Castro Ferreira and Emiel Krahmer and Sander Wubben

Tilburg center for Cognition and Communication (TiCC)

Tilburg University

The Netherlands

{tcastrof, e. j. krahmer, s. wubben}@tilburguniversity.edu

## Abstract

This study introduces a statistical model able to generate variations of a proper name by taking into account the person to be mentioned, the discourse context and variation. The model relies on the REGnames corpus, a dataset with 53,102 proper name references to 1,000 people in different discourse contexts. We evaluate the versions of our model from the perspective of how human writers produce proper names, and also how human readers process them. The corpus<sup>1</sup> and the model<sup>2</sup> are publicly available.

## 1 Introduction

In automatic text generation, Referring Expression Generation (REG) is the task responsible for generating references to discourse entities, addressing, for example, the question whether the text should refer to an entity using a definite description (*the West Coast poet and patron saint of drinking writers*), a pronoun (*he*) or a proper name (*Henry Charles Bukowski*). REG is among the tasks which have received most attention in text generation (see Krahmer and van Deemter (2012), for a survey), but the vast majority of the research has concentrated on the generation of descriptions, while proper name generation has received virtually no attention, albeit with notable exceptions (Siddharthan et al., 2011; van Deemter, 2016) to which we return below.

Still, proper names occur frequently in texts. For instance, Ferreira et al. (2016a) showed that human writers use proper names in 91% of the cases to initially refer to persons. Indeed, some

earlier research on text generation has stated that discourse-new references should be generated by using the strategy to “simply give the name of the object (if it has a name)” (Reiter and Dale, 2000). However, the *Bukowski* example already indicates that this is not as straightforward as Reiter and Dale suggest - the poet’s full name is *Henry Charles Bukowski* and his birth name is *Heinrich Karl Bukowski*, but he is more commonly known as simply *Charles Bukowski*; see also van Deemter (2016), for a discussion of this and other complicating factors in proper name generation. In addition, Reiter and Dale (2000) do not address how repeated references using a name in a text should be generated. For instance, should our discourse-old example-writer be referred to as *Charles*, *Bukowski* or some combination of these and other attributes (e.g., using a modifier like *the poet Bukowski*)?

Imagine, for the sake of argument, that we would generate proper name references in a text by initially generating the full name, after which repeated references only consist of the last name (a.k.a. the family or surname). Intuitively, it is not difficult to come up with counterexamples to this “rule”. Above we already discussed the difficulties of deciding what the most appropriate full name reference is for *Henry Charles Bukowski*, which (like *Keith Rupert Murdoch* and *Walter Bruce Willis*) seems to be the combination of middle and last names (as opposed to *Oprah Gail Winfrey* and *Serena Jameka Williams*, for who it is more common the combination of first and last names). Moreover, using the last name for repeated references may work well for the likes of *Winston Churchill* and *Angela Merkel*, but seems less suitable for *Napoleon Bonaparte* or *Madonna Ciccone*, to mention just two. Moreover, our example rule cannot account for the occurrence of modifiers. And, finally, it seems highly unlikely

<sup>1</sup><http://ilk.uvt.nl/~tcastrof/regnames/>

<sup>2</sup><http://github.com/ThiagoCF05/ProperName>

that human writers would adhere to such a strict rule. Rather, one might expect writers to vary in their choices of which name to use, depending on stylistic and discourse factors, much like the choice of referential form varies as a function of such factors (Ferreira et al., 2016a; Ferreira et al., 2016b).

In general, we know very little about how proper names should be generated in text – as far as we know, there have been hardly any systematic corpus studies and only very little concrete proposals on how to automatically generate proper name references. In this paper, we therefore present a large scale corpus analysis, and, based on this, two versions of a new probabilistic model of proper name generation: one that always chooses the most likely proper name form and one that relies on a ‘roulettwheel’ selection model and hence will generate more varied references. These models rely both on the nature of the entity referred to (what is the likelihood that a given person will be referred to using, say, the first or last name?) and on the discourse context for generating proper name references in text. In an intrinsic evaluation experiment, we compare the performance of the two versions of this model with our implementations of the two proposals that have been made before (Siddharthan et al., 2011; van Deemter, 2016). We also describe a human evaluation experiment where we compare original texts with alternative versions that include proper names generated by our model.

## 2 Related work

Even though proper name references occur frequently in written text, their generation remains seriously understudied. A recent survey of REG models (Krahmer and van Deemter, 2012) has essentially nothing to say about the topic, and general surveys of automatic text generation such as Reiter and Dale (2000) only briefly mention a very basic rule (use a proper name, if available, for first references), without further specifying or evaluating it.

Recently, van Deemter (2016) has highlighted the importance of proper name generation. After discussing why a simple rule like the one proposed by Reiter and Dale cannot account for the complexities of proper name references in text, he argues that names could just be treated like other attributes in the generation of descriptions. Put dif-

ferently, the name of an object can be modelled just like its color or size (typical attributes used in REG examples) – just as a description like *the tall man* rules out men that are not tall, so does a proper name like *Charles* rule out other people not named Charles. A standard REG algorithm, such as, for example, the Incremental Algorithm (Dale and Reiter, 1995) can then be used to compute when a name should be used and in which form. Van Deemter’s work is of a theoretical nature; he has not implemented or tested this idea, so we cannot tell how well it can account for proper name references in text. In addition, in this form, his proposal cannot account for possible variations in proper name form throughout a text.

The most detailed study of proper name generation, as far as we know, is the seminal study by Siddharthan et al. (2011), which (re-)generates references to people in news summaries. For their algorithm(s), the authors present two manually constructed rules, based on earlier theories of reference, one for discourse-new references (including the full name) and one for discourse-old references (which in full says: “Use surname only, remove all pre- and post-modifiers.”). They discuss, based on corpus analyses, how notions like discourse-new and discourse-old can be learned without manual annotation, and how they co-determine whether additional attributes such as role and affiliation should be included. Finally, they show that their model leads to improved (more coherent) summaries. While the approach offers a very interesting solution for the generation of discourse-new proper name references with modifiers for major characters in a news story (*Former East German leader Erich Honecker*), the proper name generation rule itself is very similar to the example rule discussed in the introduction (use the full name for discourse-new references and only the surname for discourse-old references). It is not specified how the full name should be realised (remember the *Henry Charles Bukowski*-example), and neither can the approach deal with exceptions to the surname-only rule (remember the *Madonna Ciccone*-example) or with intratext variation.

## 3 REGnames

For our explorations, we relied on the REGnames corpus (Ferreira et al., 2016c). REGnames is a corpus of 53,102 proper names referring to 1,000

people in 15,241 texts. The corpus consists of webpages extracted from the Wikilinks corpus (Singh et al., 2012), which was initially collected for the study of cross-document coreference and consists of more than 40 million references to almost 3 million entities in around 11 million webpages. All the references annotated in Wikilinks were grouped according to the Wikipedia page of the entity. This procedure enables easy identification of the mentioned entity and facilitates the extraction of more information about it.

To build the REGnames corpus, Ferreira et al. (2016c) selected the 1,000 most frequently mentioned people in the Wikilinks corpus. Then for each person, they selected random webpages from Wikilinks which mention the person at least once. On all selected webpages, part-of-speech tagging, lemmatization, named entity recognition, dependency parsing, syntactic parsing, sentiment analysis and coreference resolution was performed by using the Stanford CoreNLP software (Manning et al., 2014).

All extracted proper names were automatically annotated with their syntactic position (subject, object or genitive noun phrase in a sentence) and referential statuses in the text (discourse-new or discourse-old) and in the sentence (sentence-new or sentence-old). The extracted proper names were also annotated according to their form, i.e. which kind(s) of name (first, middle and/or last names), and modifier(s) (title and/or appositive) were part of the proper name. To check for the presence of first, middle and last names, a Proper Name Knowledge Base was extracted from DBpedia (Bizer et al., 2009) with all the names of the people in the corpus. Then, to check for the presence of a title or an appositive, named entity recognition information and the dependency tree were used respectively.

In the corpus analysis, Ferreira et al. (2016c) noticed that proper name references generally decrease in lengths across the text. They also concluded that a discourse-old or sentence-new proper name reference in the object position of a sentence tends to be shorter than a discourse-new or sentence-old proper name reference in the subject position of a sentence. In general, the corpus is a valuable resource which can be used to train a statistical model for proper name generation, as we show in the next section.

## 4 A model for proper name generation

Similarly to the generation of definite descriptions, our model produces a proper name reference in two sequential steps: content selection and linguistic realization.

### 4.1 Content Selection

The content selection discussed here is analogous to the selection of semantic attributes (type, color, size, etc) when generating a description of an entity (Dale and Haddock, 1991; Dale and Reiter, 1995). However, instead of attributes, the content selection step in our model aims to choose the *form* of a proper name reference (which kind(s) of name and modifier(s) are part of the proper name reference).

**Features** By analysing the REGnames corpus, Ferreira et al. (2016c) observed that proper names vary in their forms throughout a text. Moreover, as discussed in the Introduction (Section 1), a proper name form can also be influenced by the person to be mentioned. Thus, we conditioned the choice of a specific proper name form by a set of discourse features that describe the reference as well as to the person to be mentioned.

Table 1 depicts the discourse features used to describe the proper name references. We choose them based on the analysis of the REGnames corpus (Section 3).

**Forms** Our model selects a proper name form over all forms annotated on the REGnames corpus, i.e. a total of 28 possible ones. Table 2 depicts the most frequent ones. The complete list can be found at the webpage that describes the REGnames corpus<sup>3</sup>.

**Notation** Given a person  $p$  to be referred to by his/her proper name and the set of discourse features  $D$  that describe the reference, we aim to predict the form  $f \in F$  of a proper name as Equation 1 shows.

$$P(f | D, p) = \frac{P(f | p) \prod_{d \in D} P(d | f, p)}{\sum_{f' \in F} P(f' | p) \prod_{d \in D} P(d | f', p)} \quad (1)$$

To account for unseen data, the conditional probabilities are computed using the additive

<sup>3</sup><http://ilk.uvt.nl/~tcastrof/regnames/>

Feature	Description
Syntactic Position	Subject, object or a genitive noun phrase in the sentence.
Referential Status	First mention of the referent (new) or not (old) at the level of text and sentence.

smoothing technique with  $\alpha = 1$ . Equations 2 and 3 summarize the procedure.

$$P(f | p) = \frac{\text{count}(f \cap p) + \alpha}{\text{count}(p) + \alpha|F|} \quad (2)$$

$$P(d | f, p) = \frac{\text{count}(d \cap f \cap p) + \alpha}{\text{count}(f \cap p) + \alpha|D|} \quad (3)$$

**Variation** Besides the fact that proper name references may vary in their forms throughout a text and according to the person to be referred to, they may also vary in similar situations of a text. In an extrinsic evaluation comparing human- and machine-generated summaries, for instance, Sidharthan et al. (2011) reported that the lack of variation in the form of discourse-old proper names references was one of the disadvantages of their summarization system in the cases where human summaries were chosen. Our model fills this gap by performing Equation 1 over all the proper name forms given a set of similar references. That is proper name references to the same person and described by the same set of discourse feature values. This procedure results in a frequency distribution over all relevant proper name forms. Then, similar to the roulettewheel selection of Ferreira et al. (2016b) for the choice of referential forms, we can randomly apply the frequencies into a group of similar references in such a way that their forms will be representative of the distribution predicted by the model. For instance, given a group of 5 references and a frequency distribution of 0.8 for the *first+last* form and 0.2 for the *last* form, 4 references would assume the first form, whereas 1 reference would assume the other one.

## 4.2 Linguistic Realization

Once we select the form of a proper name reference to a person in a particular discourse context, we linguistically realize this reference by choosing the most likely words - including titles and proper nouns - to be part of it. The process is analogous to the linguistic realization of a set of attribute-values into a description (Bohnet, 2008; Zarriess and Kuhn, 2013). Equation 4 summarizes it.

Form	Frequency
First+Last	46.2%
Last	34.9%
First	8.5%
Middle+Last	2.8%
First+Middle+Last	2.3%
Middle	1.5%
Others	3.5%

Table 2: Most popular proper name forms in REG-names corpus and their frequencies.

$$P(n_1 \dots n_t | f, p) = \prod_t P(n_t | n_{t-1}, \{e_i\}_{i=1}^{|f|}, p) \quad (4)$$

The vocabulary used in the linguistic realization step consists of all the titles found in REGnames, all the possible names of the given person present in the corpus’ proper name knowledge base, and an *end* token, present at the end of all proper name references in the training set. The process finishes when this token is predicted ( $n_t = END$ ). The choice of a word  $n_t$  is conditioned to the previous generated word in the proper name reference ( $n_{t-1}$ ), the elements present in the given form ( $\{e_i\}_{i=1}^{|f|}$ : constrained to first, middle and last name; plus title and appositive) and the person to be referred to ( $p$ ). If  $P(n_t | n_{t-1}, \{e_i\}_{i=1}^{|f|}, p) = 0$ , we drop the less frequent element from the given proper name form. If all the elements were dropped and the probability would still be 0, we conditioned the choice only to the person ( $P(n_t | p)$ ). Regarding the cases in which the original proper name form indicates the presence of an appositive, we add a description - obtained from Wikidata (Vrandečić and Krötzsch, 2014) - at the end of the generated proper name reference.

## 5 Baselines

In order to evaluate the performance of our model, we developed three baseline models. All the models have their outputs constrained to three choices: given name, surname and full name of a person.

Given name and surname are determined by the values of the following attributes in the person’s DBpedia page: *foaf:givenName* and *foaf:surname*. Full name was defined as the combination of both values. If these attributes are missing, we use the birth name of the person, also extracted from DBpedia (*dbp:birthName*). In this situation, the full name of a person will be the proper birth name, whereas given and surnames will be the first and last tokens from the birth name, respectively.

The first baseline, called *Random*, is a baseline that randomly chooses one of the three options to generate a proper name.

The second baseline is an adaptation of the model proposed by van Deemter (2016) and will be called *Deemter*. Among the full name, given name and surname of a person, our adaptation chooses the shortest name that distinguishes the mentioned person from all other entities in the current and previous 3 sentences in the text. It is important to stress that this model is our adaptation, since the proposal of van Deemter (2016) only applies for initial references, not for repeated ones in a text.

Finally, the third system we compare against is based on Siddharthan et al. (2011) and will be called *Siddharthan*. This baseline chooses the full name of a person for discourse-new references; and his/her surname otherwise.

## 6 Automatic Evaluation

We intrinsically evaluate the models by training and testing them on a subset of the REGnames corpus. This evaluation aims to investigate how close our model can produce proper name references to the ones generated by human writers.

### 6.1 Data

We considered a subset of the REGnames corpus as our evaluation data. From the 1,000 people in the corpus, we first filtered the ones whose birth names were not mentioned, or for whom the values of the DBpedia’s attributes *foaf:name*, *foaf:givenName* and *foaf:surname* were missing. This measure was taken in order to have a consistent vocabulary to linguistically realize the proper name references, as well as to make sure that our baselines would always have a consistent output. Then, from the remaining people, we only selected the ones with at least 50 proper name references in the REGnames corpus such that we could train and

test our model properly. In total, we used 43,655 proper names references to 432 people as our evaluation data.

In order to investigate the influence of the text domain in the generation of proper names, we classified the webpages from where our evaluation data were extracted according to 3 domains: Blog, News and Wiki. All the webpages whose the url contained the substrings *blog*, *tumblr* or *wordpress* were classified as part of the blog domain. If the substrings were *new* or *article*, the webpage was classified as a news. Finally, we classified as Wiki all the webpages whose the url contained the substring *wiki*. All the other webpages were grouped into a *Other domains* category.

### 6.2 Method

10-fold-cross-validation was performed to evaluate the models. We made sure that the number of references per person was uniform among the folds. To measure the models performance in the choice of the proper name form, accuracy was used. To check the similarity among the realized proper name reference and the gold standard one, we used the string edit distance.

### 6.3 Models

We evaluated the three proposed baselines (*Random*, *Deemter* and *Siddharthan*) and two versions of our model: *PN-Variation* and *PN+Variation*.

*PN-Variation* does not take the variation into account in the content selection. In other words, this model always chooses the most likely proper name form for the references in the test set which refer to the same person and are described by the same combination of discourse feature values. On the other hand, *PN+Variation* takes variation into account by applying the distribution of proper name forms obtained from the training set to the similar references in the test set, as explained in Section 4.1.

### 6.4 Results

Table 3 summarizes the accuracy-scores of the models in the prediction of the proper name forms. Both versions of our model outperform the baselines for all the domains. *PN-Variation* is the model with the highest accuracy.

Figure 1 depicts the string edit distance among the gold standard proper names and the ones generated by the proposed models. A Repeated Measures ANOVA determined that the string edit dis-

Model	Blog	News	Wiki	Other domains	Overall
Random	0.25	0.22	0.22	0.25	0.25
Deemter	0.33	0.30	0.28	0.33	0.33
Siddharthan	0.52	0.48	0.42	0.45	0.48
PN-Variation	0.66	0.63	0.66	0.70	<b>0.68</b>
PN+Variation	0.58	0.55	0.59	0.63	0.60

Table 3: Proper name form accuracies of our two models (PN-Variation and PN+Variation) as a function of text genre and compared to three baseline models (Random, Deemter, Siddharthan).

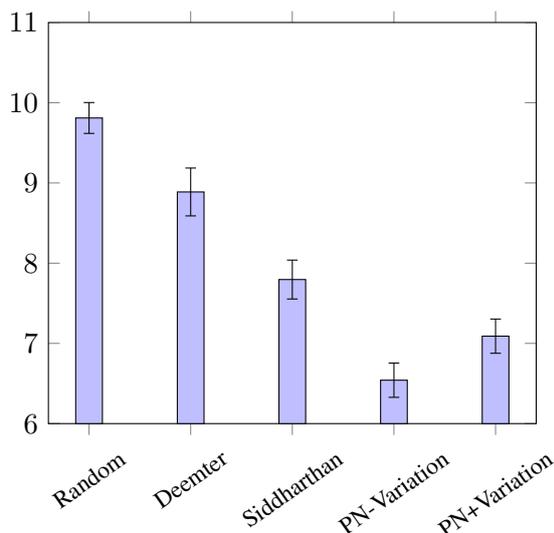

Figure 1: String edit distance in the overall corpus. Error bars represent 95% confidence intervals.

tances of the models were significantly different ( $F(4, 36) = 1630, p < .001$ ). We performed a post hoc analysis with paired t-test using Bonferroni adjusted alpha levels of 0.005 per test (0.05/10). Both versions of our model significantly outperform the baselines with all pairwise comparisons significant at  $p < .001$ . Regarding the comparison of our models, *PN-Variation* is significantly better than *PN+Variation* ( $t(9) = -38.14, p < .001$ ).

Figure 2 shows the evaluation of our models by domain. A Repeated Measures ANOVA shows that the string edit distances of the models are significantly different in all domains (Blog:  $F(4, 36) = 718.8, p < .001$ ; News:  $F(4, 36) = 308.2, p < .001$ ; Wiki:  $F(4, 36) = 118.5, p < .001$ ; Other domains:  $F(4, 36) = 2213, p < .001$ ).

We also performed a post hoc analysis for the results by domain in the same style we did for the general results. In the blog and news do-

main, both versions of our model significantly outperform all the baselines with all pairwise comparisons significant at  $p < .005$ . Among our models, *PN-Variation* is significantly better than *PN+Variation* (Blog:  $t(9) = -26.33, p < .001$ ; News:  $t(9) = -7.45, p < .001$ ).

In the wiki domain and in texts which are not part of the blog, news and wiki domain, both versions of our model also significantly outperform all the baselines with all pairwise comparisons significant at  $p < .001$ . The difference in the results of *PN-Variation* and *PN+Variation* is also significant (Wiki:  $t(9) = -4.91, p < .001$ ; Other domains:  $t(9) = -27.14, p < .001$ ).

## 7 Human Evaluation

We also performed a human evaluation aiming to compare original texts with alternative versions whose proper name references were generated by our model. This evaluation aims to investigate the quality of the proper name references from the perspective of the human reader.

### 7.1 Materials

We used 9 abstracts from English Wikipedia pages whose topic is one of the people studied in the REGnames corpus. They were extracted from DBpedia and have at least 10 proper name references to the topic.

Although our model did not yield its best results for this domain, it was chosen based on the relatively short length of the texts and the large amount of proper name references they have. Moreover, the proper name references in Wikipedia abstracts are similar to the ones generated by our *Siddharthan* baseline, i.e. a full name to discourse-new people, and surname to discourse-old people.

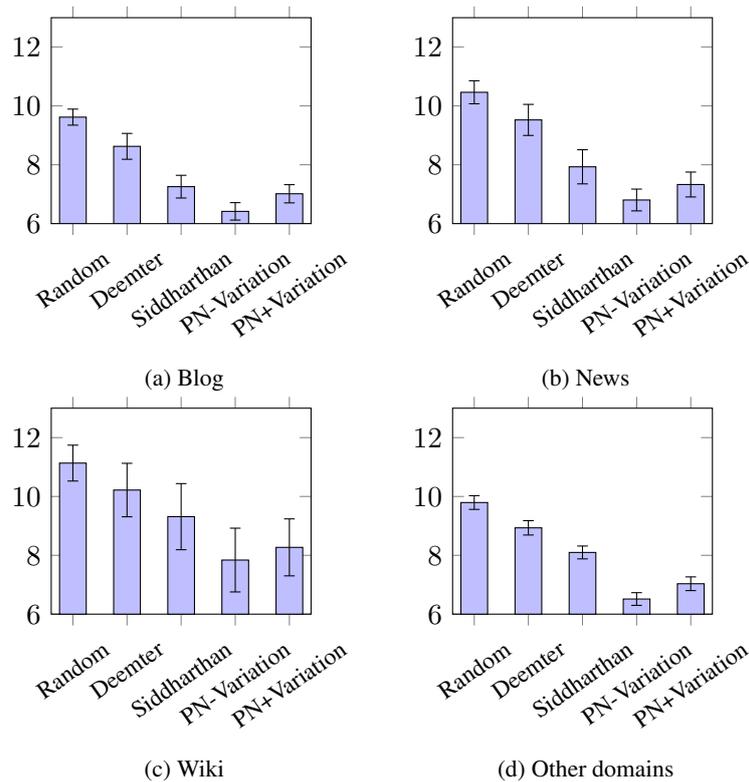

Figure 2: String edit distances of the models in the (2a) blog, (2b) news, (2c) wiki and (2d) in other domains which are not the previous ones. Error bars represent 95% confidence intervals.

## 7.2 Method

For each abstract, we designed 3 trials. In the first, we presented participants with the original text next to the version with the proper name references generated by the *PN-Variation* model (Original vs. No Variation). In the second, we presented the original text next to the version with the proper name references generated by the *PN+Variation* (Original vs. Variation). Finally, the third trial consists of the text versions with the proper name references produced by both versions of our model (No Variation vs. Variation). The trials of a text were distributed in different lists such that we obtained 3 lists with 9 texts - 3 trials of each type in a list. In all the texts, the proper name references were highlighted in yellow. For each trial, we asked participants to choose which text they preferred, taking into account the highlighted references. The experiment is publicly available<sup>4</sup>.

We recruited 60 participants through Crowdfunder – 20 per list. Of the participants, 44 were female and their average age was 36 years. All participants reported to be proficient in the English language (58 were native speakers).

<sup>4</sup><http://ilk.uvt.nl/~tcastrof/eacl2017>

## 7.3 Results

The texts of the “Original” version were the favourite of 69% of the participants in comparison with texts of the “No Variation” version (Chi-square  $\chi^2(2, 180) = 25.69, p < .001$ ), and 75% participants with the “Variation” version (Chi-square  $\chi^2(2, 180) = 45; p < .001$ ). Regarding the “No Variation vs. Variation” trials, texts of the “No Variation” version were the favourite of the participants in 59% of the cases (Chi-square  $\chi^2(2, 180) = 6.42; p < .05$ ).

## 8 General Discussion

Proper name generation is a seriously understudied phenomenon in automatic text generation. There are many different ways in which a person can be referred to in a text using their name (*Barack Hussein Obama II, Barack Obama, Obama, President Obama*, etc.) and arguably a text that uses different naming formats in different conditions is more human-like than one that relies on a fixed strategy (e.g., always use the full name).

This paper introduced a new statistical model for the generation of proper names in text, taking into account three different factors: (1) who

the person is, (2) in which discourse context the proper name reference should be generated and (3) the different forms that a proper name can assume in similar situations (variation). The model was developed based on the REGnames corpus (Ferreira et al., 2016c), which contains a large number of proper name references in various discourse situations. We also implemented two other systems for the sake of comparison: one based on the Siddharthan et al. (2011) model and one based on the ideas for proper name reference proposed by van Deemter (2016).

We developed two versions of our model: one that deterministically generated the best proper name form in a given setting (*PN-variation*), and one that relied on a probabilistic distribution over different forms, allowing for more variation in the output (*PN+Variation*). Both models were systematically compared to a random baseline and the two alternative models due to Siddharthan et al. (2011) and van Deemter (2016).

**Automatic Evaluation** We first conducted an automatic evaluation investigating to what extent the evaluated models produced proper name references similar to the ones generated by human writers, using a held-out subset of the REGnames corpus. In general, we found that both versions of our model were able to outperform a random baseline and the two reference systems, where the version without variation (*PN-Variation*) yielded the best results. Across text domains, there was variation in the performance of both versions of our model. The worst results were registered in the Wiki domain, suggesting that text domain is a factor that may be taken into account in the task of generating proper names.

**Human Evaluation** In the automatic evaluation experiment, the differences between the system with and without variation were small, so in a second study we asked whether human readers preferred the output from one of these systems over the other. For this purpose, we conducted an experiment consisting of pairwise comparisons based on texts taken from the Wikipedia domain, where we compared the output produced by the *PN-variation* and the *PN+variation* system with the original text and also among them. Interestingly, we found that people had a general preference for the no-variation model over the one that non-deterministically generated varied texts. This

suggests that readers prefer consistency in proper name references to the same topic in similar situations, which is different from the choice of referential *form* (Ferreira et al., 2016b).

Additionally, we found that participants preferred the original over the regenerated texts. We suspect that this preference was due to the initial discourse-new proper name reference, which in the Wikipedia texts has a special status. Usually, the initial reference to the topic is not the most common proper name reference in other domains, but a specific Wikipedia format which our system does not produce. For example, the original text about Magic Johnson starts with *Earvin “Magic” Johnson Jr.* in the discourse-new proper name reference, while our system simply produced *Magic Johnson*.

**Semantic web** Earlier work on REG models has concentrated on the generation of descriptions, typically assuming the existence of a knowledge base of entities (Dale and Haddock, 1991; Dale and Reiter, 1995) or introducing one to small domains (Gatt and Belz, 2010). Our REG models for proper names, however, strongly rely on the semantic web as an information resource of the entities to be referred to. Databases like DBpedia (Bizer et al., 2009) and Wikidata (Vrandečić and Krötzsch, 2014) provide information about thousands of entities and can be used in different domains.

**Baselines** We developed two powerful baselines based on proposals that have been made before. *Deemter* (van Deemter, 2016) relies on the criteria of the first developed REG models (Dale and Haddock, 1991; Dale and Reiter, 1995): given a target, produce a reference that distinguishes it from the distractors in the context. Our model as presented does not make this assumption (it does not always produce a proper name reference that distinguishes the target from the distractors). However, this could be incorporated into our model as well. For instance, given a list of the most likely proper name references produced by our model in a situation, we can choose the one with the highest likelihood that distinguishes the target from all other entities in the current and previous 3 sentences in the text (as in the *Deemter* model).

Regarding performance, *Siddharthan* is the baseline that performed best. The original version, proposed in Siddharthan et al. (2011), is

even able to decide whether to include a modifier in a discourse-new reference based on the global salience of the entity mentioned. However, the model is arguably more limited in the production of a proper name itself. By always generating a surname in discourse-old references for instance, the Siddharthan model is not able to generate at least 10% of the references in the REGnames corpus (8.5% consist of *first name* references, and 1.5% of *middle name* ones).

**Conclusion** In sum, we conclude that our model is able to generate proper name references similar to the ones produced by human writers. In future research, it would be interesting to further investigate the role of text genre in proper name references as well as the influence of variation on proper name forms.

## Abstract

Conventional graph-based dependency parsers guarantee a tree structure both during training and inference. Instead, we formalize dependency parsing as the problem of independently selecting the head of each word in a sentence. Our model which we call DENSE (as shorthand for **D**ependency **N**eural **S**election) produces a distribution over possible heads for each word using features obtained from a bidirectional recurrent neural network. Without enforcing structural constraints during training, DENSE generates (at inference time) trees for the overwhelming majority of sentences, while non-tree outputs can be adjusted with a maximum spanning tree algorithm. We evaluate DENSE on four languages (English, Chinese, Czech, and German) with varying degrees of non-projectivity. Despite the simplicity of the approach, our parsers are on par with the state of the art.<sup>1</sup>

## 1 Introduction

Dependency parsing plays an important role in many natural language applications, such as relation extraction (Fundel et al., 2007), machine translation (Carreras and Collins, 2009), language modeling (Chelba et al., 1997; Zhang et al., 2016) and ontology construction (Snow et al., 2005). Dependency parsers represent syntactic information as a set of head-dependent relational arcs, typically constrained to form a tree. Practically all models proposed for dependency parsing in recent years can be described as graph-based (McDon-

ald et al., 2005a) or transition-based (Yamada and Matsumoto, 2003; Nivre et al., 2006b).

Graph-based dependency parsers are typically arc-factored, where the score of a tree is defined as the sum of the scores of all its arcs. An arc is scored with a set of local features and a linear model, the parameters of which can be effectively learned with online algorithms (Crammer and Singer, 2001; Crammer and Singer, 2003; Freund and Schapire, 1999; Collins, 2002). In order to efficiently find the best scoring tree during training *and* decoding, various maximization algorithms have been developed (Eisner, 1996; Eisner, 2000; McDonald et al., 2005b). In general, graph-based methods are optimized globally, using features of single arcs in order to make the learning and inference tractable. Transition-based algorithms factorize a tree into a set of parsing actions. At each transition state, the parser scores a candidate action conditioned on the state of the transition system and the parsing history, and greedily selects the highest-scoring action to execute. This score is typically obtained with a classifier based on non-local features defined over a rich history of parsing decisions (Yamada and Matsumoto, 2003; Zhang and Nivre, 2011).

Regardless of the algorithm used, most well-known dependency parsers, such as the MST-Parser (McDonald et al., 2005b) and the MaltParser (Nivre et al., 2006a), rely on extensive feature engineering. Feature templates are typically manually designed and aim at capturing head-dependent relationships which are notoriously sparse and difficult to estimate. More recently, a few approaches (Chen and Manning, 2014; Lei et al., 2014a; Kiperwasser and Goldberg, 2016) apply neural networks for learning dense feature representations. The learned features are subsequently used in a conventional graph- or transition-based parser, or better de-

<sup>1</sup>Our code is available at [http://github.com/XingxingZhang/dense\\_parser](http://github.com/XingxingZhang/dense_parser).

signed variants (Dyer et al., 2015).

In this work, we propose a simple neural network-based model which learns to select the head for each word in a sentence without enforcing tree structured output. Our model which we call DENSE (as shorthand for **Dependency Neural Selection**) employs bidirectional recurrent neural networks to learn feature representations for words in a sentence. These features are subsequently used to predict the head of each word. Although there is nothing inherent in the model to enforce tree-structured output, when tested on an English dataset, it is able to generate trees for 95% of the sentences, 87% of which are projective. The remaining non-tree (or non-projective) outputs are post-processed with the Chu-Liu-Edmond (or Eisner) algorithm. DENSE uses the head selection procedure to estimate arc weights during training. During testing, it essentially reduces to a standard graph-based parser when it fails to produce tree (or projective) output.

We evaluate our model on benchmark dependency parsing corpora, representing four languages (English, Chinese, Czech, and German) with varying degrees of non-projectivity. Despite the simplicity of our approach, experiments show that the resulting parsers are on par with the state of the art.

## 2 Related Work

**Graph-based Parsing** Graph-based dependency parsers employ a model for scoring possible dependency graphs for a given sentence. The graphs are typically factored into their component arcs and the score of a tree is defined as the sum of its arcs. This factorization enables tractable search for the highest scoring graph structure which is commonly formulated as the search for the maximum spanning tree (MST). The Chu-Liu-Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967; McDonald et al., 2005b) is often used to extract the MST in the case of non-projective trees, and the Eisner algorithm (Eisner, 1996; Eisner, 2000) in the case of projective trees. During training, weight parameters of the scoring function can be learned with margin-based algorithms (Crammer and Singer, 2001; Crammer and Singer, 2003) or the structured perceptron (Freund and Schapire, 1999; Collins, 2002). Beyond basic first-order models, the literature offers a few examples of

higher-order models involving sibling and grand parent relations (Carreras, 2007; Koo et al., 2010; Zhang and McDonald, 2012). Although more expressive, such models render both training and inference more challenging.

**Transition-based Parsing** As the term implies, transition-based parsers conceptualize the process of transforming a sentence into a dependency tree as a sequence of transitions. A transition system typically includes a stack for storing partially processed tokens, a buffer containing the remaining input, and a set of arcs containing all dependencies between tokens that have been added so far (Nivre, 2003; Nivre et al., 2006b). A dependency tree is constructed by manipulating the stack and buffer, and appending arcs with predetermined operations. Most popular parsers employ an *arc-standard* (Yamada and Matsumoto, 2003; Nivre, 2004) or *arc-eager* transition system (Nivre, 2008). Extensions of the latter include the use of non-local training methods to avoid greedy error propagation (Zhang and Clark, 2008; Huang and Sagae, 2010; Zhang and Nivre, 2011; Goldberg and Nivre, 2012).

**Neural Network-based Features** Neural network representations have a long history in syntactic parsing (Mayberry and Miikkulainen, 1999; Henderson, 2004; Titov and Henderson, 2007). Recent work uses neural networks in lieu of the linear classifiers typically employed in conventional transition- or graph-based dependency parsers. For example, Chen and Manning (2014) use a feed forward neural network to learn features for a transition-based parser, whereas Lei et al. (2014a) do the same for a graph-based parser. Lei et al. (2014b) apply tensor decomposition to obtain word embeddings in their syntactic roles, which they subsequently use in a graph-based parser. Dyer et al. (2015) redesign components of a transition-based system where the buffer, stack, and action sequences are modeled separately with stack long short-term memory networks. The hidden states of these LSTMs are concatenated and used as features to a final transition classifier. Kiperwasser and Goldberg (2016) use bidirectional LSTMs to extract features for a transition- and graph-based parser, whereas Cross and Huang (2016) build a greedy arc-standard parser using similar features.

In our work, we formalize dependency parsing

as the task of finding for each word in a sentence its most probable head. Both head selection and the features it is based on are learned using neural networks. The idea of modeling child-parent relations independently dates back to Hall (2007) who use an edge-factored model to generate  $k$ -best parse trees which are subsequently reranked using a model based on rich global features. Later Smith (2010) show that a head selection variant of their loopy belief propagation parser performs worse than a model which incorporates tree structure constraints. Our parser is conceptually simpler: we rely on head selection to do most of the work and decode the best tree *directly* without using a reranker. In common with recent neural network-based dependency parsers, we aim to alleviate the need for hand-crafting feature combinations. Beyond feature learning, we further show that it is possible to simplify the training of a graph-based dependency parser in the context of bidirectional recurrent neural networks.

### 3 Dependency Parsing as Head Selection

In this section we present our parsing model, DENSE, which tries to predict the head of each word in a sentence. Specifically, the model takes as input a sentence of length  $N$  and outputs  $N$  ⟨head, dependent⟩ arcs. We describe the model focusing on unlabeled dependencies and then discuss how it can be straightforwardly extended to the labeled setting. We begin by explaining how words are represented in our model and then give details on how DENSE makes predictions based on these learned representations. Since there is no guarantee that the outputs of DENSE are trees (although they mostly are), we also discuss how to extend DENSE in order to enforce projective and non-projective tree outputs. Throughout this paper, lowercase boldface letters denote vectors (e.g.,  $\mathbf{v}$  or  $\mathbf{v}_i$ ), uppercase boldface letters denote matrices (e.g.,  $\mathbf{M}$  or  $\mathbf{M}_b$ ), and lowercase letters denote scalars (e.g.,  $w$  or  $w_i$ ).

#### 3.1 Word Representation

Let  $S = (w_0, w_1, \dots, w_N)$  denote a sentence of length  $N$ ; following common practice in the dependency parsing literature (Kübler et al., 2009), we add an artificial ROOT token represented by  $w_0$ . Analogously, let  $A = (\mathbf{a}_0, \mathbf{a}_1, \dots, \mathbf{a}_N)$  denote the representation of sentence  $S$ , with  $\mathbf{a}_i$  representing word  $w_i$  ( $0 \leq i \leq N$ ). Besides encoding infor-

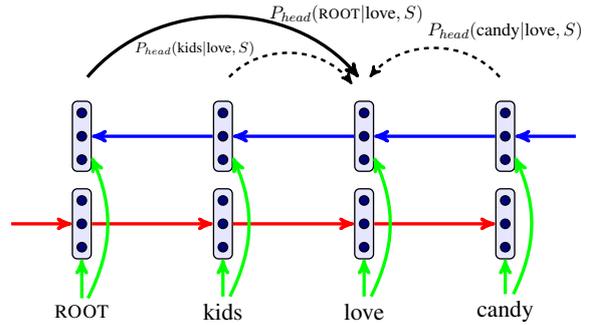

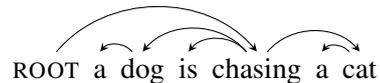

Figure 1: DENSE estimates the probability a word being the head of another word based on bidirectional LSTM representations for the two words.  $P_{head}(\text{ROOT}|\text{love}, S)$  is the probability of ROOT being the head of *love* (dotted arcs denote candidate heads; the solid arc is the goldstandard).

mation about each  $w_i$  in isolation (e.g., its lexical meaning or POS tag),  $\mathbf{a}_i$  must also encode  $w_i$ 's positional information within the sentence. Such information has been shown to be important in dependency parsing (McDonald et al., 2005a). For example, in the following sentence:

the head of the first *a* is *dog*, whereas the head of the second *a* is *cat*. Without considering positional information, a model cannot easily decide which *a* (nearer or farther) to assign to *dog*.

Long short-term memory networks (Hochreiter and Schmidhuber, 1997; LSTMs), a type of recurrent neural network with a more complex computational unit, have proven effective at capturing long-term dependencies. In our case LSTMs allow to represent each word on its own and within a sequence leveraging long-range contextual information. As shown in Figure 1, we first use a forward LSTM ( $\text{LSTM}^F$ ) to read the sentence from left to right and then a backward LSTM ( $\text{LSTM}^B$ ) to read the sentence from right to left, so that the entire sentence serves as context for each word:<sup>2</sup>

$$\mathbf{h}_i^F, \mathbf{c}_i^F = \text{LSTM}^F(\mathbf{x}_i, \mathbf{h}_{i-1}^F, \mathbf{c}_{i-1}^F) \quad (1)$$

$$\mathbf{h}_i^B, \mathbf{c}_i^B = \text{LSTM}^B(\mathbf{x}_i, \mathbf{h}_{i+1}^B, \mathbf{c}_{i+1}^B) \quad (2)$$

where  $\mathbf{x}_i$  is the feature vector of word  $w_i$ ,  $\mathbf{h}_i^F \in \mathbb{R}^d$  and  $\mathbf{c}_i^F \in \mathbb{R}^d$  are the hidden states and memory cells for the  $i$ th word  $w_i$  in  $\text{LSTM}^F$  and  $d$  is

<sup>2</sup>For more detail on LSTM networks, see e.g., Graves (2012) or Goldberg (2016).

the hidden unit size.  $\mathbf{h}_i^F$  is also the representation for  $w_{0:i}$  ( $w_i$  and its left neighboring words) and  $\mathbf{c}_i^F$  is an internal state maintained by LSTM<sup>F</sup>.  $\mathbf{h}_i^B \in \mathbb{R}^d$  and  $\mathbf{c}_i^B \in \mathbb{R}^d$  are the hidden states and memory cells for the backward LSTM<sup>B</sup>. Each token  $w_i$  is represented by  $\mathbf{x}_i$ , the concatenation of two vectors corresponding to  $w_i$ 's lexical and POS tag embeddings:

$$\mathbf{x}_i = [\mathbf{W}_e \cdot e(w_i); \mathbf{W}_t \cdot e(t_i)] \quad (3)$$

where  $e(w_i)$  and  $e(t_i)$  are one-hot vector representations of token  $w_i$  and its POS tag  $t_i$ ;  $\mathbf{W}_e \in \mathbb{R}^{s \times |V|}$  and  $\mathbf{W}_t \in \mathbb{R}^{q \times |T|}$  are the word and POS tag embedding matrices, where  $|V|$  is the vocabulary size,  $s$  is the word embedding size,  $|T|$  is the POS tag set size, and  $q$  the tag embedding size. The hidden states of the forward and backward LSTMs are concatenated to obtain  $\mathbf{a}_i$ , the final representation of  $w_i$ :

$$\mathbf{a}_i = [\mathbf{h}_i^F; \mathbf{h}_i^B] \quad i \in [0, N] \quad (4)$$

Note that bidirectional LSTMs are one of many possible ways of representing word  $w_i$ . Alternative representations include embeddings obtained from feed-forward neural networks (Chen and Manning, 2014; Lei et al., 2014a), character-based embeddings (Ballesteros et al., 2015), and more conventional features such as those introduced in McDonald et al. (2005a).

### 3.2 Head Selection

We now move on to discuss our formalization of dependency parsing as head selection. We begin with unlabeled dependencies and then explain how the model can be extended to predict labeled ones.

In a dependency tree, a head can have multiple dependents, whereas a dependent can have only one head. Based on this fact, dependency parsing can be formalized as follows. Given a sentence  $S = (w_0, w_1, \dots, w_N)$ , we aim to find for each word  $w_i \in \{w_1, w_2, \dots, w_n\}$  the most probable head  $w_j \in \{w_0, w_1, \dots, w_N\}$ . For example, in Figure 1, to find the head for the token *love*, we calculate probabilities  $P_{head}(\text{ROOT}|\text{love}, S)$ ,  $P_{head}(\text{kids}|\text{love}, S)$ , and  $P_{head}(\text{candy}|\text{love}, S)$ , and select the highest. More formally, we estimate the probability of token  $w_j$  being the head of token  $w_i$  in sentence  $S$  as:

$$P_{head}(w_j|w_i, S) = \frac{\exp(g(\mathbf{a}_j, \mathbf{a}_i))}{\sum_{k=0}^N \exp(g(\mathbf{a}_k, \mathbf{a}_i))} \quad (5)$$

where  $\mathbf{a}_i$  and  $\mathbf{a}_j$  are vector-based representations of  $w_i$  and  $w_j$ , respectively (described in Section 3.1);  $g(\mathbf{a}_j, \mathbf{a}_i)$  is a neural network with a single hidden layer that computes the associative score between representations  $\mathbf{a}_i$  and  $\mathbf{a}_j$ :

$$g(\mathbf{a}_j, \mathbf{a}_i) = \mathbf{v}_a^\top \cdot \tanh(\mathbf{U}_a \cdot \mathbf{a}_j + \mathbf{W}_a \cdot \mathbf{a}_i) \quad (6)$$

where  $\mathbf{v}_a \in \mathbb{R}^{2d}$ ,  $\mathbf{U}_a \in \mathbb{R}^{2d \times 2d}$ , and  $\mathbf{W}_a \in \mathbb{R}^{2d \times 2d}$  are weight matrices of  $g$ . Note that the candidate head  $w_j$  can be the ROOT, while the dependent  $w_i$  cannot. Equations (5) and (6) compute the probability of adding an arc between two words, in a fashion similar to the neural attention mechanism in sequence-to-sequence models (Bahdanau et al., 2015).

We train our model by minimizing the negative log likelihood of the gold standard ⟨head, dependent⟩ arcs in all training sentences:

$$J(\theta) = -\frac{1}{|\mathcal{T}|} \sum_{S \in \mathcal{T}} \sum_{i=1}^{N_S} \log P_{head}(h(w_i)|w_i, S) \quad (7)$$

where  $\mathcal{T}$  is the training set,  $h(w_i)$  is  $w_i$ 's gold standard head<sup>3</sup> within sentence  $S$ , and  $N_S$  the number of words in  $S$  (excluding ROOT). During inference, for each word  $w_i$  ( $i \in [1, N_S]$ ) in  $S$ , we greedily choose the most likely head  $w_j$  ( $j \in [0, N_S]$ ):

$$w_j = \arg \max_{w_j: j \in [0, N_S]} P_{head}(w_j|w_i, S) \quad (8)$$

Note that the prediction for each word  $w_i$  is made independently of the other words in the sentence.

Given our greedy inference method, there is no guarantee that predicted ⟨head, dependent⟩ arcs form a tree (maybe there are cycles). However, we empirically observed that most outputs during inference are indeed trees. For instance, on an English dataset, 95% of the arcs predicted on the development set are trees, and 87% of them are projective, whereas on a Chinese dataset, 87% of the arcs form trees, 73% of which are projective. This indicates that although the model does not explicitly model tree structure during training, it is able to figure out from the data (which consists of trees) that it should predict them.

So far we have focused on unlabeled dependencies, however it is relatively straightforward to extend DENSE to produce labeled dependencies. We basically train an additional classifier

<sup>3</sup>Note that  $h(w_i)$  can be ROOT.

to predict labels for the arcs which have been already identified. The classifier takes as input features  $[\mathbf{a}_i; \mathbf{a}_j; \mathbf{x}_i; \mathbf{x}_j]$  representing properties of the arc  $\langle w_j, w_i \rangle$ . These consist of  $\mathbf{a}_i$  and  $\mathbf{a}_j$ , the LSTM-based representations for  $w_i$  and  $w_j$  (see Equation (4)), and their word and part-of-speech embeddings,  $\mathbf{x}_i$  and  $\mathbf{x}_j$  (see Equation (3)). Specifically, we use a trained DENSE model to go through the training corpus and generate features and corresponding dependency labels as training data. We employ a two-layer rectifier network (Glorot et al., 2011) for the classification task.

### 3.3 Maximum Spanning Tree Algorithms

As mentioned earlier, greedy inference may not produce well-formed trees. In this case, the output of DENSE can be adjusted with a maximum spanning tree algorithm. We use the Chu-Liu-Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967) for building non-projective trees and the Eisner (1996) algorithm for projective ones.

Following McDonald et al. (2005b), we view a sentence  $S = (w_0 = \text{ROOT}, w_1, \dots, w_N)$  as a graph  $G_S = \langle V_S, E_S \rangle$  with the sentence words and the dummy root symbol as vertices and a directed edge between every pair of distinct words and from the root symbol to every word. The directed graph  $G_S$  is defined as:

$$\begin{aligned} V_S &= \{w_0 = \text{ROOT}, w_1, \dots, w_N\} \\ E_S &= \{\langle i, j \rangle : i \neq j, \langle i, j \rangle \in [0, N] \times [1, N]\} \\ s(i, j) &= P_{\text{head}}(w_i | w_j, S) \quad \langle i, j \rangle \in E_S \end{aligned}$$

where  $s(i, j)$  is the weight of edge  $\langle i, j \rangle$  and  $P_{\text{head}}(w_i | w_j, S)$  is known. The problem of dependency parsing now boils down to finding the tree with the highest score which is equivalent to finding a MST in  $G_S$  (McDonald et al., 2005b).

**Non-projective Parsing** To build a non-projective parser, we solve the MST problem with the Chu-Liu-Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967). The algorithm selects for each vertex (excluding ROOT) the in-coming edge with the highest weight. If a tree results, it must be the maximum spanning tree and the algorithm terminates. Otherwise, there must be a cycle which the algorithm identifies, contracts into a single vertex and recalculates edge weights going into and out of the cycle. The greedy inference strategy described in Equation (8)) is essentially a sub-procedure in the Chu-Liu-Edmonds algorithm

with the algorithm terminating after the first iteration. In implementation, we only run the Chu-Liu-Edmonds algorithm through graphs with cycles, i.e., non-tree outputs.

**Projective Parsing** For projective parsing, we solve the MST problem with the Eisner (1996) algorithm. The time complexity of the Eisner algorithm is  $O(N^3)$ , while checking if a tree is projective can be done reasonably faster, with a  $O(N \log N)$  algorithm. Therefore, we only apply the Eisner algorithm to the non-projective output of our greedy inference strategy. Finally, it should be noted that the *training* of our model does not rely on the Chu-Liu-Edmonds or Eisner algorithm, or any other graph-based algorithm. MST algorithms are only used at *test* time to correct non-tree outputs which are a minority; DENSE acquires underlying tree structure constraints from the data without an explicit learning algorithm.

## 4 Experiments

We evaluated our parser in a projective and non-projective setting. In the following, we describe the datasets we used and provide training details for our models. We also present comparisons against multiple previous systems and analyze the parser’s output.

### 4.1 Datasets

In the projective setting, we assessed the performance of our parser on the English Penn Treebank (PTB) and the Chinese Treebank 5.1 (CTB). Our experimental setup closely follows Chen and Manning (2014) and Dyer et al. (2015).

For English, we adopted the Stanford basic dependencies (SD) representation (De Marneffe et al., 2006).<sup>4</sup> We follow the standard splits of PTB, sections 2–21 were used for training, section 22 for development, and section 23 for testing. POS tags were assigned using the Stanford tagger (Toutanova et al., 2003) with an accuracy of 97.3%. For Chinese, we follow the same split of CTB5 introduced in Zhang and Clark (2008). In particular, we used sections 001–815, 1001–1136 for training, sections 886–931, 1148–1151 for development, and sections 816–885, 1137–1147 for testing. The original constituency trees in CTB were converted to dependency trees with the

<sup>4</sup>We obtained SD representations using the Stanford parser v.3.3.0.

Dataset	# Sentences	(%) Projective
English	39,832	99.9
Chinese	16,091	100.0
Czech	72,319	76.9
German	38,845	72.2

Penn2Malt tool.<sup>5</sup> We used gold segmentation and gold POS tags as in Chen and Manning (2014) and Dyer et al. (2015).

In the non-projective setting, we assessed the performance of our parser on Czech and German, the largest non-projective datasets released as part of the CoNLL 2006 multilingual dependency parsing shared task. Since there is no official development set in either dataset, we used the last 374/367 sentences in the Czech/German training set as development data.<sup>6</sup> Projective statistics of the four datasets are summarized in Table 1.

## 4.2 Training Details

We trained our models on an Nvidia GPU card; training takes one to two hours. Model parameters were uniformly initialized to  $[-0.1, 0.1]$ . We used Adam (Kingma and Ba, 2014) to optimize our models with hyper-parameters recommended by the authors (i.e., learning rate 0.001, first momentum coefficient 0.9, and second momentum coefficient 0.999). To alleviate the gradient exploding problem, we rescaled the gradient when its norm exceeded 5 (Pascanu et al., 2013). Dropout (Srivastava et al., 2014) was applied to our model with the strategy recommended in the literature (Zaremba et al., 2014; Semeniuta et al., 2016). On all datasets, we used two-layer LSTMs and set  $d = s = 300$ , where  $d$  is the hidden unit size and  $s$  is the word embedding size.

As in previous neural dependency parsing work (Chen and Manning, 2014; Dyer et al., 2015), we used pre-trained word vectors to initialize our word embedding matrix  $\mathbf{W}_e$ . For the PTB experiments, we used 300 dimensional pre-trained GloVe<sup>7</sup> vectors (Pennington et al., 2014). For the CTB experiments, we trained 300 dimensional

GloVe vectors on the Chinese Gigaword corpus which we segmented with the Stanford Chinese Segmenter (Tseng et al., 2005). For Czech and German, we did not use pre-trained word vectors. The POS tag embedding size was set to  $q = 30$  in the English experiments,  $q = 50$  in the Chinese experiments and  $q = 40$  in both Czech and German experiments.

## 4.3 Results

For both English and Chinese experiments, we report unlabeled (UAS) and labeled attachment scores (LAS) on the development and test sets; following Chen and Manning (2014) punctuation is excluded from the evaluation.

Experimental results on PTB are shown in Table 2. We compared our model with several recent papers following the same evaluation protocol and experimental settings. The first block in the table contains mostly graph-based parsers which do not use neural networks: Bohnet10 (Bohnet, 2010), Martins13 (Martins et al., 2013), and Z&M14 (Zhang and McDonald, 2014). Z&N11 (Zhang and Nivre, 2011) is a transition-based parser with non-local features. Accuracy results for all four parsers are reported in Weiss et al. (2015).

The second block in Table 2 presents results obtained from neural network-based parsers. C&M14 (Chen and Manning, 2014) is a transition-based parser using features learned with a feed

forward neural network. Although very fast, its performance is inferior compared to graph-based parsers or strong non-neural transition based parsers (e.g., Z&N11). Dyer15 (Dyer et al., 2015) uses (stack) LSTMs to model the states of the buffer, the stack, and the action sequence of a transition system. Weiss15 (Weiss et al., 2015) is another transition-based parser, with a more elaborate training procedure. Features are learned with a neural network model similar to C&M14, but much larger with two layers. The hidden states of the neural network are then used to train a structured perceptron for better beam search decoding. Andor16 (Andor et al., 2016) is similar to Weiss15, but uses a globally normalized training algorithm instead.

Unlike all models above, DENSE does not use any kind of transition- or graph-based algorithm during training and inference. Nonetheless, it obtains a UAS of 94.02%. Around 95% of the model’s outputs after inference are trees, 87% of which are projective. When we post-process the remaining 13% of non-projective outputs with the Eisner algorithm (DENSE+E), we obtain a slight improvement on UAS (94.10%).

tures from bidirectional LSTMs and feed them to a graph- (K&G16 *graph*) and transition-based parser (K&G16 *trans*). Their LSTMs are jointly trained with the parser objective. DENSE yields very similar performance to their transition-based parser while it outperforms K&G16 *graph*. A key difference between DENSE and K&G16 lies in the training objective. The objective of DENSE is log-likelihood based *without* tree structure constraints (the model is trained to produce a distribution over possible heads for each word, where each head selection is independent), while K&G16 employ a max-margin objective *with* tree structure constraints. Although our probabilistic objective is non-structured, it is perhaps easier to train compared to a margin-based one.

We also assessed the importance of the bidirectional LSTM on its own by replacing our LSTM-based features with those obtained from a feed-forward network. Specifically, we used the 1-order-atomic features introduced in Lei et al. (2014a) which represent POS-tags, modifiers, heads, and their relative positions. As can be seen in Table 2 (DENSE-Pei), these features are less effective compared to LSTM-based ones and the contribution of the MST algorithm (Eisner) during decoding is more pronounced (DENSE-Pei+E). We observe similar trends in the Chinese, German, and Czech datasets (see Tables 3 and 5).

Results on CTB follow a similar pattern. As shown in Table 3, DENSE outperforms all previous neural models (see the test set columns) on UAS and LAS. DENSE performs competitively with Z&M14, a non-neural model with a com-

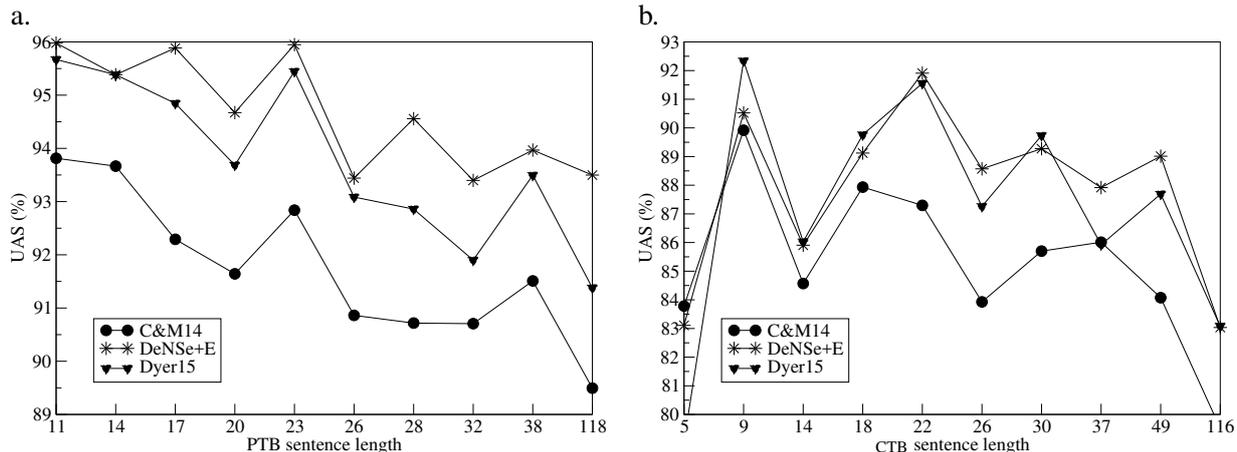

Figure 2: UAS against sentence length on PTB and CTB (development set). Sentences are sorted by length in ascending order and divided equally into 10 bins. The horizontal axis is the length of the last sentence in each bin.

plex high order decoding algorithm involving cube pruning and strategies for encouraging diversity. Post-processing the output of the parser with the Eisner algorithm generally improves performance (by 0.21%; see last row in Table 3). Again we observe that 1-order-atomic features (Lei et al., 2014a) are inferior compared to the LSTM. Table 4 reports unlabeled sentence level exact match (UEM) in Table 4 for English and Chinese. Interestingly, even when using the greedy inference strategy, DENSE yields a UEM comparable to Dyer15 on PTB. Finally, in Figure 2 we analyze the performance of our parser on sentences of different length. On both PTB and CTB, DENSE has an advantage on long sentences compared to C&M14 and Dyer15.

For Czech and German, we closely follow the evaluation setup of CoNLL 2006. We report both UAS and LAS, although most previous work has focused on UAS. Our results are summarized in Table 5. We compare DENSE against three non-projective graph-based dependency parsers: the MST parser (McDonald et al., 2005b), the Turbo parser (Martins et al., 2013), and the RBG parser (Lei et al., 2014b). We show the performance of these parsers in the first order setting (e.g., MST-1st) and in higher order settings (e.g., Turbo-3rd). The results of MST-1st, MST-2nd, RBG-1st and RBG-3rd are reported in Lei et al. (2014b) and the results of Turbo-1st and Turbo-3rd are reported in Martins et al. (2013). We show results for our parser with greedy inference (see DENSE in the table) and when we use the Chu-

Table 6: Percentage of trees and projective trees on the development set before and after DENSE uses a MST algorithm. On PTB and CTB, we use the Eisner algorithm and on Czech and German, we use the Chu-Liu-Edmonds algorithm.

Liu-Edmonds algorithm to post-process non-tree outputs (DENSE+CLE).

As can be seen, DENSE outperforms all other first (and second) order parsers on both German and Czech. As in the projective experiments, we observe slight a improvement (on both UAS and LAS) when using a MST algorithm. On German, DENSE is comparable with the best third-order parser (Turbo-3rd), while on Czech it lags behind Turbo-3rd and RBG-3rd. This is not surprising considering that DENSE is a first-order parser and only uses words and POS tags as features. Comparison systems use a plethora of hand-crafted features and more sophisticated high-order decoding algorithms. Finally, note that a version of DENSE with features in (Lei et al., 2014a) is consistently worse (see the second block in Table 5).

Our experimental results demonstrate that using a MST algorithm during inference can slightly improve the model’s performance. We further ex-

amined the extent to which the MST algorithm is necessary for producing dependency trees. Table 6 shows the percentage of trees before and after the application of the MST algorithm across the four languages. In the majority of cases DENSE outputs trees (ranging from 87.0% to 96.7%) and a significant proportion of them are projective (ranging from 65.5% to 86.6%). Therefore, only a small proportion of outputs (14.0% on average) need to be post-processed with the Eisner or Chu-Liu-Edmonds algorithm.

## 5 Conclusions

In this work we presented DENSE, a neural dependency parser which we train without a transition system or graph-based algorithm. Experimental results show that DENSE achieves competitive performance across four different languages and can seamlessly transfer from a projective to a non-projective parser simply by changing the post-processing MST algorithm during inference. In the future, we plan to increase the coverage of our parser by using tri-training techniques (Li et al., 2014) and multi-task learning (Luong et al., 2015).

## Abstract

Error propagation is a common problem in NLP. Reinforcement learning explores erroneous states during training and can therefore be more robust when mistakes are made early in a process. In this paper, we apply reinforcement learning to greedy dependency parsing which is known to suffer from error propagation. Reinforcement learning improves accuracy of both labeled and unlabeled dependencies of the Stanford Neural Dependency Parser, a high performance greedy parser, while maintaining its efficiency. We investigate the portion of errors which are the result of error propagation and confirm that reinforcement learning reduces the occurrence of error propagation.

## 1 Introduction

Error propagation is a common problem for many NLP tasks (Song et al., 2012; Quirk and Corston-Oliver, 2006; Han et al., 2013; Gildea and Palmer, 2002; Yang and Cardie, 2013). It can occur when NLP tools applied early on in a pipeline make mistakes that have negative impact on higher-level tasks further down the pipeline. It can also occur within the application of a specific task, when sequential decisions are taken and errors made early in the process affect decisions made later on.

When reinforcement learning is applied, a system actively tries out different sequences of actions. Most of these sequences will contain some errors. We hypothesize that a system trained in this manner will be more robust and less susceptible to error propagation.

We test our hypothesis by applying reinforcement learning to greedy transition-based parsers (Yamada and Matsumoto, 2003; Nivre, 2004),

which have been popular because of superior efficiency and accuracy nearing state-of-the-art. They are also known to suffer from error propagation. Because they work by carrying out a sequence of actions without reconsideration, an erroneous action can exert a negative effect on all subsequent decisions. By rendering correct parses unreachable or promoting incorrect features, the first error induces the second error and so on. McDonald and Nivre (2007) argue that the observed negative correlation between parsing accuracy and sentence length indicates error propagation is at work.

We compare reinforcement learning to supervised learning on Chen and Manning (2014)'s parser. This high performance parser is available as open source. It does not make use of alternative strategies for tackling error propagation and thus provides a clean experimental setup to test our hypothesis. Reinforcement learning increased both unlabeled and labeled accuracy on the Penn TreeBank and German part of SPMRL (Seddah et al., 2014). This outcome shows that reinforcement learning has a positive effect, but does not yet prove that this is indeed the result of reduced error propagation. We therefore designed an experiment which identified which errors are the result of error propagation. We found that around 50% of avoided errors were cases of error propagation in our best arc-standard system. Considering that 27% of the original errors were caused by error propagation, this result confirms our hypothesis.

This paper provides the following contributions:

1. We introduce Approximate Policy Gradient (APG), a new algorithm that is suited for dependency parsing and other structured prediction problems.
2. We show that this algorithm improves the accuracy of a high-performance greedy parser.

3. We design an experiment for analyzing error propagation in parsing.
4. We confirm our hypothesis that reinforcement learning reduces error propagation.

To our knowledge, this paper is the first to experimentally show that reinforcement learning can reduce error propagation in NLP.

The rest of this paper is structured as follows. We discuss related work in Section 2. This is followed by a description of the parsers used in our experiments in Section 3. Section 4 outlines our experimental setup and presents our results. The error propagation experiment and its outcome are described in Section 5. Finally, we conclude and discuss future research in Section 6.

## 2 Related Work

In this section, we address related work on dependency parsing, including alternative approaches for reducing error propagation, and reinforcement learning.

### 2.1 Dependency Parsing

We use Chen and Manning (2014)’s parser as a basis for our experiments. Their parser is open-source and has served as a reference point for many recent publications (Dyer et al., 2015; Weiss et al., 2015; Alberti et al., 2015; Honnibal and Johnson, 2015, among others). They provide an efficient neural network that learns dense vector representations of words, PoS-tags and dependency labels. This small set of features makes their parser significantly more efficient than other popular parsers, such as the Malt (Nivre et al., 2007) or MST (McDonald et al., 2005) parser while obtaining higher accuracy. They acknowledge the error propagation problem of greedy parsers, but leave addressing this through (e.g.) beam search for future work.

Dyer et al. (2015) introduce an approach that uses Long Short-Term Memory (LSTM). Their parser still works incrementally and the number of required operations grows linearly with the length of the sentence, but it uses the complete buffer, stack and history of parsing decisions, giving the model access to global information. Weiss et al. (2015) introduce several improvements on Chen and Manning (2014)’s parser. Most importantly, they put a globally-trained perceptron layer instead of a softmax output layer. Their model uses

smaller embeddings, rectified linear instead of cubic activation function, and two hidden layers instead of one. They furthermore apply an averaged stochastic gradient descent (ASGD) learning scheme. In addition, they apply beam search and increase training data by using unlabeled data through the tri-training approach introduced by Li et al. (2014), which leads to further improvements.

Kiperwasser and Goldberg (2016) introduce a new way to represent features using a bidirectional LSTM and improve the results of a greedy parser. Andor et al. (2016) present a mathematical proof that globally normalized models are more expressive than locally normalized counterparts and propose to use global normalization with beam search at both training and testing.

Our approach differs from all of the work mentioned above, in that it manages to improve results of Chen and Manning (2014) *without changing the architecture of the model nor the input representation*. The only substantial difference lies in the way the model is trained. In this respect, our research is most similar to training approaches using dynamic oracles (Goldberg and Nivre, 2012). Traditional static oracles can generate only one sequence of actions per sentence. A dynamic oracle gives *all* trajectories leading to the best possible result from every valid parse configuration. They can therefore be used to generate more training sequences including those containing errors. A drawback of this approach is that dynamic oracles have to be developed specifically for individual transition systems (e.g. arc-standard, arc-eager). Therefore, a large number of dynamic oracles have been developed in recent years (Goldberg and Nivre, 2012; Goldberg and Nivre, 2013; Goldberg et al., 2014; Gomez-Rodriguez et al., 2014; Björkelund and Nivre, 2015). In contrast, the reinforcement learning approach proposed in this paper is more general and can be applied to a variety of systems.

Zhang and Chan (2009) present the only study we are aware of that also uses reinforcement learning for dependency parsing. They compare their results to Nivre et al. (2006b) using the same features, but they also change the model and apply beam search. It is thus unclear to what extent their improvements are due to reinforcement learning.

Even though most approaches mentioned above improve the results reported by Chen and Manning (2014) and even more impressive results on

dependency parsing have been achieved since (notably, Andor et al. (2016)), Chen and Manning’s parser provides a better baseline for our purposes. We aim at investigating the influence of reinforcement learning on error propagation and want to test this in a clean environment, where reinforcement learning does not interfere with other methods that address the same problem.

## 2.2 Reinforcement Learning

Reinforcement learning has been applied to several NLP tasks with success, e.g. agenda-based parsing (Jiang et al., 2012), semantic parsing (Berant and Liang, 2015) and simultaneous machine translation (Grissom II et al., 2014). To our knowledge, however, none of these studies investigated the influence of reinforcement learning on error propagation.

Learning to Search (L2S) is probably the most prominent line of research that applies reinforcement learning (more precisely, imitation learning) to NLP. Various algorithms, e.g. SEARN (Daumé III et al., 2009) and DAGger (Ross et al., 2011), have been developed sharing common high-level steps: a *roll-in* policy is executed to generate training states from which a *roll-out* policy is used to estimate the loss of certain actions. The concrete instantiation differs from one algorithm to another with choices including a referent policy (static or dynamic oracle), learned policy, or a mixture of the two. Early work in L2S focused on reducing reinforcement learning into binary classification (Daumé III et al., 2009), but newer systems favored regressors for efficiency (Chang et al., 2015, Supplementary material, Section B). Our algorithm APG is simpler than L2S in that it uses only one policy (pre-trained with standard supervised learning) and applies the existing classifier directly without reduction (the only requirement is that it is probabilistic). Nevertheless, our results demonstrate its effectiveness.

APG belongs to the family of policy gradient algorithms (Sutton et al., 1999), i.e. it maximizes the expected reward directly by following its gradient w.r.t. the parameters. The advantage of using a policy gradient algorithm in NLP is that gradient-based optimization is already widely used. REINFORCE (Williams, 1992; Ranzato et al., 2016) is a widely-used policy gradient algorithm but it is also well-known for suffering from high variance (Sutton et al., 1999).

We directly compare our approach to REINFORCE, whereas we leave a direct comparison to L2S for future work. Our experiments show that our algorithm results in lower variance and achieves better performance than REINFORCE.

Recent work addresses the approximation of reinforcement learning gradient in the context of machine translation. Shen et al. (2016)’s algorithm is roughly equivalent to the combination of an oracle and random sampling. Their approach differs from ours, because it does not retain memory across iteration as in our best-performing model (see Section 3.4).

## 2.3 Reinforcement and error propagation

As mentioned above, previous work that applied reinforcement learning to NLP has, to our knowledge, not shown that it improved results by reducing error propagation.

Work on identifying the impact of error propagation in parsing is rare, Ng and Curran (2015) being a notable exception. They provide a detailed error analysis for parsing and classify which kind of parsing errors are involved with error propagation. There are four main differences between their approaches and ours. First, Ng and Curran correct arcs in the tree and our algorithm corrects decisions of the parsing algorithm. Second, our approach distinguishes between cases where one erroneous action deterministically leads to multiple erroneous arcs and cases where an erroneous action leads to conditions that indirectly result in further errors (see Section 5.1 for a detailed explanation). Third, Ng and Curran’s algorithm corrects all erroneous arcs that are the same type of parsing error and point out that they cannot examine the interaction between multiple errors of the same type in a sentence. Our algorithm corrects errors incrementally and therefore avoids this issue. Finally, the classification and analysis presented in Ng and Curran (2015) are more extensive and detailed than ours. Our algorithm can, however, easily be extended to perform similar analysis. Overall, Ng and Curran’s approach for error analysis and ours are complementary. Combining them and applying them to various systems would form an interesting direction for future work.

## 3 A Reinforced Greedy Parser

This section describes the systems used in our experiments. We first describe the arc-standard al-

Step	Transition	Stack	Buffer	Arcs
0		<ROOT>	waves hit ... Big Board	$\emptyset$
1	SHIFT	<ROOT> waves	hit stocks ... Big Board	$\emptyset$
2	SHIFT	<ROOT> waves hit	stocks themselves ... Big Board	$\emptyset$
3	LEFT <sub>nsubj</sub>	<ROOT> hit	stocks themselves ... Big Board	$A_1 = \{ hit \xrightarrow{nsubj} waves \}$
4	SHIFT	<ROOT> hit stocks	themselves on the Big Board	$A_1$
5	SHIFT	<ROOT> hit stocks themselves	on the Big Board	$A_1$
6	RIGHT <sub>dep</sub>	<ROOT> hit stocks	on the Big Board	$A_2 = A_1 \cup \{ stock \xrightarrow{dep} themselves \}$
7	RIGHT <sub>doobj</sub>	<ROOT> hit	on the Big Board	$A_3 = A_2 \cup \{ hit \xrightarrow{doobj} stock \}$

Table 1: Parsing oracle walk-through

gorithm, because familiarity with it helps to understand our error propagation analysis. Next, we briefly point out the main differences between the arc-standard algorithm and the alternative algorithms we experimented with (arc-eager and swap-standard). We then outline the traditional and our novel machine learning approaches. The features we used are identical to those described in Chen and Manning (2014). We are not aware of research identifying the best feature for a neural parser with arc-eager or swap-standard so we use the same features for all transition systems.

### 3.1 Transition-Based Dependency Parsing

In an arc-standard system (Nivre, 2004), a parsing configuration consists of a triple  $\langle \Sigma, \beta, A \rangle$ , where  $\Sigma$  is a stack,  $\beta$  is a buffer containing the remaining input tokens and  $A$  are the dependency arcs that are created during parsing process. At initiation, the stack contains only the root symbol ( $\Sigma = [\text{ROOT}]$ ), the buffer contains the tokens of the sentence ( $\beta = [w_1, \dots, w_n]$ ) and the set of arcs is empty ( $A = \emptyset$ ).

The arc-standard system supports three transitions. When  $\sigma_1$  is the top element and  $\sigma_2$  the second element on the stack, and  $\beta_1$  the first element of the buffer:<sup>1</sup>

**LEFT<sub>l</sub>** adds an arc  $\sigma_1 \xrightarrow{l} \sigma_2$  to  $A$  and removes  $\sigma_2$  from the stack.

**RIGHT<sub>l</sub>** adds an arc  $\sigma_2 \xrightarrow{l} \sigma_1$  to  $A$  and removes  $\sigma_1$  from the stack.

**SHIFT** moves  $\beta_1$  to the stack.

When the buffer is empty, the stack contains only the root symbol and  $A$  contains a parse tree, the configuration is completed. For a sentence of

<sup>1</sup>Naturally, the transitions LEFT<sub>l</sub> and RIGHT<sub>l</sub> can only take place if the stack contains at least two elements and SHIFT can only occur when there is at least one element on the buffer.

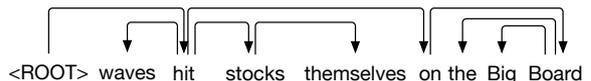

Figure 1: Correct dependencies for a simplified example from Penn TreeBank

$N_w$  tokens, a full parse takes  $2N_w + 1$  transitions to complete (including the initiation). Figure 1 provides the gold parse tree for a (simplified) example from the Penn Treebank. The steps taken to create the dependencies between the sentence’s head word *hit* and its subject and direct object are provided in Table 1.

To demonstrate that reinforcement learning can train different systems, we also carried out experiments with arc-eager (Nivre, 2003) and swap-standard (Nivre, 2009). Arc-eager is designed for incremental parsing and included in the popular MaltParser (Nivre et al., 2006a). Swap-standard is a simple and effective solution to unprojective dependency trees. Because arc-eager does not guarantee complete parse trees, we used a variation that employs an action called UNSHIFT to resume processing of tokens that would otherwise not be attached to a head (Nivre and Fernández-González, 2014).

### 3.2 Training with a Static Oracle

In transition-based dependency parsing, it is common to convert a dependency treebank  $\mathcal{D} \ni (x, y)$  into a collection of input features  $s \in \mathcal{S}$  and corresponding gold-standard actions  $a \in \mathcal{A}$  for training, using a static oracle  $\mathcal{O}$ . In Chen and Manning (2014), a neural network works as a function mapping input features to probabilities of actions:  $f_{NN} : \mathcal{S} \times \mathcal{A} \rightarrow [0, 1]$ . The neural network is trained to minimize negative log-likelihood loss

on the converted treebank:

$$\mathcal{L} = \sum_{(x,y) \in \mathcal{D}} \sum_{(s,a) \in \mathcal{O}(x,y)} -\log f_{NN}(s, a; \theta) \quad (1)$$

### 3.3 Reinforcement Learning

Following Maes et al. (2009), we view transition-based dependency parsing as a deterministic Markov Decision Process. The problem is summarized by a tuple  $\langle \mathcal{S}, \mathcal{A}, \mathcal{T}, r \rangle$  where  $\mathcal{S}$  is the set of all possible states,  $\mathcal{A}$  contains all possible actions,  $\mathcal{T}$  is a mapping  $\mathcal{S} \times \mathcal{A} \rightarrow \mathcal{S}$  called *transition function* and  $r : \mathcal{S} \times \mathcal{A} \rightarrow \mathbb{R}$  is a reward function.

A state corresponds to a configuration and is summarized into input features. Possible actions are defined for each transition system described in Section 3.1. We keep the training approach simple by using only one reward  $r(\bar{y})$  at the end of each parse.

Given this framework, a stochastic policy guides our parser by mapping each state to a probabilistic distribution of actions. During training, we use function  $f_{NN}$  described in Section 3.2 as a stochastic policy. At test time, actions are chosen in a greedy fashion following existing literature. We aim at finding the policy that maximizes the expected reward (or, equivalently, minimizes the expected loss) on the training dataset:

$$\text{maximize } \eta = \sum_{(x,y) \in \mathcal{D}} \sum_{a_{1:m} \sim f} r(\bar{y}) \prod_{i=1}^m f_{NN}(s_i, a_i; \theta) \quad (2)$$

where  $a_{1:m}$  is a sequence of actions obtained by following policy  $f_{NN}$  until termination and  $s_{1:m}$  are corresponding states (with  $s_{m+1}$  being the termination state).

### 3.4 Approximate Policy Gradient

Gradient ascent can be used to maximize the expected reward in Equation 2. The gradient of expected reward w.r.t. parameters is (note that  $dz = \text{zd}(\log z)$ ):

$$\frac{\partial \eta}{\partial \theta} = \sum_{(x,y) \in \mathcal{D}} \sum_{a_{1:m} \sim f_{NN}} r(\bar{y}) \prod_{i=1}^m f_{NN}(s_i, a_i) \sum_{i=1}^m \frac{\partial}{\partial \theta} \log f_{NN}(s_i, a_i; \theta) \quad (3)$$

Because of the exponential number of possible trajectories, calculating the gradient exactly is not

possible. We propose to replace it by an approximation (hence the name *Approximate Policy Gradient*) by summing over a small subset  $U$  of trajectories. Following common practice, we also use a baseline  $b(y)$  that only depends on the correct dependency tree. The parameter is then updated by following the approximate gradient:

$$\Delta \theta \propto \sum_{(x,y) \in \mathcal{D}} \sum_{a_{1:m} \in U} (r(\bar{y}) - b(y)) \prod_{i=1}^m f_{NN}(s_i, a_i) \sum_{i=1}^m \frac{\partial}{\partial \theta} \log f_{NN}(s_i, a_i; \theta) \quad (4)$$

Instead of sampling one trajectory at a time as in REINFORCE, Equation 4 has the advantage that sampling over multiple trajectories could lead to more stable training and higher performance. To achieve that goal, the choice of  $U$  is critical. We empirically evaluate three strategies:

**RL-ORACLE:** only includes the oracle transition sequence.

**RL-RANDOM:** randomly samples  $k$  distinct trajectories at each iteration. Every action is sampled according to  $f_{NN}$ , i.e. preferring trajectories for which the current policy assigns higher probability.

**RL-MEMORY:** samples randomly as the previous method but retains  $k$  trajectories with highest rewards across iterations in a separate memory. Trajectories are “forgotten” (removed) randomly with probability  $\rho$  before each iteration.<sup>2</sup>

Intuitively, trajectories that are more likely and produce higher rewards are better training examples. It follows from Equation 3 that they also bear bigger weight on the true gradient. This is the rationale behind RL-RANDOM and RL-ORACLE. For a suboptimal parser, however, these objectives sometimes work against each other. RL-MEMORY was designed to find the right balance between them. It is furthermore important that the parser is pretrained to ensure good samples. Algorithm 1 illustrates the procedure of training a dependency parser using the proposed algorithms.

<sup>2</sup>We assign a random number (drawn uniformly from  $[0, 1]$ ) to each trajectory in memory and remove those assigned a number less than  $\rho$ .

```

MemorySeqs  $\leftarrow$   $\emptyset$ ;
foreach training batch  $b$  do
  foreach sentence  $s \in b$  do
    OracleSeq  $\leftarrow$  Oracle( $s$ );
    SystemSeqs  $\leftarrow$  (sample  $k$  parsing
      transition sequences for  $s$ );
    if RL-Oracle then
      | ComputeGradients(OracleSeq);
    else if RL-Random then
      | ComputeGradients(SystemSeqs);
    else if RL-Memory then
       $m \leftarrow$  MemorySeqs[ $s$ ];
      foreach  $q \in m$  do
        if RandomNumber()  $< \rho$  then
          | Remove  $q$  from  $m$ ;
        end
      end
      foreach  $q \in$  SystemSeqs do
        if  $|m| < k$  then
          | Insert  $q$  into  $m$ ;
        else
           $p \leftarrow$  (sequence with
            smallest reward in  $m$ );
          if reward( $q$ )  $>$  reward( $p$ )
            then
              | Replace  $p$  by  $q$  in  $m$ ;
            end
          end
        end
      ComputeGradients( $m$ );
    end
  Perform one gradient descent step;
end

```

**Algorithm 1:** Training a dependency parser with approximate policy gradient.

## 4 Reinforcement Learning Experiments

We first train a parser using a supervised learning procedure and then improve its performance using APG. We empirically tested that training a second time with supervised learning has little to no effect on performance.

### 4.1 Experimental Setup

We use PENN Treebank 3 with standard split (training, development and test set) for our experiments with arc-standard and arc-eager. Because the swap-standard parser is mainly suited for non-projective structures, which are rare in the PENN Treebank, we evaluate this parser on the German

	Arc-standard		Arc-eager		Swap-standard	
	UAS	LAS	UAS	LAS	UAS	LAS
SL	91.3	89.4	88.3	85.8	84.3	81.3

RL-O	91.8	90.2	88.9	86.5	86.8	83.9
RL-R	<b>92.2</b>	<b>90.6</b>	89.4	87.0	87.5	84.5
RL-M	<b>92.2</b>	<b>90.6</b>	<b>89.8</b>	<b>87.4</b>	<b>87.6</b>	<b>84.6</b>

Table 2: Comparing training methods on PENN Treebank (arc-standard and arc-eager) and German part of SPMRL-2014 (swap-standard).

section of the SPMRL dataset. For PENN Treebank, we follow Chen and Manning’s preprocessing steps. We also use their pretrained model<sup>3</sup> for arc-standard and train our own models in similar settings for other transition systems.

For reinforcement learning, we use AdaGrad for optimization. We do not use dropout because we observed that it destabilized the training process. The reward  $r(\bar{y})$  is the number of correct labeled arcs (i.e. LAS multiplied by number of tokens).<sup>4</sup> The baseline is fixed to half the number of tokens (corresponding to a 0.5 LAS score). As training takes a lot of time, we tried only few values of hyperparameters on the development set and picked  $k = 8$  and  $\rho = 0.01$ . 1,000 updates were performed (except for REINFORCE which was trained for 8,000 updates) with each training batch contains 512 randomly selected sentences. The Stanford dependency scorer<sup>5</sup> was used for evaluation.

### 4.2 Effectiveness of Reinforcement Learning

Table 2 displays the performance of different approaches to training dependency parsers. Although we used Chen and Manning (2014)’s pretrained model and Stanford open-source software, the results of our baseline are slightly worse than what is reported in their paper. This could be due to minor differences in settings and does not affect our conclusions.

Across transition systems and two languages, APG outperforms supervised learning, verifying our hypothesis. Moreover, it is not simply because the learners are exposed to more examples than their supervised counterparts. RL-ORACLE

<sup>3</sup>We use PTB\_Stanford\_params.txt.gz downloaded from <http://nlp.stanford.edu/software/nndep.shtml> on December 30<sup>th</sup>, 2015.

<sup>4</sup>Punctuation is not taken into account, following Chen and Manning (2014).

<sup>5</sup>Downloaded from <http://nlp.stanford.edu/software/lex-parser.shtml>.

is trained on exactly the same examples as the standard supervised learning system (SL), yet it is consistently superior. This can only be explained by the superiority of the reinforcement learning objective function compared to negative log-likelihood.

The results support our hypothesis that APG is better than REINFORCE (abbreviated as RE in Table 2) as RL-MEMORY always outperforms the classical algorithm and the other two heuristics do in two out of three cases. The usefulness of training examples that contain errors is evident through the better performance of RL-RANDOM and RL-MEMORY in comparison to RL-ORACLE.

Table 3 shows the importance of samples for RL-RANDOM. The algorithm hurts performance when only one sample is used whereas training with two or more samples improves the results. The difference cannot be explained by the total number of observed samples because one-sample training is still worse after 8,000 iterations compared to a sample size of 8 after 1,000 iterations. The benefit of added samples is twofold: increased performance and decreased variance. Because these benefits saturate quickly, we did not test sample sizes beyond 32.

## 5 Error Propagation Experiment

We hypothesized that reinforcement learning avoids error propagation. In this section, we describe our algorithm and the experiment that identifies error propagation in the arc-standard parsers.

### 5.1 Error Propagation

Section 3.1 explained that a transition-based parser goes through the sentence incrementally and must select a transition from [SHIFT, LEFT<sub>l</sub>,

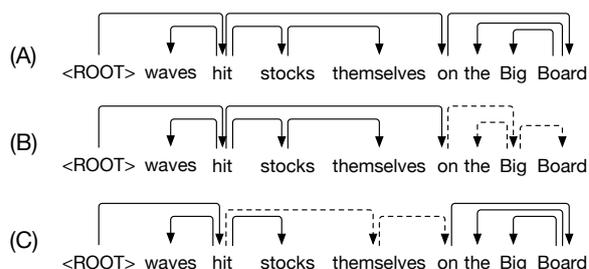

Figure 2: Three dependency graphs: gold (A), arc errors caused by one decision error (B) and arc errors caused by multiple decision errors (C).

RIGHT<sub>l</sub>] at each step. We use the term *arc error* to refer to an erroneous arc in the resulting tree. The term *decision error* refers to a transition that leads to a loss in parsing accuracy. Decision errors in the parsing process lead to one or more arc errors in the resulting tree. There are two ways in which a single decision error may lead to multiple arc errors. First, the decision can deterministically lead to more than one arc error, because (e.g.) an erroneously formed arc also blocks other correct arcs. Second, an erroneous parse decision changes some of the features that the model uses for future decisions and these changes can lead to further (decision) errors down the road.

We illustrate both cases using two incorrect derivations presented in Figure 2. The original gold tree is repeated in (A). The dependency graph in Figure 2 (B) contains three erroneous dependency arcs (indicated by dashed arrows). The first error must have occurred when the parser executed RIGHT<sub>amod</sub> creating the arc *Big* → *Board*. After this error, it is impossible to create the correct relations *on* → *Board* and *Board* → *the*. The wrong arcs *Big* → *the* and *on* → *Big* are thus all the result of a single decision error.

Figure 2 (C) represents the dependency graph that is actually produced by our parser.<sup>6</sup> It contains two erroneous arcs: *hit* → *themselves* and *themselves* → *on*. Table 4 provides a possible sequence of steps that led to this derivation, starting from the moment *stocks* was added to the stack (Step 4). The first error is introduced in Step 5', where *hit* combines with *stocks* before *stocks* has picked up its dependent *themselves*. At that point, *themselves* can no longer be combined with the right head. The proposition *on*, on the other hand, can

<sup>6</sup>The example is a fragment of a more complex sentence consisting of 33 tokens. The parser does provide the correct output when it analyzes this sequence in isolation.

Step	Transition	Stack	Buffer	Arcs
4	SHIFT	<ROOT> hit stocks	themselves on the Big Board	$A_1$
5'	RIGHT <sub>dobj</sub>	<ROOT> hit	themselves on the Big Board	$A_2 = A_1 \cup \{hit \xrightarrow{dobj} stock\}$
6'	SHIFT	<ROOT> hit themselves	on the Big Board	$A_2$
7'	SHIFT	<ROOT> hit themselves on	the Big Board	$A_2$
...				
10'	SHIFT	<ROOT> hit themselves on the Big Board		$A_2$
11'	LEFT <sub>nn</sub>	<ROOT> hit themselves on the Board		$A_3 = A_2 \cup \{Board \xrightarrow{nn} Big\}$
12'	LEFT <sub>det</sub>	<ROOT> hit themselves on Board		$A_4 = A_3 \cup \{Board \xrightarrow{det} the\}$
13'	RIGHT <sub>pobj</sub>	<ROOT> hit themselves on		$A_5 = A_4 \cup \{on \xrightarrow{pobj} Board\}$
14'	RIGHT <sub>dep</sub>	<ROOT> hit themselves		$A_6 = A_5 \cup \{themselves \xrightarrow{dep} on\}$

Table 4: Possible parsing walk-through with error

still be combined with the correct head. This error is introduced in Step 7', where the parser moves *on* to the stack rather than creating an arc from *hit* to *themselves*.<sup>7</sup> There are thus two decision errors that lead to the arc errors in Figure 2 (C). The second decision error can, however, be caused indirectly by the first error. If a decision error causes additional decision errors later in the parsing process, we talk of error propagation. This cannot be known just by looking at the derivation.

## 5.2 Examining the impact of decision errors

We examine the impact of individual decision errors on the overall parse results in our test set by combining a dynamic oracle and a recursive function. We use a dynamic oracle based on Goldberg et al. (2014) which gives us the overall loss at any point during the derivation. The loss is equal to the minimal number of arc errors that will have been made once the parse is complete. We can thus deduce how many arc errors are deterministically caused by a given decision error.

The propagation of decision errors cannot be determined by simply examining the increase in loss during the parsing process. We use a recursive function to identify whether a particular parse suffered from this. While parsing the sentence, we register which decisions lead to an increase in loss. We then recursively reparse the sentence correcting one additional decision error during each run until the parser produces the gold. If each erroneous decision has to be corrected in order to arrive at the gold, we assume the decision errors are

<sup>7</sup>Note that technically, *on* can still become a dependent of *hit*, but this can only happen if *on* becomes the head of *themselves* which would also be an error.

	SL	RL-O	RL-R	RL-M
Total Loss	7069	6227	6042	6144
Dec. Errors	5177	4410	4345	4476
Err. Prop.	1399	1124	992	1035
New errors	411	432	403	400
Loss/error	1.37	1.41	1.39	1.37
Err. Prop. (%)	27.0	25.5	22.8	23.1

Table 5: Overview of average impact of decision errors

independent of each other. If, on the other hand, the correction of a specific decision also fixes other decisions down the road, the original parse suffers from error propagation.

The results are presented in Table 5. *Total Loss* indicates the number of arc errors in the corpus, *Dec. Errors* the number of decision errors and *Err. Prop.* the number of decision errors that were the result of error propagation. This number was obtained by comparing the number of decision errors in the original parse to the number of decision errors that needed to be fixed to obtain the gold parse. If less errors had to be fixed than originally present, we counted the difference as error propagation. Note that fixing errors sometimes leads to new decision errors during the derivation. We also counted the cases where more decision errors needed to be fixed than were originally present and report them in Table 5.<sup>8</sup>

<sup>8</sup>We ran an alternative analysis where we counted all cases where fixing one decision error in the derivation reduced the overall number of decision errors in the parse by more than one. Under this alternative analysis, similar reductions in the proportion of error propagation were observed for reinforcement learning.

On average, decision errors deterministically lead to more than one arc error in the resulting parse tree. This remains stable across systems (around 1.4 arc errors per decision error). We furthermore observe that the proportion of decision errors that are the result of error propagation has indeed reduced for all reinforcement learning models. Among the errors avoided by APG, 35.9% were propagated errors for RL-ORACLE, 48.9% for RL-RANDOM, and 51.9% for RL-MEMORY. These percentages are all higher than the proportion of propagated errors occurring in the corpus parsed by SL (27%). This outcome confirms our hypothesis that reinforcement learning is indeed more robust for making decisions in imperfect environments and therefore reduces error propagation.

## 6 Conclusion

This paper introduced Approximate Policy Gradient (APG), an efficient reinforcement learning algorithm for NLP, and applied it to a high-performance greedy dependency parser. We hypothesized that reinforcement learning would be more robust against error propagation and would hence improve parsing accuracy.

To verify our hypothesis, we ran experiments applying APG to three transition systems and two languages. We furthermore introduced an experiment to investigate which portion of errors were the result of error propagation and compared the output of standard supervised machine learning to reinforcement learning. Our results showed that: (a) reinforcement learning indeed improved parsing accuracy and (b) propagated errors were over-represented in the set of avoided errors, confirming our hypothesis.

To our knowledge, this paper is the first to show experimentally that reinforcement learning can reduce error propagation in an NLP task. This result was obtained by a straight-forward implementation of reinforcement learning. Furthermore, we only applied reinforcement learning in the training phase, leaving the original efficiency of the model intact. Overall, we see the outcome of our experiments as an important first step in exploring the possibilities of reinforcement learning for tackling error propagation.

Recent research on parsing has seen impressive improvement during the last year achieving UAS around 94% (Andor et al., 2016). This improve-

ment is partially due to other approaches that, at least in theory, address error propagation, such as beam search. Both the reinforcement learning algorithm and the error propagation study we developed can be applied to other parsing approaches. There are two (related) main questions to be addressed in future work in the domain of parsing. The first addresses whether our method is complementary to alternative approaches and could also improve the current state-of-the-art. The second question would address the impact of various approaches on error propagation and the kind of errors they manage to avoid (following Ng and Curran (2015)).

APG is general enough for other structured prediction problems. We therefore plan to investigate whether we can apply our approach to other NLP tasks such as coreference resolution or semantic role labeling and investigate if it can also reduce error propagation for these tasks.

The source code of all experiments is publicly available at <https://bitbucket.org/ctt1/redep-java>.

## Acknowledgments

The research for this paper was supported by the Netherlands Organisation for Scientific Research (NWO) via the Spinoza-prize Vossen projects (SPI 30-673, 2014-2019) and the VENI project *Reading between the lines* (VENI 275-89-029). Experiments were carried out on the Dutch national e-infrastructure with the support of SURF Cooperative. We would like to thank our friends and colleagues Piek Vossen, Roser Morante, Tommaso Caselli, Emiel van Miltenburg, and Ngoc Do for many useful comments and discussions. We would like to extend our thanks the anonymous reviewers for their feedback which helped improving this paper. All remaining errors are our own.

# Noisy-context surprisal as a human sentence processing cost model

Richard Futrell and Roger Levy

Massachusetts Institute of Technology  
{futrell, rplevy}@mit.edu

## Abstract

We use the noisy-channel theory of human sentence comprehension to develop an incremental processing cost model that unifies and extends key features of expectation-based and memory-based models. In this model, which we call **noisy-context surprisal**, the processing cost of a word is the surprisal of the word given a noisy representation of the preceding context. We show that this model accounts for an outstanding puzzle in sentence comprehension, language-dependent structural forgetting effects (Gibson and Thomas, 1999; Vasishth et al., 2010; Frank et al., 2016), which are previously not well modeled by either expectation-based or memory-based approaches. Additionally, we show that this model derives and generalizes locality effects (Gibson, 1998; Demberg and Keller, 2008), a signature prediction of memory-based models. We give corpus-based evidence for a key assumption in this derivation.

## 1 Introduction

Models of human sentence processing difficulty can be divided into two kinds, **expectation-based** and **memory-based**. Expectation-based models predict the processing difficulty of a word from the word’s surprisal given previous material in the sentence (Hale, 2001; Levy, 2008a). These models have good coverage: they can account for effects of syntactic construction frequency and resolution of ambiguity on incremental processing difficulty. Memory-based models, on the other hand, explain difficulty resulting from working memory limitations during incremental parsing (Gibson, 1998;

Lewis and Vasishth, 2005); a major prediction of these models is **locality effects**, where processing a word is difficult when it is far from other words with which it must be syntactically integrated. Expectation-based models do not intrinsically capture this difficulty.

Integrating these two approaches at a high level has proven challenging. A major hurdle is that the theories are typically stated at different levels of analysis: expectation-based theories are computational-level theories (Marr, 1982) specifying what computational problem the human sentence processing system is solving—the problem of how update one’s belief about a sentence given a new word—without specifying implementation details. Memory-based theories such as Lewis and Vasishth (2005) are for the most part based in mechanistic algorithmic-level theories describing the actions of a specific incremental parser.

Previous theories that capture both surprisal and locality effects have typically done so by augmenting parsing models with a special prediction-verification operation to capture surprisal effects (Demberg and Keller, 2009; Demberg et al., 2013), or by combining surprisal and memory-based cost derived from a parsing model as separate factors in a linear model (Shain et al., 2016). These models capture surprisal and locality effects at the same time, but they do not clearly capture phenomena involving the interaction of memory and probabilistic expectations such as language-dependent structural forgetting (see Section 3).

Here we develop a computational-level model capturing both memory and expectation effects from a single set of principles, without reference to a specific parsing algorithm. In our model, the processing cost of a word is a function of its surprisal given a *noisy* representation of previous context (Section 2). We show that the model can reproduce structural forgetting effects, including

the difference between English and German (Section 3), a phenomenon not previously captured by memory-based or expectation-based models in isolation. We also give a derivation of the existence of locality effects in the model; these effects were previously accounted for only in mechanistic memory-based models (Section 4). The derivation yields a generalization of classic locality effects which we call **information locality**: sentences are predicted to be easier to process when words with high mutual information are close. We give corpus-based evidence that words in syntactic dependencies have high mutual information, meaning that classical dependency locality effects can be seen as a subset of information locality effects.

## 2 Noisy-Context Surprisal

In surprisal theory, the processing cost of a word is asserted to be proportional to extent to which one must change one’s beliefs given that word (Hale, 2001; Smith and Levy, 2013). So the cost of a word is (up to proportionality):

$$C_{\text{surprisal}}(w_i|w_{1:i-1}) = -\log p_L(w_i|w_{1:i-1}), \quad (1)$$

where  $p_L(\cdot|\cdot)$  is the conditional probability of a word in context in a probabilistic language  $L$ .

Standard surprisal assumes that the comprehender has perfect access to a representation of  $w_i$ ’s full context, including the words preceding it in the sentence ( $w_{1:i-1}$ ) and also extra-sentential context (which we leave implicit). But given that human working memory is limited, the assumption of perfect access is unrealistic. We propose that processing cost at a word is better modeled as the cost of belief updates given a *noisy representation* of the previous input. The probability of a word given a noisy context is modeled as the noisy channel probability of the word, assuming that people do noisy channel inference on their context representation (Levy, 2008b; Gibson et al., 2013). Given this model, the expected processing cost of a word is its expected surprisal over the possible noisy representations of its context.

The noisy-context surprisal processing cost function is thus:<sup>1</sup>

$$C(w_i|w_{1:i-1}) = \mathbb{E}_{V|w_{1:i-1}} [-\log p_L^{\text{NC}}(w_i|V)] \quad (2)$$

$$= -\sum_V p_N(V|w_{1:i-1}) \log p_L^{\text{NC}}(w_i|V) \quad (3)$$

<sup>1</sup>Neglecting the implicit proportionality term in Equation 1.

where  $V$  is the noisy representation of the previous material  $w_{1:i-1}$ , the **noise distribution**  $p_N$  characterizes how memory of previous material may be corrupted, and  $p_L^{\text{NC}}(\cdot|\cdot)$  is the noisy-channel probability of a word given a noisy context, computed via marginalization:

$$p_L^{\text{NC}}(w_i|V) = \sum_{w_{1:i-1}} p_L(w_i|w_{1:i-1}) p^{\text{NC}}(w_{1:i-1}|V)$$

with  $p^{\text{NC}}(w_{1:i-1}|V)$  computed via Bayes Rule:

$$p^{\text{NC}}(w_{1:i-1}|V) \propto p_N(V|w_{1:i-1}) p_L(w_{1:i-1}).$$

Note here that  $w_i$ ’s cost is computed using its true identity but a noisy representation of the context: from the incremental perspective,  $w_i$  is observed now, but context is stored and retrieved in a potentially noisy storage medium. This asymmetry between noise levels for proximal versus distal input differs from the noisy-channel surprisal model of Levy (2011), and is crucial to the derivation of information locality we present in Section 4.

Here we use two types of noise distributions for  $p_N$ : erasure noise and deletion noise. In **erasure noise**, a symbol in the context is probabilistically erased and replaced with a special symbol  $\mathbb{E}$  with probability  $e$ . In **deletion noise**, a symbol is erased from the sequence completely, leaving no trace. Given deletion noise, a comprehender does not know how many symbols were in the original context; with erasure noise, the comprehender knows exactly which symbols were affected by noise. In both cases, we assume that the application or non-application of noise is probabilistically independent among elements in the context. We use these concrete noise distributions for convenience, but we believe our results should generalize to larger classes of noise distributions.

## 3 Structural Forgetting Effects

Here we show that noisy-context surprisal as a processing cost model can reproduce effects that were not previously well-explained by either expectation-based or memory-based theories. In particular, we take up the puzzle of **structural forgetting effects**, where comprehenders seem to forget structural elements of a sentence prefix when predicting the rest of the sentence. The result is that some ungrammatical sentences have lower processing cost and higher acceptability than some complex grammatical sentences: with

doubly nested relative clauses, for instance, subjects rate ungrammatical sentence (1) as more acceptable than sentence (2), forgetting about the VP predicted by the second noun (Gibson and Thomas, 1999).

(1) \*The apartment<sub>1</sub> that the maid<sub>2</sub> who the cleaning service<sub>3</sub> had<sub>3</sub> sent over was<sub>1</sub> well-decorated.

(2) The apartment<sub>1</sub> that the maid<sub>2</sub> who the cleaning service<sub>3</sub> had<sub>3</sub> sent over was<sub>2</sub> cleaning every week was<sub>1</sub> well-decorated.

Vasishth et al. (2010) show this same effect in reading times at the last verb: in English native speakers are more surprised to encounter a third VP than not to. However, this effect is language-specific: the same authors find that in German, native speakers are more surprised when a third VP is missing than when it is present. Frank et al. (2016) show further that native speakers do not show the effect in Dutch, but Dutch-native L2 speakers of English do show the effect in English. The result shows that the memory resources taxed by these structures are themselves meaningfully shaped by the distributional statistics of the language.

The verb forgetting effect is a challenge for both expectation-based and memory-based models. Pure expectation-based models cannot reproduce the effect: they have no mechanism for forgetting an established VP prediction and thus they assign small or zero probability to ungrammatical sentences. On the other hand, memory-based models will have to account for why the same structures are forgotten in English but not in German. Here we show that noisy-context surprisal provides the first purely computational-level account for the language-dependent verb forgetting effect. The essential mechanism is that when verb-final nested structures are more probable in a language, then they will be better preserved in a noisy memory representation.

### 3.1 Model of Verb Forgetting

Table 1 presents a toy probabilistic context-free grammar for the constructions involved in verb forgetting. The grammar generates strings over the alphabet of N (noun), V (verb), C (complementizer), P (preposition). We apply deletion noise with by-symbol deletion probability  $d$ . So for example, given a prefix NCNCNVV, the prefix can be corrupted to NCNNVV with probability proportional to  $d$ , representing one deletion. In that

Rule	Probability
$S \rightarrow NP V$	1
$NP \rightarrow N$	$1 - m$
$NP \rightarrow N RC$	$mr$
$NP \rightarrow N PP$	$m(1 - r)$
$PP \rightarrow P NP$	1
$RC \rightarrow C V NP$	$s$
$RC \rightarrow C NP V$	$1 - s$

Table 1: Toy grammar used to demonstrate verb forgetting. Nouns are postmodified with probability  $m$ ; a postmodifier is a relative clause with probability  $r$ , and a relative clause is V-initial with probability  $s$ . For practical reasons we bound non-terminal rewrites of NP at 2.

case a noisy-channel comprehender might incorrectly infer that the original prefix was in fact NCNPNVV, and thus fail to predict a third verb.

To illustrate that noisy surprisal can account for language-dependent verb forgetting, we show in Figure 1 the differences between noisy surprisal values for grammatical (V) and ungrammatical (end-of-sentence) continuations of prefixes NCNCNVV under parameter settings reflecting the difference between English and German, and compare these differences with self-paced reading times observed after the final verb by Vasishth et al. (2010). Noisy surprisal qualitatively reproduces language-dependent verb forgetting: in English the ungrammatical continuation is higher surprisal, but in German the grammatical continuation is higher surprisal. The English–German difference in the model is entirely accounted for by the parameter  $s$ , which determines the proportion of relative clauses that are verb-initial. In English, most relative clauses are subject-extracted and those are verb-initial, so for English  $s \approx .8$  (Roland et al., 2007). German, in contrast, has  $s \approx 0$ , since its relative clauses are obligatorily verb-final. When verb-final relative clauses have higher prior probability, a doubly-nested RC prefix NCNCVV is more likely to be preserved by a rational noisy-channel comprehender.

The results of Figure 1 do not speak, however, to the generality of the model’s predictions regarding verb forgetting. To explore this matter, we partition the model’s four-dimensional parameter space into regions distinguishing whether noisy-context surprisal is lower for (G) grammatical continuations or (U) ungrammatical contin-

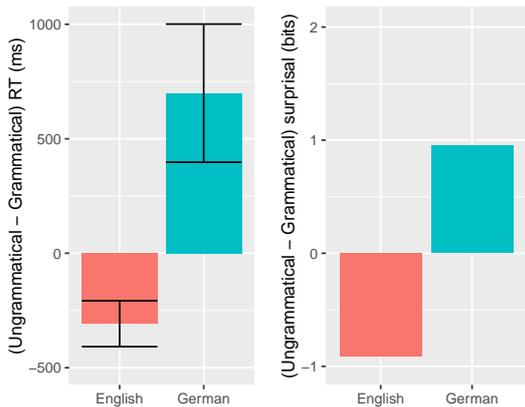

Figure 1: Differences in reaction times for ungrammatical continuations minus grammatical continuations, compared to noisy surprisal differences. RT data comes from self-paced reading experiments in Vasishth et al. (2010) in the post-VP region. The noisy surprisal predictions are produced with  $d = .2$ ,  $m = .5$ ,  $r = .5$  fixed, and  $s = .8$  for English and  $s = 0$  for German.

uations for (1) singly-embedded NCNV and (2) doubly-embedded NCNCNVV contexts. Figure 2 shows this partition for a range of  $r$ ,  $s$ ,  $m$ , and  $d$ . In the blue region, grammatical continuations are lower-cost than ungrammatical continuations for both singly and doubly embedded contexts, as in German ( $G_1G_2$ ); in the red region, the ungrammatical continuation is lower-cost for both contexts ( $U_1U_2$ ). In the green region, the grammatical continuation is lower cost for single embedding, but higher cost for double embedding, as in English ( $G_1U_2$ ). No combination of parameter values instantiates  $U_1G_2$  (for either the depicted or other possible values of  $m$  and  $d$ ). Thus both the English and German behavioral patterns are quite generally predicted by the model. Furthermore, each language’s statistics place it in a region of parameter space plausibly corresponding to its behavioral pattern: the English-type forgetting effect is predicted mostly for high  $s$ , the German-type for low  $s$ .

The only previous formalized account of language-specific verb forgetting, Frank et al. (2016), showed that Simple Recurrent Networks (SRNs) trained on English and Dutch data partly reproduce the verb forgetting effect in the surprisals they assign to the final verb. Our model provides an explanation of the SRN’s behavior. When an SRN predicts words, it effectively uses

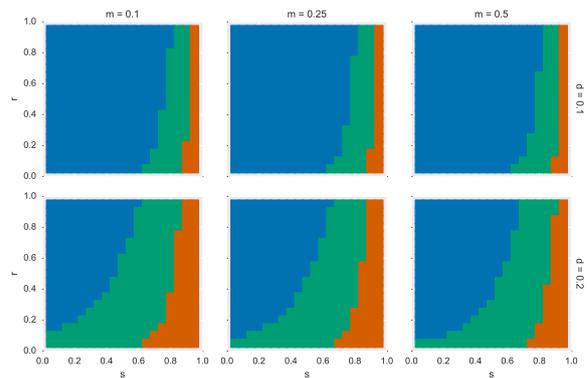

Figure 2: Regions of different model behavior with respect to parameters  $r$ ,  $s$ ,  $m$ , and  $d$  (see Table 1). Blue:  $G_1G_2$ ; red:  $U_1U_2$ ; green:  $G_1U_2$  (see text).

a lossily compressed representation of the previous words. This lossy compression is analogous to the noisy representation posited here.

#### 4 Information Locality

Here we show how, given an appropriate noise distribution, noisy surprisal gives rise to locality effects. Standard locality effects are related to syntactic dependencies: the claim is that processing is difficult when the parser must make a syntactic connection with an element that has been in memory for a long time. In Section 4.1, we derive a more general prediction: that processing is difficult when any elements with high mutual information are far from one another. The effect arises under noisy surprisal because context elements that would have been helpful for predicting a word might have been forgotten. We call this principle **information locality**. In Section 4.3, we argue that words in syntactic dependencies have higher mutual information than other word pairs, which leads to a view of dependency locality effects as a special case of information locality effects.

##### 4.1 Derivation of Information Locality

Viewing processing cost as a function of word order, noisy surprisal gives rise to the generalization that cost is minimized when elements with high mutual information are close. We show this by decomposing the noisy surprisal cost of a word into many terms of higher-order mutual information with the context, then showing that applying a certain kind of erasure noise to the context causes

these terms to be downweighted based on their distance to the word. Thus the best word order puts the words that have high mutual information with a word close to that word.

#### 4.1.1 Noise Distribution

Noisy surprisal gives rise to information locality under a family of noise distributions which we call **progressive erasure noise**, which is any noise function that erases discrete elements of a sequence with increasing probability the earlier those elements are in the sequence. Formally, in progressive erasure noise, the  $i$ th element in a sequence  $X$  with length  $|X|$  is erased with probability proportional to some monotonically increasing function of how far left that element is in the sequence:  $f(|X| - i)$ . As a concrete example of progressive erasure noise, consider an exponential decay function, such that the probability that an element  $i$  in  $X$  remains unerased is  $(1 - e)^{|X| - i}$  for some probability  $e$ . The exponential decay function corresponds to a noise model where the context sequence is hit with erasure noise successively as each word is processed. Any progressive erasure noise distribution suffices for the derivation here to go through.

#### 4.1.2 Decomposing Surprisal Cost

In noisy surprisal theory, the cost of a word  $w_i$  in context  $w_{1:i-1}$  is:

$$\begin{aligned} C(w_i|w_{1:i-1}) &= \mathbb{E}_{V|w_{1:i-1}} [-\log p(w_i|V)] \\ &= \mathbb{E}_{V|w_{1:i-1}} [h(w_i) - \text{pmi}(w_i; V)] \\ &= h(w_i) - \mathbb{E}_{V|w_{1:i-1}} [\text{pmi}(w_i; V)], \end{aligned} \quad (4)$$

where  $h(\cdot)$  is surprisal (here unconditional, equivalent to log inverse-frequency) and  $\text{pmi}(\cdot; \cdot)$  is **pointwise mutual information** between two values under a joint distribution:

$$\text{pmi}(x; y) = h(x) + h(y) - h(x, y). \quad (5)$$

Essentially, each word has an inherent cost determined by its log inverse probability, mitigated to the extent that it is predictable from context ( $\text{pmi}(w_i; w_{1:i-1})$ ).

Now define the **interaction information** between a sequence of  $m$  values  $\{a\}$  drawn from a sequence of  $m$  random variables  $\{\alpha\}$  (McGill,

1955; Bell, 2003) as:<sup>2</sup>

$$i(a_1; \dots; a_m) = \sum_{n=1}^m \sum_{I \in \binom{1:m}{n}} (-1)^{m-n-1} h(a_{I_1}, \dots, a_{I_n}),$$

where the notation  $\binom{1:m}{n}$  means all cardinality- $n$  subsets of the set of integers 1 through  $m$ . The equation amounts to alternately adding and subtracting the joint surprisals of all subsets of values. For  $m = 2$ , expanding the equation reveals that mutual information is a special case of interaction information.

Supposing that the noisy representation of context  $V$  is the result of running the veridical context  $w_{1:i-1}$  through progressive erasure noise, we can see  $V$  as a sequence of values  $v_{1:i-1}$ , where each  $v_i$  is equal to either  $w_i$  or the erasure symbol  $\text{E}$ . Rewriting  $\text{pmi}(w_i; V)$  as  $\text{pmi}(w_i; v_{1:i-1})$ , we can decompose it into interaction informations as follows:

$$\text{pmi}(w_i; v_{1:i-1}) = \sum_{n=1}^{i-1} \sum_{I \in \binom{1:i-1}{n}} i(w_i; v_{I_1}; \dots; v_{I_n}). \quad (6)$$

The equation expresses a sum of interaction informations between the current word  $w_i$  and all subsets of the context values.<sup>3</sup>

<sup>2</sup>Higher-order information terms are typically defined using a different sign convention and referred to as **coinformation** or **multivariate mutual information** (Bell, 2003). For even orders, interaction information is equal to coinformation. For odd orders, interaction information is equal to negative coinformation. We adopt our particular sign convention to make the generalization of information locality easier to express.

<sup>3</sup>To see that this is true, first note that we can express joint surprisal in terms of interaction information:

$$h(a_1, \dots, a_m) = - \sum_{n=1}^m \sum_{I \in \binom{1:m}{n}} i(a_{I_1}; \dots; a_{I_n}).$$

Now consider the  $\text{pmi}$  of a value  $a_i$  with a sequence  $a_{1:i-1}$ . Using the decomposition of joint surprisal to expand the definition of  $\text{pmi}$  in Equation 5, we get:

$$\begin{aligned} \text{pmi}(a_i; a_{1:i-1}) &= h(a_i) + h(a_{1:i-1}) - h(a_i, a_{1:i-1}) \\ &= h(a_i) + h(a_{1:i-1}) - h(a_{1:i}) \\ &= h(a_i) - \sum_{n=1}^{i-1} \sum_{I \in \binom{1:i-1}{n}} i(a_{I_1}; \dots; a_{I_n}) \\ &\quad + \sum_{n=1}^i \sum_{I \in \binom{1:i}{n}} i(a_{I_1}; \dots; a_{I_n}) \end{aligned}$$

In the final expression, all the terms that do not contain  $a_i$

Now combining Equations 4 and 6, we get:

$$\begin{aligned}
C(w_i|w_{1:i-1}) &= h(w_i) - \\
&\mathbb{E}_{v|w_{1:i-1}} \left[ \sum_{n=1}^{i-1} \sum_{I \in \binom{1:i-1}{n}} i(w_i; v_{I_1}; \dots; v_{I_n}) \right] \\
&= h(w_i) - \sum_{n=1}^{i-1} \sum_{I \in \binom{1:i-1}{n}} \sum_v p_N(v|w_{1:i-1}) i(w_i; v_{I_1}; \dots; v_{I_n}).
\end{aligned}$$

Now if any element of an interaction information term is  $\mathbb{E}$ , then that whole interaction information term is equal to 0. This happens because the probability that an element is erased is independent of the identity of other elements in the sequence, and thus  $\mathbb{E}$  has no interaction information with any subset of those elements. That is,  $i(w_i; v_{I_1}; \dots; v_{I_n}) = 0$  unless  $v_{I_j} = w_{I_j}$  for all  $j$ . This allows us to write:

$$\begin{aligned}
C(w_i|w_{1:i-1}) &= h(w_i) - \\
&\sum_{n=1}^{i-1} \sum_{I \in \binom{1:i-1}{n}} i(w_i; w_{I_1}; \dots; w_{I_n}) \sum_{m \in \{0,1\}^{i-1}} p_N(m) m_I
\end{aligned}$$

where the variable  $m$  ranges over bit-masks of length  $i-1$ , and  $m_I$  is equal to 1 when all indices  $I$  in  $m$  are equal to 1, and 0 otherwise. Now  $\sum_{m \in \{0,1\}^{i-1}} p_N(m) m_I$  is the total probability that all of a set of indices  $I$  survives erasure. Thus, informally:

$$\begin{aligned}
C(w_i|w_{1:i-1}) &= h(w_i) - \\
&\sum_{n=1}^{i-1} \sum_{I \in \binom{1:i-1}{n}} p_N(I \text{ survives}) i(w_i; w_{I_1}; \dots; w_{I_n}).
\end{aligned} \tag{7}$$

That is, the cost of a word is its inherent cost minus its interaction informations with context, which are weighted by the probability that all elements of those interactions survive erasure.

cancel out, leaving:

$$\begin{aligned}
\text{pmi}(a_i; a_{1:i-1}) &= h(a_i) + \sum_{n=0}^{i-1} \sum_{I \in \binom{1:i-1}{n}} i(a_i; a_{I_1}; \dots; a_{I_n}) \\
&= h(a_i) + \sum_{n=1}^{i-1} \sum_{I \in \binom{1:i-1}{n}} i(a_i; a_{I_1}; \dots; a_{I_n}) - h(a_i) \\
&= \sum_{n=1}^{i-1} \sum_{I \in \binom{1:i-1}{n}} i(a_i; a_{I_1}; \dots; a_{I_n}),
\end{aligned}$$

which gives Equation 6 when applied to  $w_i$  and  $v_{1:i-1}$ .

Under progressive erasure noise, the probability that a subset of variables is erased increases the farther left those variables are in the context. Therefore, Equation 7 expresses information locality: context elements which are predictive of  $w_i$  will only get to mitigate the cost of processing  $w_i$  if they are close to it. The surprisal-mitigating effect of a context element on a word  $w_i$  decreases as that element gets farther from  $w_i$ .

## 4.2 Noisy Surprisal and Dependency Locality

Memory-based models of sentence processing account for apparent **dependency locality effects**, which is processing cost apparently arising from two words linked in a syntactic dependency appearing far from one another (Gibson, 1998). Dependency length has been proposed as a rough measure of comprehension and production difficulty, and studied as a predictor of reaction times (Grodner and Gibson, 2005; Demberg and Keller, 2008; Mitchell et al., 2010; Shain et al., 2016), and also as a theory of production preferences and linguistic typology, under the assumption that people prefer to produce sentences with short dependencies (dependency length minimization) (Hawkins, 1994; Gildea and Temperley, 2010; Futrell et al., 2015; Rajkumar et al., 2016).

Dependency locality follows from information locality if words linked in a syntactic dependency have particularly high mutual information. To see this, consider only the lowest-order interaction information terms in Equation 7, truncating the summation over  $n$  at 1. We can write

$$C(w_i|w_{1:i-1}) = h(w_i) - \sum_{j=1}^{i-1} f(i-j) \text{pmi}(w_i; w_j) + R,$$

where  $R$  collects all the interaction information terms of order greater than 2, and  $f(d)$  is the monotonically decreasing survival probability of a  $d$ -back word, described in Section 4.1.1. The effects of  $R$  are bounded because higher-order mutual information terms are more penalized by erasure noise than lower-order terms, simply because large sets of context items are more likely to experience at least one erasure.

If the effects of  $R$  are negligible, then the cost of a whole utterance  $w$  as a function of word order is determined only by pairwise information locality:

$$C(w) \approx \sum_{i=1}^{|w|} h(w_i) - \sum_{i=2}^{|w|} \sum_{j=1}^{i-1} f(i-j) \text{pmi}(w_i; w_j).$$

If words linked in a dependency have higher mutual information than words that are not, then the processing cost as a function of word order is a monotonically increasing function of dependency length. Under this assumption, for which we provide evidence below, dependency locality effects can be seen as a special case of information locality effects. As a theory of production preferences or typology, processing cost as a monotonically increasing function of dependency length suffices to derive the predictions of dependency length minimization (Ferrer i Cancho, 2015).

### 4.3 Mutual Information and Syntactic Dependency

We have shown that noisy-context surprisal derives information locality, and argued that dependency locality can be seen as a special case of information locality. However, deriving dependency locality requires a crucial assumption that words linked in a dependency have higher mutual information than those words that are not.

To test this assumption, we calculated mutual information between wordforms in various dependency relations in the Google Syntactic  $n$ -gram corpus (Goldberg and Orwant, 2013). We compared the mutual information of content words in a direct dependency relationship to content words in grandparent–grandchild and sister–sister dependency relationships. Mutual information was estimated using maximum likelihood estimation from frequencies, treating the corpus as samples from a distribution over (head, dependent) pairs. In order to exclude nonlinguistic forms, we only included wordforms if they were among the top 10000 most frequent wordforms in the corpus. The direct head–dependent frequencies were calculated from the same corpus as the grandparent-grandchild frequencies, so that all mutual information estimates are affected by the same frequency cutoff. The results are shown in Table 2: direct head–dependent pairs indeed have the highest mutual information.

To test the crosslinguistic validity of this generalization about syntactic dependency and mutual information, we calculated mutual information between the distributions over POS tags for dependency pairs of 43 languages in the Universal Dependencies corpus (Nivre et al., 2016). For this calculation, we used mutual information over POS tags rather than wordforms to avoid data sparsity issues. The results are shown in Figure 3.

Relation	MI (bits)
Head–dependent	1.79
Grandparent–dependent	1.34
Sister–sister	1.19

Table 2: Mutual information over wordforms in different dependency relations in the Syntactic  $n$ -gram corpus. The pairwise comparison of head–dependent and grandparent–dependent MI is significant at  $p < 0.005$  by Monte Carlo permutation tests over  $n$ -grams with 500 samples. The comparison of head–dependent and sister–sister MI is not significant.

Again, we find that mutual information is highest for direct head–dependency pairs, and falls off for more distant relations. These results show that two words in a syntactic dependency relationship are more predictive of each other than two words in some other kinds of relationship.

We also compared the mutual information of word pairs in and out of dependency relationships while controlling for distance. This test has a dual purpose. First, it allows us to control for distance when claiming that words in dependency relationships have high mutual information. Second, it allows us to test a simple prediction of information locality as applied to language production: that words with high mutual information should be close together. For pairs of words  $(w_i, w_{i+k})$ , we calculated the pmi values among POS tags of the words. Figure 4 shows the average pmi of all words at each distance compared with the average pmi of the subset of words in a direct dependency relationship at that distance. In all languages, we find that words in a dependency relationship have higher pmi than the baseline, especially at close distances. Furthermore, we find that words at close distances tend to have higher pmi, regardless of whether they are in a dependency relationship.

### 4.4 Discussion

Information locality can be seen as a decay in the effectiveness of contextual cues for predicting words. Precisely such a decay in cue effectiveness was found to be effective for predicting entropy distributions across sentences in Qian and Jaeger (2012), although that work did not distinguish between an inherent, noise-based decay in cue effectiveness or optimized placement of cues.

Figure 3: Mutual information over POS tags for dependency relations in the Universal Dependencies 1.4 corpus, for languages with over 500 sentences. All pairwise MI comparisons are significant at  $p < 0.005$  by Monte Carlo permutation tests over dependency observations with 500 samples.

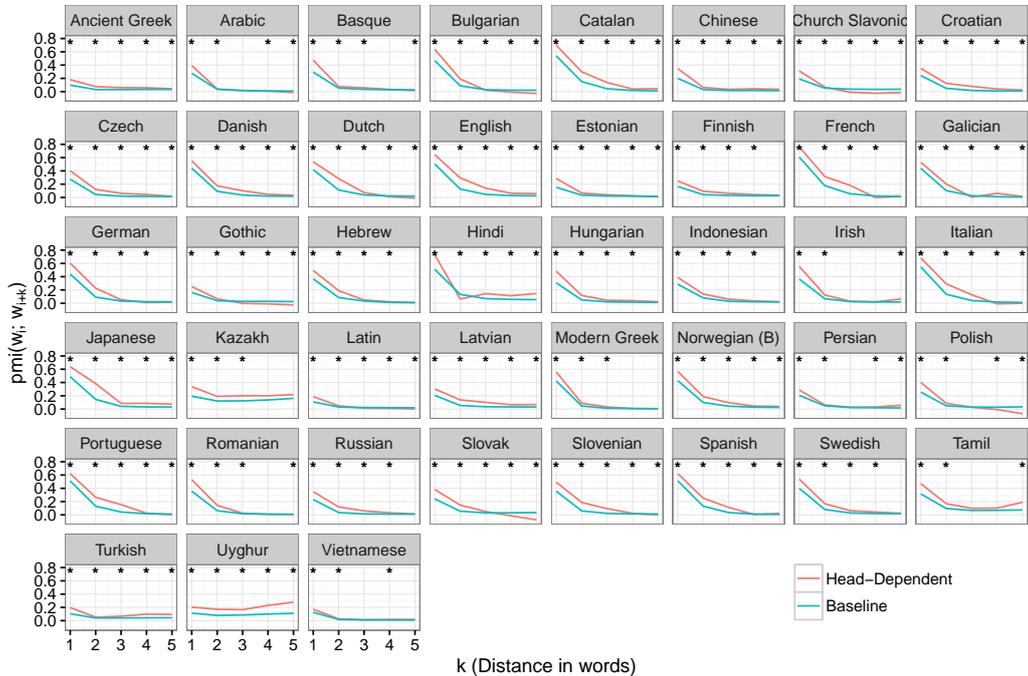

Figure 4: Average pointwise mutual information over POS tags for word pairs with  $k$  words intervening, for all words (baseline) and for words in a direct dependency relationship. Asterisks mark distances where the difference between the baseline and words in a dependency relationship is significant at  $p < 0.005$  by Monte Carlo permutation tests over word pair observations with 500 samples.

The result of Gildea and Jaeger (2015), which shows that word orders in languages are optimized to minimize trigram surprisal of words, can be taken to show maximization of information locality under the noise distribution where context is truncated deterministically at length 2. Whereas Gildea and Jaeger (2015) treat dependency length minimization and trigram surprisal minimization as separate factors, under the view in this paper these two phenomena emerge as two aspects of information locality. In general, the mutual information of linguistic elements has been found to decrease with distance (Li, 1989; Lin and Tegmark, 2016), although this claim has only been tested for letters, not for larger linguistic units such as morphemes. The fact that linguistic units that are close typically have high mutual information could result from optimization of word order for information locality.

The idea that syntactically dependent words have high mutual information is also ubiquitously implicit in probabilistic models of language and in practical NLP models. For example, it is implied by head-outward generative models (Eisner, 1996; Eisner, 1997; Klein and Manning, 2004), the first successful models for grammar induction. Mutual information has been used directly for unsupervised discovery of syntactic dependencies (Yuret, 1998) and evaluation of dependency parses (de Paiva Alves, 1996), as well as commonly for collocation detection (Church and Hanks, 1990). In addition to providing evidence for a crucial assumption in the derivation of information locality, our results also give evidence backing up the theoretical validity of such models and methods.

The derivation of information locality given here assumed progressive erasure noise for concreteness, but we believe it should be possible to derive this generalization for a large family of noise distributions.

## 5 Conclusion

We have introduced a computational-level model of incremental sentence processing difficulty based on the principle that comprehenders have uncertainty about the previous input and act rationally on that uncertainty. Noisy-context surprisal accounts for key effects predicted by expectation-based and memory-based models, in addition to providing the first computational-level explanation of language-specific structural forgetting,

which involves subtle interactions between memory and probabilistic expectations. Noisy-context surprisal also leads to a general principle of information locality offering a new interpretation of syntactic locality effects, and leading to broader and potentially different predictions than purely memory-based models.

Here we have used qualitative arguments and have used different specific noise distributions to make different points. Our aim has been to argue for the theoretical viability of noisy-context surprisal, without committing the theory to a particular noise distribution. We believe our predictions will be derivable under very general classes of noise distributions, and we plan to pursue these more general derivations in future work.

A more psychologically accurate model will likely use a more nuanced noise distribution than the simple decay functions in this paper, which do not capture the subtleties of human memory. In particular, simple decay functions do not capture memory retrieval effects of the kind described in Anderson and Schooler (1991), where different items in a sequence have different propensities to be forgotten, in accordance with rational allocation of resources for retrieval. Seen as a noise distribution, this memory model implies that the erasure probability of a word is a function of the word's identity, and not only the word's position in the sequence as in Section 4.1.1. Including such noise distributions in the noisy-context surprisal model could provide a rich set of predictions to test the model more extensively.

# Task-Specific Attentive Pooling of Phrase Alignments Contributes to Sentence Matching

Wenpeng Yin, Hinrich Schütze

The Center for Information and Language Processing  
LMU Munich, Germany  
wenpeng@cis.lmu.de

## Abstract

This work studies comparatively two typical sentence matching tasks: textual entailment (TE) and answer selection (AS), observing that weaker phrase alignments are more critical in TE, while stronger phrase alignments deserve more attention in AS. The key to reach this observation lies in phrase detection, phrase representation, phrase alignment, and more importantly how to connect those aligned phrases of different matching degrees with the final classifier.

Prior work (i) has limitations in phrase generation and representation, or (ii) conducts alignment at word and phrase levels by handcrafted features or (iii) utilizes a single framework of alignment without considering the characteristics of specific tasks, which limits the framework’s effectiveness across tasks.

We propose an architecture based on Gated Recurrent Unit that supports (i) representation learning of phrases of *arbitrary granularity* and (ii) task-specific attentive pooling of phrase alignments between two sentences. Experimental results on TE and AS match our observation and show the effectiveness of our approach.

## 1 Introduction

How to model a pair of sentences is a critical issue in many NLP tasks, including textual entailment (Marelli et al., 2014a; Bowman et al., 2015a; Yin et al., 2016a) and answer selection (Yu et al., 2014; Yang et al., 2015; Santos et al., 2016). A key challenge common to these tasks is the lack of explicit alignment annotation between the sentences of the pair. Thus, inferring and assessing the semantic relations between words and phrases in the two sentences is a core issue.

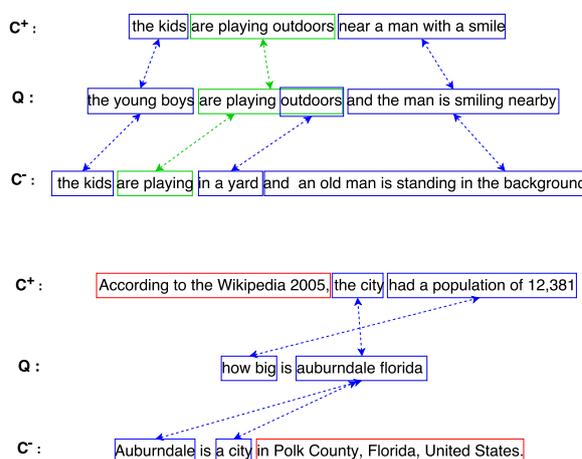

Figure 1: Alignment examples in TE (top) and AS (bottom). Green color: identical (subset) alignment; blue color: relatedness alignment; red color: unrelated alignment. Q: the first sentence in TE or the question in AS;  $C^+$ ,  $C^-$ : the correct or incorrect counterpart in the sentence pair ( $Q$ ,  $C$ ).

Figure 1 shows examples of human annotated phrase alignments. In the TE example, we try to figure out  $Q$  entails  $C^+$  (positive) or  $C^-$  (negative). As human beings, we discover the relationship of two sentences by studying the alignments between linguistic units. We see that some phrases are kept: “are playing outdoors” (between  $Q$  and  $C^+$ ), “are playing ” (between  $Q$  and  $C^-$ ). Some phrases are changed into related semantics on purpose: “the young boys” ( $Q$ )  $\rightarrow$  “the kids” ( $C^+$  &  $C^-$ ), “the man is smiling nearby” ( $Q$ )  $\rightarrow$  “near a man with a smile” ( $C^+$ ) or  $\rightarrow$  “an old man is standing in the background” ( $C^-$ ). We can see that the kept parts have stronger alignments (green color), and changed parts have weaker alignments (blue color). Here, by “strong” / “weak” we mean how semantically close the two aligned phrases are. To successfully identify the relationships of ( $Q$ ,  $C^+$ ) or ( $Q$ ,  $C^-$ ), studying the changed parts is crucial. Hence, we argue that TE should pay more attention to weaker alignments.

In AS, we try to figure out: does sentence  $C^+$  or sentence  $C^-$  answer question  $Q$ ? Roughly, the content in candidates  $C^+$  and  $C^-$  can be classified into aligned part (e.g., repeated or relevant parts) and negligible part. This differs from TE, in which it is hard to claim that some parts are negligible or play a minor role, as TE requires to make clear that each part can entail or be entailed. Hence, TE is considerably sensitive to those “unseen” parts. In contrast, *AS is more tolerant of negligible parts and less related parts*. From the AS example in Figure 1, we see that “Auburndale Florida” ( $Q$ ) can find related part “the city” ( $C^+$ ), and “Auburndale”, “a city” ( $C^-$ ); “how big” ( $Q$ ) also matches “had a population of 12,381” ( $C^+$ ) very well. And some unaligned parts exist, denoted by red color. *Hence, we argue that stronger alignments in AS deserve more attention.*

The above analysis suggests that: (i) alignments connecting two sentences can happen between phrases of arbitrary granularity; (ii) phrase alignments can have different intensities; (iii) tasks of different properties require paying different attention to alignments of different intensities.

Alignments at word level (Yih et al., 2013) or phrase level (Yao et al., 2013) both have been studied before. For example, Yih et al. (2013) make use of WordNet (Miller, 1995) and Probase (Wu et al., 2012) for identifying hyper- and hyponymy. Yao et al. (2013) use POS tags, WordNet and paraphrase database for alignment identification. Their approaches rely on manual feature design and linguistic resources. We develop a deep neural network (DNN) to learn representations of phrases of arbitrary lengths. As a result, alignments can be searched in a more automatic and exhaustive way.

DNNs have been intensively investigated in sentence pair classifications (Blacoe and Lapata, 2012; Socher et al., 2011; Yin and Schütze, 2015b), and attention mechanisms are also applied to individual tasks (Santos et al., 2016; Rocktäschel et al., 2016; Wang and Jiang, 2016); however, most attention-based DNNs have implicit assumption that stronger alignments deserve more attention (Yin et al., 2016a; Santos et al., 2016; Yin et al., 2016b). Our examples in Figure 1, instead, show that this assumption does not hold invariably. Weaker alignments in certain tasks such as TE can be the indicator of the final decision. Our inspiration comes from the analysis of some prior work. For TE, Yin et al. (2016a)

show that considering the pairs in which overlapping tokens are removed can give a boost. This simple trick matches our motivation that weaker alignment should be given more attention in TE. However, Yin et al. (2016a) remove overlapping tokens completely, potentially obscuring complex alignment configurations. In addition, Yin et al. (2016a) use the same attention mechanism for TE and AS, which is less optimal based on our observations.

This motivates us in this work to introduce DNNs with a flexible attention mechanism that is adaptable for specific tasks. For TE, it can make our system pay more attention to weaker alignments; for AS, it enables our system to focus on stronger alignments. We can treat the pre-processing in (Yin et al., 2016a) as a hard way, and ours as a soft way, as our phrases have more flexible lengths and the existence of overlapping phrases decreases the risk of losing important alignments. In experiments, we will show that this attention scheme is very effective for different tasks.

We make the following contributions. (i) We use GRU (Gated Recurrent Unit (Cho et al., 2014)) to learn representations for phrases of arbitrary granularity. Based on phrase representations, we can detect phrase alignments of different intensities. (ii) We propose attentive pooling to achieve flexible choice among alignments, depending on the characteristics of the task. (iii) We achieve state-of-the-art on TE task.

## 2 Related Work

**Non-DNN for sentence pair modeling.** Heilman and Smith (2010) describe tree edit models that generalize tree edit distance by allowing operations that better account for complex re-ordering phenomena and by learning from data how different edits should affect the model’s decisions about sentence relations. Wang and Manning (2010) cope with the alignment between a sentence pair by using a probabilistic model that models tree-edit operations on dependency parse trees. Their model treats alignments as structured latent variables, and offers a principled framework for incorporating complex linguistic features. Guo and Diab (2012) identify the degree of sentence similarity by modeling the missing words (words that are not in the sentence) so as to relieve the sparseness issue of sentence modeling. Yih et

al. (2013) try to improve the shallow semantic component, lexical semantics, by formulating sentence pair as a semantic matching problem with a latent word-alignment structure as in (Chang et al., 2010). More fine-grained word overlap and alignment between two sentences are explored in (Lai and Hockenmaier, 2014), in which negation, hypernym/hyponym, synonym and antonym relations are used. Yao et al. (2013) extend word-to-word alignment to phrase-to-phrase alignment by a semi-Markov CRF. Such approaches often require more computational resources. In addition, using syntactic/semantic parsing during run-time to find the best matching between structured representation of sentences is not trivial.

**DNN for sentence pair classification.** There recently has been great interest in using DNNs for classifying sentence pairs as they can reduce the burden of feature engineering.

For TE, Bowman et al. (2015b) employ recursive DNN to encode entailment on SICK (Marelli et al., 2014b). Rocktäschel et al. (2016) present an attention-based LSTM (long short-term memory, Hochreiter and Schmidhuber (1997)) for the SNLI corpus (Bowman et al., 2015a).

For AS, Yu et al. (2014) present a bigram CNN (convolutional neural network (LeCun et al., 1998)) to model question and answer candidates. Yang et al. (2015) extend this method and get state-of-the-art performance on the WikiQA dataset. Feng et al. (2015) test various setups of a bi-CNN architecture on an insurance domain QA dataset. Tan et al. (2015) explore bidirectional LSTM on the same dataset. Other sentence matching tasks such as paraphrase identification (Socher et al., 2011; Yin and Schütze, 2015a), question – Freebase fact matching (Yin et al., 2016b) etc. are also investigated.

Some prior work aims to solve a general sentence matching problem. Hu et al. (2014) present two CNN architectures for paraphrasing, sentence completion (SC), tweet-response matching tasks. Yin and Schütze (2015b) propose the Multi-GranCNN architecture to model general sentence matching based on phrase matching on multiple levels of granularity. Wan et al. (2016) try to match two sentences in AS and SC by multiple sentence representations, each coming from the local representations of two LSTMs.

**Attention-based DNN for alignment.** DNNs have been successfully developed to detect align-

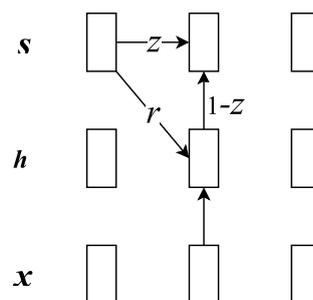

Figure 2: Gated Recurrent Unit

ments, e.g., in machine translation (Bahdanau et al., 2015; Luong et al., 2015) and text reconstruction (Li et al., 2015; Rush et al., 2015). In addition, attention-based alignment is also applied in natural language inference (e.g., Rocktäschel et al. (2016), Wang and Jiang (2016)). However, most of this work aligns word-by-word. As Figure 1 shows, many sentence relations can be better identified through phrase level alignments. This is one motivation of our work.

### 3 Model

This section first gives a brief introduction of GRU and how it performs phrase representation learning, then describes the different attentive poolings for phrase alignments w.r.t TE and AS tasks.

#### 3.1 GRU Introduction

GRU is a simplified version of LSTM. Both are found effective in sequence modeling, as they are order-sensitive and can capture long-range context. The tradeoffs between GRU and its competitor LSTM have not been fully explored yet. According to empirical evaluations in (Chung et al., 2014; Jozefowicz et al., 2015), there is not a clear winner. In many tasks both architectures yield comparable performance and tuning hyper-parameters like layer size is probably more important than picking the ideal architecture. GRU have fewer parameters and thus may train a bit faster or need less data to generalize. Hence, we use GRU, as shown in Figure 2, to model text:

$$\mathbf{z} = \sigma(\mathbf{x}_t \mathbf{U}^z + \mathbf{s}_{t-1} \mathbf{W}^z) \quad (1)$$

$$\mathbf{r} = \sigma(\mathbf{x}_t \mathbf{U}^r + \mathbf{s}_{t-1} \mathbf{W}^r) \quad (2)$$

$$\mathbf{h}_t = \tanh(\mathbf{x}_t \mathbf{U}^h + (\mathbf{s}_{t-1} \circ \mathbf{r}) \mathbf{W}^h) \quad (3)$$

$$\mathbf{s}_t = (1 - \mathbf{z}) \circ \mathbf{h}_t + \mathbf{z} \circ \mathbf{s}_{t-1} \quad (4)$$

$x$  is the input sentence with token  $\mathbf{x}_t \in \mathbb{R}^d$  at position  $t$ ,  $\mathbf{s}_t \in \mathbb{R}^h$  is the hidden state at  $t$ , supposed to

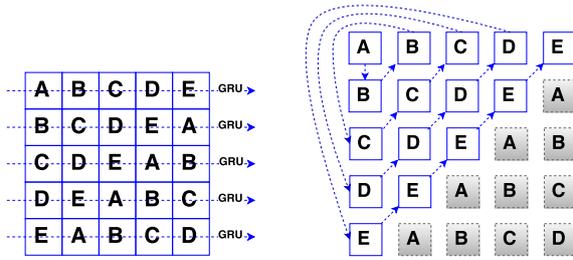

Figure 3: Phrase representation learning by GRU (left), sentence reformatting (right)

encode the history  $x_1, \dots, x_{t-1}$ .  $\mathbf{z}$  and  $\mathbf{r}$  are two gates. All  $\mathbf{U} \in \mathbb{R}^{d \times h}$ ,  $\mathbf{W} \in \mathbb{R}^{h \times h}$  are parameters in GRU.

### 3.2 Representation Learning for Phrases

For a general sentence  $s$  with five consecutive words: ABCDE, with each word represented by a word embedding of dimensionality  $d$ , we first create four fake sentences,  $s^1$ : “BCDEA”,  $s^2$ : “CDEAB”,  $s^3$ : “DEABC” and  $s^4$ : “EABCD”, then put them in a matrix (Figure 3, left).

We run GRUs on each row of this matrix in parallel. As GRU is able to encode the whole sequence up to current position, this step generates representations for any consecutive phrases in original sentence  $s$ . For example, the GRU hidden state at position “E” at coordinates (1,5) (i.e., 1st row, 5th column) denotes the representation of the phrase “ABCDE” which in fact is  $s$  itself, the hidden state at “E” (2,4) denotes the representation of phrase “BCDE”, . . . , the hidden state of “E” (5,1) denotes phrase representation of “E” itself. Hence, for each token, we can learn the representations for all phrases ending with this token. Finally, all phrases of any lengths in  $s$  can get a representation vector. GRUs in those rows are set to share weights so that all phrase representations are comparable in the same space.

Now, we reformat sentence “ABCDE” into  $s^* =$  “(A) (B) (AB) (C) (BC) (ABC) (D) (CD) (BCD) (ABCD) (E) (DE) (CDE) (BCDE) (ABCDE)”, as shown by arrows in Figure 3 (right), the arrow direction means phrase order. Each sequence in parentheses is a phrase (we use parentheses just for making the phrase boundaries clear). Randomly taking a phrase “CDE” as an example, its representation comes from the hidden state at “E” (3,3) in Figure 3 (left). Shaded parts are discarded. The main advantage of reformatting sentence “ABCDE” into the *new sentence*  $s^*$  is to cre-

ate phrase-level semantic units, but at the same time we maintain the order information.

Hence, the sentence “how big is Auburndale Florida” in Figure 1 will be reformatted into “(how) (big) (how big) (is) (big is) (how big is) (Auburndale) (is Auburndale) (big is Auburndale) (how big is Auburndale) (Florida) (Auburndale Florida) (is Auburndale Florida) (big is Auburndale Florida) (how big is Auburndale Florida)”. We can see that phrases are exhaustively detected and represented.

In the experiments of this work, we explore the phrases of maximal length 7 instead of arbitrary lengths.

### 3.3 Attentive Pooling

As each sentence  $s^*$  consists of a sequence of phrases, and each phrase is denoted by a representation vector generated by GRU, we can compute an *alignment matrix*  $\mathbf{A}$  between two sentences  $s_1^*$  and  $s_2^*$ , by comparing each two phrases, one from  $s_1^*$  and one from  $s_2^*$ . Let  $s_1^*$  and  $s_2^*$  also denote lengths respectively, thus  $\mathbf{A} \in \mathbb{R}^{s_1^* \times s_2^*}$ . While there are many ways of computing the entries of  $\mathbf{A}$ , we found that cosine works well in our setting.

The first step then is to detect the best alignment for each phrase by leveraging  $\mathbf{A}$ . To be concrete, for sentence  $s_1^*$ , we do row-wise max-pooling over  $\mathbf{A}$  as attention vector  $\mathbf{a}_1$ :

$$\mathbf{a}_{1,i} = \max(\mathbf{A}[i, :]) \quad (5)$$

In  $\mathbf{a}_1$ , the entry  $\mathbf{a}_{1,i}$  denotes the best alignment for  $i^{\text{th}}$  phrase in sentence  $s_1^*$ . Similarly, we can do column-wise max-pooling to generate attention vector  $\mathbf{a}_2$  for sentence  $s_2^*$ .

Now, the problem is that we need to pay most attention to the phrases aligned very well or phrases aligned badly. According to the analysis of the two examples in Figure 1, we need to pay more attention to weaker (resp. stronger) alignments in TE (resp. AS). To this end, we adopt different second step over attention vector  $\mathbf{a}_i$  ( $i = 1, 2$ ) for TE and AS.

For TE, in which weaker alignments are supposed to contribute more, we do *k-min-pooling* over  $\mathbf{a}_i$ , i.e., we only keep the  $k$  phrases which are aligned worst. For the  $(Q, C^+)$  pair in TE example of Figure 1, we expect this step is able to put most of our attention to the phrases “the kids”, “the young boys”, “near a man with a smile” and “and the man is smiling nearby” as they have rela-

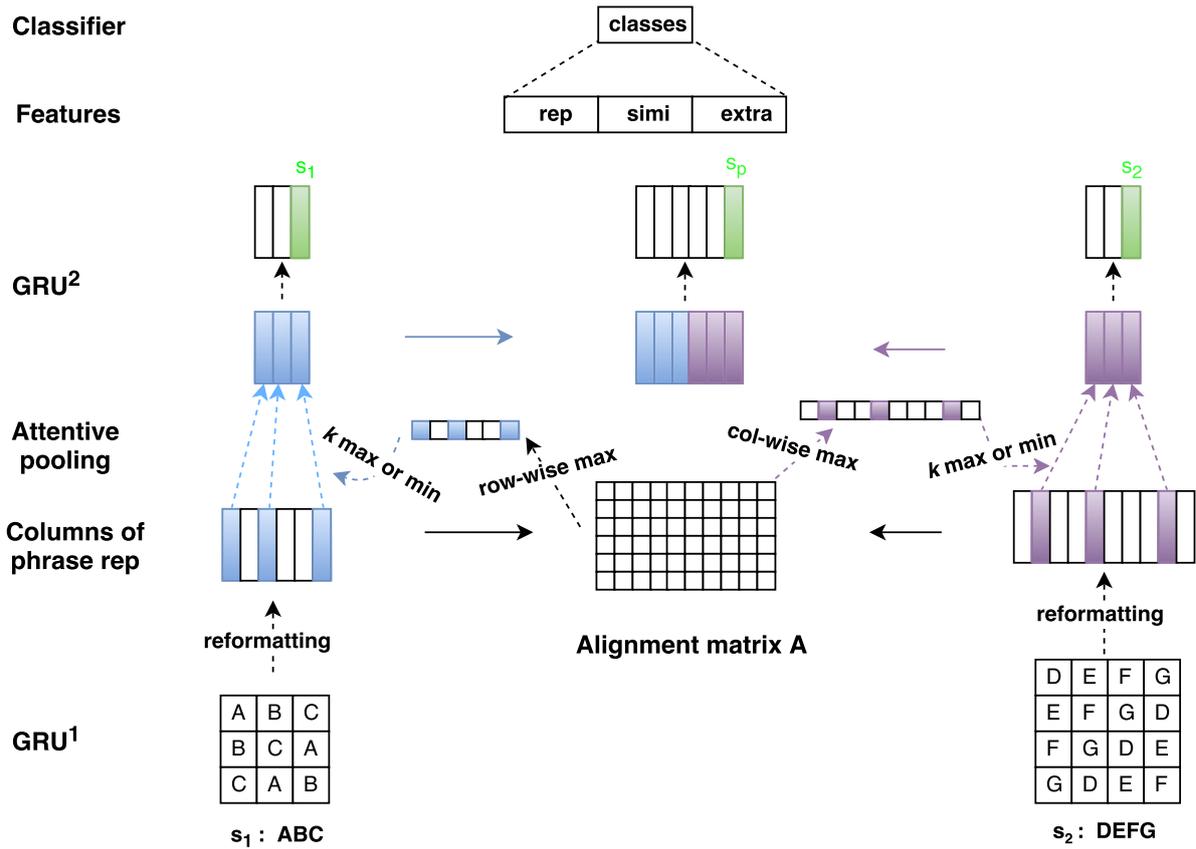

Figure 4: The whole architecture

tively weaker alignments while their relations are the indicator of the final decision.

For AS, in which stronger alignments are supposed to contribute more, we do  $k$ -max-pooling over  $\mathbf{a}_i$ , i.e., we only keep the  $k$  phrases which are aligned best. For the  $(Q, C^+)$  pair in AS example of Figure 1, we expect this  $k$ -max-pooling is able to put most of our attention to the phrases “how big” “Auburndale Florida”, “the city” and “had a population of 12,381” as they have relatively stronger alignments and their relations are the indicator of the final decision. We keep the original order of extracted phrases after  $k$ -min/max-pooling.

In summary, for TE, we first do row-wise max-pooling over alignment matrix, then do  $k$ -min-pooling over generated alignment vector; we use  $k$ -min-max-pooling to denote the whole process. In contrast, we use  $k$ -max-max-pooling for AS. We refer to this method of using two successive min or max pooling steps as *attentive pooling*.

### 3.4 The Whole Architecture

Now, we present the whole system in Figure 4. We take sentences  $s_1$  “ABC” and  $s_2$  “DEFG” as illustration. Each token, i.e., A to F, in the figure is denoted by an embedding vector, hence each sentence is represented as an order-3 tensor as input (they are depicted as rectangles just for simplicity). Based on tensor-style sentence input, we have described the phrase representation learning by GRU1 in Section 3.2 and attentive pooling in Section 3.3.

Attentive pooling generates a new feature map for each sentence, as shown in Figure 4 (the third layer from the bottom), and each column representation in the feature map denotes a key phrase in this sentence that, based on our modeling assumptions, should be a good basis for the correct final decision. For instance, we expect such a feature map to contain representations of “the young boys”, “outdoors” and “and the man is smiling nearby” for the sentence  $Q$  in the TE example of Figure 1.

Now, we do another GRU2 step for: 1) the new

	$d$	lr	bs	$L_2$	$div$	$k$
TE	[256,256]	.0001	1	.0006	.06	5
AS	[50,50]	.0001	1	.0006	.06	6

Table 1: Hyperparameters.  $d$ : dimensionality of hidden states in GRU layers; lr: learning rate; bs: mini-batch size;  $L_2$ :  $L_2$  normalization;  $div$ : diversity regularizer;  $k$ :  $k$ -min/max-pooling.

feature map of each sentence mentioned above, to encode all the key phrases as the sentence representation; 2) a concatenated feature map of the two new sentence feature maps, to encode all the key phrases in the two sentences sequentially as the representation of the *sentence pair*. As GRU generates a hidden state at each position, we always choose the last hidden state as the representation of the sentence or sentence pair. In Figure 4 (the fourth layer), these final GRU-generated representations for sentence  $s_1$ ,  $s_2$  and the sentence pair are depicted as green columns:  $s_1$ ,  $s_2$  and  $s_p$  respectively.

As for the input of the final classifier, it can be flexible, such as representation vectors (*rep*), similarity scores between  $s_1$  and  $s_2$  (*simi*), and extra linguistic features (*extra*). This can vary based on the specific tasks. We give details in Section 4.

## 4 Experiments

We test the proposed architectures on TE and AS benchmark datasets.

### 4.1 Common Setup

For both TE and AS, words are initialized by 300-dimensional GloVe embeddings<sup>1</sup> (Pennington et al., 2014) and not changed during training. A single randomly initialized embedding is created for all unknown words by uniform sampling from  $[-.01, .01]$ . We use ADAM (Kingma and Ba, 2015), with a first momentum coefficient of 0.9 and a second momentum coefficient of 0.999,<sup>2</sup>  $L_2$  regularization and Diversity Regularization (Xie et al., 2015). Table 1 shows the values of the hyperparameters, tuned on dev.

**Classifier.** Following Yin et al. (2016a), we use three classifiers – logistic regression in DNN, logistic regression and linear SVM with default parameters<sup>3</sup> directly on the feature vector – and report performance of the best.

<sup>1</sup>[nlp.stanford.edu/projects/glove/](http://nlp.stanford.edu/projects/glove/)

<sup>2</sup>Standard configuration recommended by Kingma and Ba

<sup>3</sup><http://scikit-learn.org/stable/> for both.

**Common Baselines.** (i) **Addition.** We sum up word embeddings element-wise to form sentence representation, then concatenate two sentence representation vectors ( $s_1^0, s_2^0$ ) as classifier input. (ii) **A-LSTM.** The pioneering attention based LSTM system for a specific sentence pair classification task “natural language inference” (Rocktäschel et al., 2016). A-LSTM has the same dimensionality as our GRU system in terms of initialized word representations and the hidden states. (iii) **ABCNN** (Yin et al., 2016a). The state-of-the-art system in both TE and AS.

Based on the motivation in Section 1, the main hypothesis to be tested in experiments is:  $k$ -min-max-pooling is superior for TE and  $k$ -max-max-pooling is superior for AS. In addition, we would like to determine whether the second pooling step in attention pooling, i.e., the  $k$ -min/max-pooling, is more effective than a “full-pooling” in which *all* the generated phrases are forwarded into the next layer.

### 4.2 Textual Entailment

SemEval 2014 Task 1 (Marelli et al., 2014a) evaluates system predictions of textual entailment (TE) relations on sentence pairs from the SICK dataset (Marelli et al., 2014b). The three classes are entailment, contradiction and neutral. The sizes of SICK train, dev and test sets are 4439, 495 and 4906 pairs, respectively. *We choose SICK benchmark dataset so that our result is directly comparable with that of (Yin et al., 2016a), in which non-overlapping text are utilized explicitly to boost the performance. That trick inspires this work.*

Following Lai and Hockenmaier (2014), we train our final system (after fixing of hyperparameters) on train and dev (4,934 pairs). Our evaluation measure is accuracy.

#### 4.2.1 Feature Vector

The final feature vector as input of classifier contains three parts: *rep*, *simi*, *extra*.

**Rep.** Totally five vectors, three are the top sentence representation  $s_1, s_2$  and the top sentence pair representation  $s_p$  (shown in green in Figure 4), two are  $s_1^0, s_2^0$  from *Addition* baseline.

**Simi.** Four similarity scores, cosine similarity and euclidean distance between  $s_1$  and  $s_2$ , cosine similarity and euclidean distance between  $s_1^0$  and  $s_2^0$ . Euclidean distance  $\| \cdot \|$  is transformed into  $1/(1 + \| \cdot \|)$ .

	method	acc
SemEval Top3	(Jimenez et al., 2014)	83.1
	(Zhao et al., 2014)	83.6
	(Lai and Hockenmaier, 2014)	84.6
TrRNTN	(Bowman et al., 2015b)	76.9
Addition	no features	73.1
	plus features	79.4
A-LSTM	no features	78.0
	plus features	81.7
ABCNN	(Yin et al., 2016a)	86.2
GRU <i>k</i> -min-max ablation	– rep	86.4
	– simi	85.1
	– extra	85.5
GRU	<i>k</i> -max-max-pooling	84.9
	full-pooling	85.2
	<i>k</i> -min-max-pooling	<b>87.1*</b>

Table 2: Results on SICK. Significant improvement over both *k*-max-max-pooling and full-pooling is marked with \* (test of equal proportions,  $p < .05$ ).

**Extra.** We include the same 22 linguistic features as Yin et al. (2016a). They cover 15 machine translation metrics between the two sentences; whether or not the two sentences contain negation tokens like “no”, “not” etc; whether or not they contain synonyms, hypernyms or antonyms; two sentence lengths. See Yin et al. (2016a) for details.

#### 4.2.2 Results

Table 2 shows that GRU with *k*-min-max-pooling gets state-of-the-art performance on SICK and significantly outperforms *k*-max-max-pooling and full-pooling. Full-pooling has more phrase input than the combination of *k*-max-max-pooling and *k*-min-max-pooling, this might bring two problems: (i) noisy alignments increase; (ii) sentence pair representation  $s_p$  is no longer discriminative –  $s_p$  does not know its semantics comes from phrases of  $s_1$  or  $s_2$ : as different sentences have different lengths, the boundary location separating two sentences varies across pairs. However, this is crucial to determine whether  $s_1$  entails  $s_2$ .

ABCNN (Yin et al., 2016a) is based on assumptions similar to *k*-max-max-pooling: words/phrases with higher matching values should contribute more in this task. However, ABCNN gets the optimal performance by combining a reformatted SICK version in which

	method	MAP	MRR
Baselines	CNN-Cnt	0.6520	0.6652
	Addition	0.5021	0.5069
	Addition-Cnt	0.5888	0.5929
	A-LSTM	0.5321	0.5469
	A-LSTM-Cnt	0.6388	0.6529
	AP-CNN	0.6886	0.6957
GRU <i>k</i> -max-max ablation	ABCNN	0.6921	0.7127
	– rep	0.6913	0.6994
	– simi	0.6764	0.6875
GRU	– extra	0.6802	0.6899
	<i>k</i> -min-max-pooling	0.6674	0.6791
	full-pooling	0.6693	0.6785
	<i>k</i> -max-max-pooling	<b>0.7124*</b>	<b>0.7237*</b>

Table 3: Results on WikiQA. Significant improvement over both *k*-min-max-pooling and full-pooling is marked with \* ( $t$ -test,  $p < .05$ ). STOA: 74.17 (MAP)/75.88 (MRR) in (Tymoshenko et al., 2016)

overlapping tokens in two sentences are removed. This instead hints that non-overlapping units can do a big favor for this task, which is indeed the superiority of our “*k*-min-max-pooling”.

#### 4.3 Answer Selection

We use WikiQA<sup>4</sup> subtask that assumes there is at least one correct answer for a question. This dataset consists of 20,360, 1130 and 2352 question-candidate pairs in train, dev and test, respectively. Following Yang et al. (2015), we truncate answers to 40 tokens and report mean average precision (MAP) and mean reciprocal rank (MRR).

Apart from the common baselines Addition, A-LSTM and ABCNN, we compare further with: (i) **CNN-Cnt** (Yang et al., 2015): combine CNN with two linguistic features “WordCnt” (the number of non-stopwords in the question that also occur in the answer) and “WgtWordCnt” (reweight the counts by the IDF values of the question words); (ii) **AP-CNN** (Santos et al., 2016).

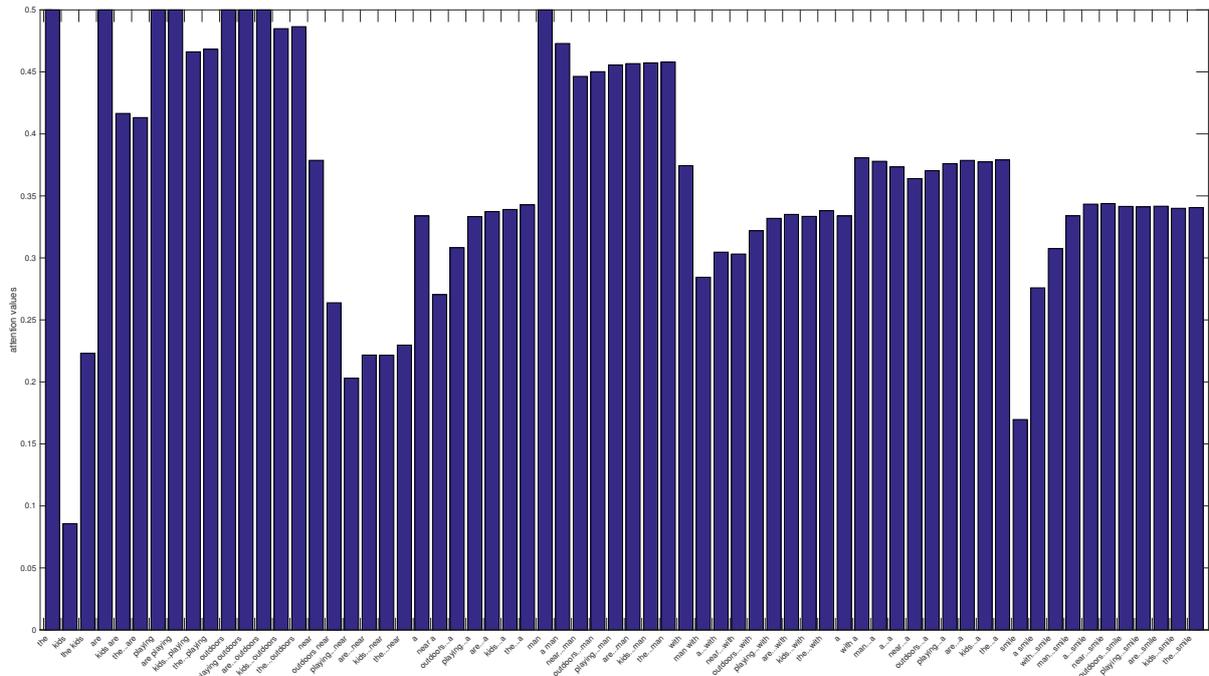

##### 4.3.1 Feature Vector

The final feature vector in AS has the same (*rep*, *simi*, *extra*) structure as TE, except that **simi** consists of only two cosine similarity scores, and **extra** consists of four entries: two sentence lengths, WordCnt and WgtWordCnt.

Figure 5: Attention Visualization

### 4.3.2 Results

Table 3 shows that GRU with  $k$ -max-max-pooling is significantly better than its  $k$ -min-max-pooling and full-pooling versions. GRU with  $k$ -max-max-pooling has similar assumption with ABCNN (Yin et al., 2016a) and AP-CNN (Santos et al., 2016): units with higher matching scores are supposed to contribute more in this task. Our improvement

can be due to that: i) our linguistic units cover more exhaustive phrases, it enables alignments in a wider range; ii) we have two max-pooling steps in our attention pooling, especially the second one is able to remove some noisily aligned phrases. Both ABCNN and AP-CNN are based on convolutional layers, the phrase detection is constrained by filter sizes. Even though ABCNN tries a second

CNN layer to detect bigger-granular phrases, their phrases in different CNN layers cannot be aligned directly as they are in different spaces. GRU in this work uses the same weights to learn representations of arbitrary-granular phrases, hence, all phrases can share the representations in the same space and can be compared directly.

#### 4.4 Visual Analysis

In this subsection, we visualize the attention distributions over phrases, i.e.,  $a_i$  in Equation 5, of example sentences in Figure 1 (for space limit, we only show this for TE example). Figures 5(a)-5(b) respectively show the attention values of each phrase in  $(Q, C^+)$  pair in TE example in Figure 1. We can find that  $k$ -min-pooling over this distributions can indeed detect some key phrases that are supposed to determine the pair relations. Taking Figure 5(a) as an example, phrases “young boys”, phrases ending with “and”, phrases “smiling”, “is smiling”, “nearby” and a couple of phrases ending with “nearby” have lowest attention values. According to our  $k$ -min-pooling step, these phrases will be detected as key phrases. Considering further the Figure 5(b), phrases “kids”, phrases ending with “near”, and a couple of phrases ending with “smile” are detected as key phrases.

If we look at the key phrases in both sentences, we can find that the discovering of those key phrases matches our analysis in Section 1 for TE example: “kids” corresponds to “young boys”, “smiling nearby” corresponds to “near...smile”.

Another interesting phenomenon is that, taking Figure 5(b) as example, even though “are playing outdoors” can be well aligned as it appears in both sentences, nevertheless the visualization figures show that the attention values of “are playing outdoors and” in  $Q$  and “are playing outdoors near” drop dramatically. This hints that our model can get rid of some surface matching, as the key token “and” or “near” makes the semantics of “are playing outdoors and” and “are playing outdoors near” be pretty different with their sub-phrase “are playing outdoors”. This is important as “and” or “near” is crucial unit to connect the following key phrases “smiling nearby” in  $Q$  or “a smile” in  $C^+$ . If we connect those key phrases sequentially as a new fake sentence, as we did in attentive pooling layer of Figure 4, we can see that the fake sentence roughly “reconstructs” the meaning of the original sentence while it is composed of phrase-level se-

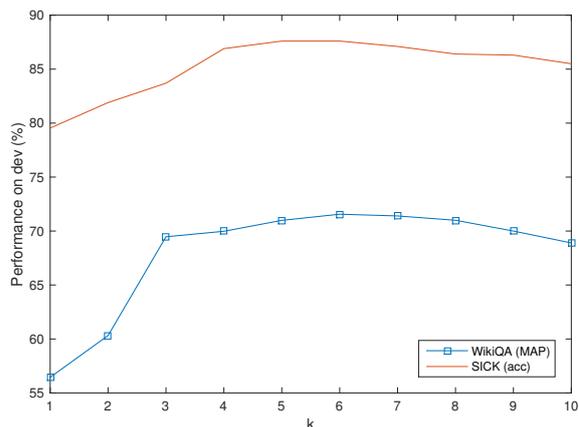

Figure 6: Effects of pooling size  $k$  (cf. Table Table 1)

mantic units now.

#### 4.5 Effects of Pooling Size $k$

The key idea of the proposed method is achieved by the  $k$ -min/max pooling. We show how the hyperparameter  $k$  influences the results by tuning on the dev sets.

In Figure 6, we can see the performance trends of changing  $k$  value between 1 and 10 in the two tasks. Roughly  $k > 4$  can give competitive results, but larger values bring performance drop.

### 5 Conclusion

In this work, we investigate the contribution of different intensities of phrase alignments for different tasks. We argue that it is not true that stronger alignments always matter more. We found TE task prefers weaker alignments while AS task prefers stronger alignments. We proposed flexible attentive poolings in GRU system to satisfy the different requirements of different tasks. Experimental results show the soundness of our argument and the effectiveness of our attention pooling based GRU systems.

As future work, we plan to investigate phrase representation learning in context and how to conduct the attentive pooling automatically regardless of the categories of the tasks.

## Abstract

We approach the recognition of textual entailment using logical semantic representations and a theorem prover. In this setup, lexical divergences that preserve semantic entailment between the source and target texts need to be explicitly stated. However, recognising subsentential semantic relations is not trivial. We address this problem by monitoring the proof of the theorem and detecting unprovable sub-goals that share predicate arguments with logical premises. If a linguistic relation exists, then an appropriate axiom is constructed on-demand and the theorem proving continues. Experiments show that this approach is effective and precise, producing a system that outperforms other logic-based systems and is competitive with state-of-the-art statistical methods.

## 1 Introduction

Recognising Textual Entailment (RTE) is a challenging NLP application where the objective is to judge whether a text fragment  $H$  logically follows from another text fragment  $T$  (Dagan et al., 2013). Advances in RTE have potentially positive implications in other areas such as fact checking, question-answering or information retrieval. Solutions to the RTE problem span a wide array of methods. Some methods are purely statistical (Lai and Hockenmaier, 2014; Zhao et al., 2014), where a classifying function is estimated using lexical or syntactic features. Other methods are purely se-

mantic (Bos et al., 2004), where logical formulas that represent the text fragments are constructed and used in a formal proof system. And yet others are hybrid systems (Beltagy et al., 2013), where a combination of statistical features and logical formulas are used to judge entailment relations.

In this paper, we adopt a strategy based on logics, encouraged by the high-performance that these systems achieve in linguistically challenging datasets (Abzianidze, 2015; Mineshima et al., 2015). An important advantage of these systems (including ours) is that they are unsupervised, thus no training data is necessary and no parameters need to be adjusted.

Under the perspective of these logic-based systems, there are mainly two associated challenges when solving RTE problems. The first challenge is to model the logics of the language with the purpose to represent the semantics of text fragments accurately. To this end, we follow the standard practice in formal semantics where the meaning of sentences is represented using logical formulas. The second challenge is to account for lexical relations between text fragments, typically between words or non-compositional phrases. We dedicate our efforts to the latter challenge, and assume that wide coverage linguistic resources are available to signal potential relations between lexical items in text fragments. The question is then how to make the best use of these linguistic resources to close the lexical gap between source and target text fragments.

Our contribution is a precise mechanism that allows to construct and use linguistic axioms on-demand. This mechanism monitors the progress

of a logical proof, detects unprovable sub-goals, and inserts axioms when necessary if a lexical relation is found in an external linguistic resource. These linguistic axioms encode lexical relations between specific segments of the source and target text fragments, thus accounting for lexical divergences that preserve semantic inclusion. To the best of our knowledge, this is the first attempt to integrate on-demand axiom injection into a purely logical natural deduction proof to recognise textual entailment. In the SICK dataset, our system obtains the highest accuracy among the logic systems, and competitive results with respect to machine learning approaches. We believe that our formulation is general enough to be extended to other semantic systems and to introduce lexical knowledge from ontological resources or statistical classifiers efficiently and effectively.

## 2 Related Work

Our work on recognising textual entailment is primarily inspired by Bos and Markert (2005), where first-order logic interpretations of sentences are used to prove entailment relations with theorem provers and model builders. These semantic interpretations were composed using Boxer (Bos et al., 2004) from derivations of a Combinatory Categorical Grammar (CCG) (Steedman, 2000) automatically obtained by C&C, a wide-coverage CCG parser (Clark and Curran, 2007). This system was later extended into Nutcracker (Bjerva et al., 2014), where WordNet (Miller, 1995) and relations from Paraphrase Database (PPDB) (Ganitkevitch et al., 2013) are used to introduce external linguistic resources to account for lexical divergences (Pavlick et al., 2015). Pavlick et al. (2015) study the characteristics of linguistic relations that may signal entailment or contradiction at sub-sentential level. However, they ignore the logical context in which these linguistic relations occur in the entailment problem. Moreover, Nutcracker is not a purely logical system in that it uses a proof-approximation method with model-builders.

By contrast, our system is purely logic-based, in that it solely relies on proof constructions based on natural deduction system to make entailment judgements. In addition, as we will see below, a goal-directed proof construction procedure in our system is naturally combined with on-demand axiom injection, as opposed to simply selecting any two arbitrary phrases from  $T$  and  $H$  that display

any linguistic relation.

Beltagy et al. (2013) also use Boxer for their logical semantic representations but assign distributional similarity scores to any two phrases from  $T$  and  $H$  on-the-fly. Their approach is different from ours in that they use probabilistic logic as an underlying logic. Furthermore, the method to create relevant axioms in Beltagy et al. (2013) is based on a naïve enumeration, and they ignore the logical clues on when two phrases are candidates to be related, which we argue against.

Abzianidze (2015) presents a purely logic-based RTE system that uses CCG parsers and a natural-logic-based tableaux prover. However, his logical representations are based on a non-standard natural logic, which requires the definition of new inference rules for each logical word (e.g. *every*, *some*, *no*) and for which generic theorem provers are not reusable. Regarding the introduction of linguistic knowledge, the author uses only WordNet. However, during the learning phase, he adds missing knowledge manually (e.g. *note* is a hyponym of *paper*), whereas we restrict our results to those automatically generated.

Perhaps the most similar strategies to ours are those of Tian et al. (2014) and Beltagy et al. (2016), where the authors produce on-the-fly knowledge when the hypothesis  $H$  cannot be proved. In the work of Tian et al. (2014), propositions between  $T$  and  $H$  are aligned using logical clues; then, dependency paths are extracted between these propositions and WordNet or word vectors are used to assess the similarity between paths. However, the expressive power of their underlying representation system in Dependency-based Compositional Semantics (DCS) is rather limited and much weaker than the full first-order logic (Liang et al., 2013). Several extensions have been proposed (Tian et al., 2014; Dong et al., 2014), yet these DCS-based inference systems are a non-standard axiomatic system with many axioms and tend to be ad hoc. Whereas their semantic representations are specific to their logic framework, ours are well-understood, logically transparent representations that are generic to most state-of-the-art theorem provers using first-order logic.

Beltagy et al. (2016) use a Modified Robinson Resolution strategy to align clauses and literals between  $T$  and  $H$ . These alignments also constrain how the unaligned fragments of  $T$  and  $H$  may correspond to each other, reducing the

problem to a word or phrasal entailment recognition using a statistical classifier. However, that work only considers one possible set of alignments between  $T$ - $H$  fragments, which has a decaying coverage when there is repetitions of content words and meta-predicates (typically occurring in medium and long sentences). Instead, we consider multiple alignments by backtracking the decisions on variable and predicate unifications, which is a more powerful strategy. Beltagy et al. (2016) use Markov Logic Networks (MLNs), which is an elegant framework that combines logics and probabilistic reasoning. However, the construction of their Markov Networks is limited by first-order logic, which may pose problems to represent modality or generalised quantifiers. Instead, our logical representations can also be used in a more expressive, higher-order inference system such as the one in Martínez-Gómez et al. (2016), as it was shown by Mineshima et al. (2015) and Mineshima et al. (2016) in a practical application for RTE.

### 3 Background

This section provides some basic background on our logic-based approach to Recognising Textual Entailment (RTE). RTE is a task of determining whether or not a given text ( $T$ ) entails a given hypothesis ( $H$ ). In logic-based approaches,  $T$  and  $H$  are mapped onto logical formulas; whether  $T$  entails  $H$  is then determined by checking whether  $T \rightarrow H$  is a theorem in a logical system, possibly with the help of a knowledge base.

To obtain logical formulas for input sentences, we use the framework of Combinatory Categorical Grammar (CCG) (Steedman, 2000), a lexicalized grammar formalism that provides a transparent interface between syntax and semantics. We follow the standard method of building compositional semantics in CCG-based systems (Blackburn and Bos, 2005; Bos, 2008), where each syntactic category is schematically assigned a meaning representation formally specified as a  $\lambda$ -term. By combining the meanings of constituent words that appear in a CCG derivation tree, we can obtain a logical formula that serves as a semantic representation of an input sentence.

For semantic representations, we adopt Neo-Davidsonian Event Semantics (Parsons, 1990; Bos, 2008; Jurafsky and Martin, 2009). For instance, the sentence in (1) is mapped not to a sim-

ple formula (2) but to a formula (3) that involves an event variable.

- (1) John greets Mary.
- (2)  $\text{greet}(\text{john}, \text{mary})$
- (3)  $\exists v(\text{greet}(v) \wedge (\text{Subj}(v) = \text{john}) \wedge (\text{Obj}(v) = \text{mary}))$

The sentence (3) expresses that there is an event of greeting such that its subject is John and its object is Mary. In our Neo-Davidsonian approach, every verb is decomposed into a one-place predicate over events and a set of functional expressions such as  $\text{Subj}(v) = \text{john}$ , which relates an event to its participant.

VP-modifiers such as adverbs and prepositional phrases are also analysed as event predicates. For instance, (4) and (5) are analysed as having the semantic representations in (6) and (7), respectively.

- (4) John greets Mary warmly.
- (5) John walks to a station.
- (6)  $\exists v(\text{greet}(v) \wedge (\text{Subj}(v) = \text{john}) \wedge (\text{Obj}(v) = \text{mary}) \wedge \text{warmly}(v))$
- (7)  $\exists v(\text{walk}(v) \wedge (\text{Subj}(v) = \text{john}) \wedge \exists x(\text{station}(x) \wedge (\text{Goal}(v) = x)))$

There are several advantages of using event semantic formulas as representations for natural language inferences. First, it logically derives an entailment pattern to drop adverbial modifiers, such as the one from (4) to (1) and the one from (5) to *John walks*. Another advantage over simple representations like (2) is that it provides a uniform way of capturing the lexical relationship between verbs. For instance, the hypernym relation between the transitive verb *greet* and the intransitive verb *move* is represented as a simple axiom  $\forall v(\text{greet}(v) \rightarrow \text{move}(v))$ . This is possible because both verbs are analysed as one-place predicates over events, rather than as predicates with different arities such as  $\text{greet}(x, y)$  and  $\text{move}(x)$ . All these inferences are derivable using the standard first-order logic. For these reasons, event semantic formulas are suitable for the purpose of performing logical inferences with lexical knowledge in our setting.

## 4 Methodology

### 4.1 Preliminaries: proving strategy

We adopt *natural deduction* (Prawitz, 1965) as a proof calculus. Here, a typical proving strategy is to decompose the logical formulas of  $T$  into atoms (subformulas with no logical connectives) and add them into a pool  $P$  of logical premises,

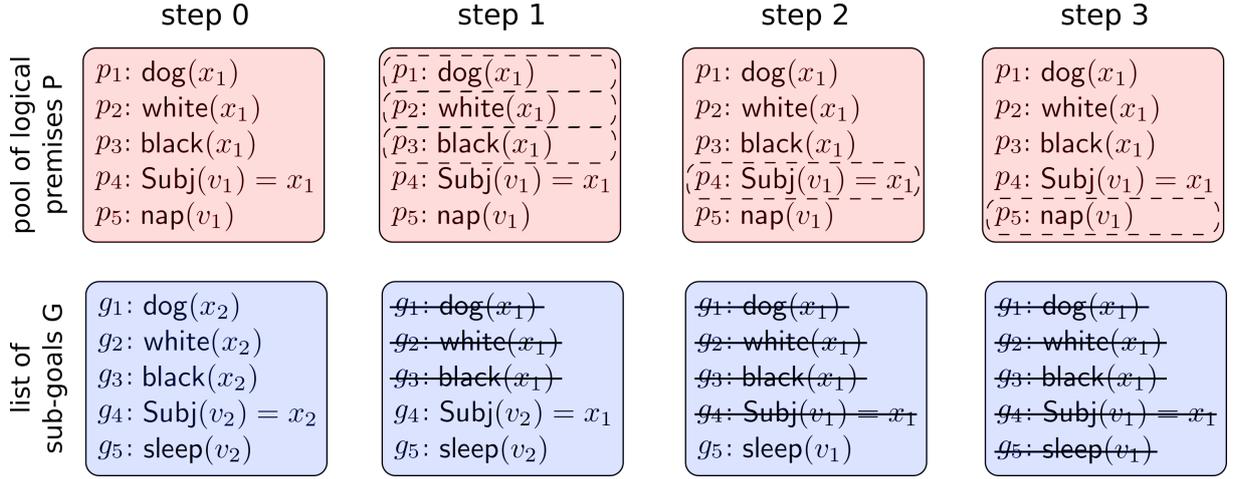

Figure 1: Trace of a proof in natural deduction. In step 0,  $T$  and  $H$  are decomposed into a pool of logical premises  $P$  and a list of sub-goals  $G$ . In step 1,  $g_1$ ,  $g_2$  and  $g_3$  are proved using  $p_1$ ,  $p_2$  and  $p_3$  and the variable unification  $x_2 := x_1$ . In step 2,  $g_4$  is proved with  $p_4$  and variable unification  $v_2 := v_1$ . Finally,  $g_5$  can be proved from  $p_4$  and the external axiom  $\forall v. \text{nap}(v) \rightarrow \text{sleep}(v)$ , resulting in a proved theorem.

$P = \{p_0(\theta_0), \dots, p_n(\theta_n)\}$ , where  $p_i$  are predicates (function names) and  $\theta_i$  are lists of (possibly structured) arguments of predicates  $p_i$ . The logical formula of  $H$  is similarly decomposed and its atoms are added either to the pool  $P$  or to a list of sub-goals  $G = \{p'_0(\theta'_0), \dots, p'_m(\theta'_m)\}$ .

As a running example, consider the  $T$ - $H$  pair in (8) and (9), analysed as in (10) and (11):

- (8) A black and white dog naps.  
(9) A black and white dog sleeps.  
(10)  $\exists x_1 v_1 (\text{dog}(x_1) \wedge \text{white}(x_1) \wedge \text{black}(x_1) \wedge \text{nap}(v_1) \wedge \text{Subj}(v_1) = x_1)$   
(11)  $\exists x_2 v_2 (\text{dog}(x_2) \wedge \text{white}(x_2) \wedge \text{black}(x_2) \wedge \text{sleep}(v_2) \wedge \text{Subj}(v_2) = x_2)$

As we can observe in Figure 1,  $T$  would be decomposed into the pool of logical premises

$$P = \{\text{dog}(x_1), \text{white}(x_1), \text{black}(x_1), \text{nap}(v_1), \text{Subj}(v_1) = x_1\}$$

and  $H$  into the list of sub-goals

$$G = \{\text{dog}(x_2), \text{white}(x_2), \text{black}(x_2), \text{sleep}(v_2), \text{Subj}(v_2) = x_2\}.$$

In general, existentially quantified formulas whose subformulas are connected only with logical conjunctions (e.g.  $\exists \theta. A(\theta) \wedge B(\theta)$ ) are decomposed into subformulas  $A(\theta)$  and  $B(\theta)$ , and added to  $P$  or  $G$  if they originate from  $T$  and  $H$ , respectively. Universally quantified formulas with logical implications (e.g.  $\forall \theta. A(\theta) \rightarrow B(\theta)$ ) are not decomposed if such constructions appear in  $T$ ; if they

appear in  $H$ ,  $B(\theta)$  is added as a sub-goal in  $G$  and  $A(\theta)$  is added as a logical premise in  $P$ . Decomposing higher-order constructions is possible, but we do not treat it here.

The proving then proceeds by selecting a sub-goal  $p'_j(\theta'_j)$ , searching  $P$  for a logical premise  $p_i(\theta_i)$  for which  $p'_j$  and  $p_i$  and their arguments  $\theta'_j$  and  $\theta_i$  are equal (or they unify). If such a logical premise is found, then the sub-goal is proved and removed from  $G$ . That is the case of the sub-goals  $g_1$  to  $g_4$  in steps 1 and 2 of Figure 1, where predicates match those of  $p_1$  to  $p_4$  and variables unify as  $x_2 := x_1$  and  $v_2 := v_1$ . If all sub-goals are proved, then the theorem is proved and the entailment judgement can be produced.

## 4.2 Detecting candidate sub-goals

However, there are theorems for which not all sub-goals can be proved. These cases occur when the source text fragment  $T$  does not entail the hypothesis  $H$ , or when there is a sub-goal for which no premise predicate matches. That is the case of sub-goal  $g_5 : \text{sleep}(v_1)$  in Figure 1, which does not match any logical premise  $p_i$ . Due to the symbolic nature of logic provers, two different predicates with entailing semantics (e.g.  $\text{nap}$  and  $\text{sleep}$ ) are considered unrelated, unless stated otherwise. For that reason, such a semantic relation, if it exists, needs to be made explicit in our framework.

In our natural deduction system, this operation is modeled as an *on-line axiom injection*, where candidate sub-goals are detected at proof-

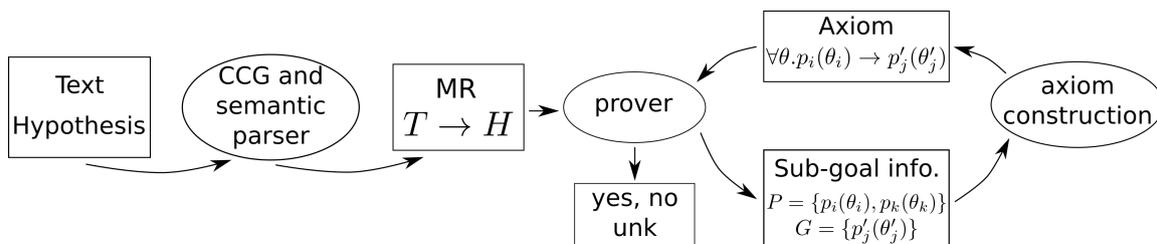

Figure 2: Pipeline for recognising textual entailment. Text and the Hypothesis are syntactically parsed with a CCG parser, and their logical meaning representations (MRs) are composed. A theorem  $T \rightarrow H$  is constructed and a prover attempts to test it. If an unprovable sub-goal  $p'_j(\theta'_j)$  is found, the axiom construction module attempts to build an axiom  $\forall\theta.p_i(\theta_i) \rightarrow p'_j(\theta'_j)$  that is fed back into the theorem.

time, and their semantic relations (if any) with the premises are introduced in the form of axioms.

A sub-goal  $p'_j(\theta'_j)$  is detected as a candidate to form an axiom if there is any logical premise  $p_i(\theta_i)$  in  $P$  such that they share at least one argument, that is,  $|\theta'_j \cap \theta_i| > 0$ . Instead of requiring the set of arguments  $\theta'_j$  and  $\theta_i$  to be equal, we only require them to share at least one argument, to allow sub-goal predicates to underspecify arguments (e.g. drop the object or the subject of the sentence). The set  $R_j$  of possible relations between premise predicates  $p_i$  and a sub-goal predicate  $p'_j$  can then be defined as:

$$R_j = \{p_i \mid p_i(\theta_i) \in T \wedge |\theta'_j \cap \theta_i| > 0\} \quad (1)$$

In the example above, the sub-goal  $\text{sleep}(v_1)$  is a candidate sub-goal to form an axiom, and its list of possible relations is  $R_{\text{sleep}} = \{\text{nap}\}$ .

### 4.3 On-demand axiom construction

Given a candidate sub-goal  $p'_j(\theta'_j)$ ,  $R_j$  is a list of possible predicates that may semantically subsume or exclude the meaning of  $p'_j$ . At this point, we only need to classify each  $p_i \in R_j$  as subsuming (entailing)  $p'_j$ , excluding (contradicting) it, or unrelated. In this work, we choose to use WordNet and VerbOcean (Chklovski and Pantel, 2004) as sources of external linguistic knowledge for their high precision. However, one could use other databases, ontologies or statistical classifiers, but we leave those considerations out of the scope of this paper.

There are two possible types of axioms that can be created: either entailing axioms  $\forall\theta.p_i(\theta_i) \rightarrow p'_j(\theta'_j)$ , or contradiction axioms  $\forall\theta.p_i(\theta_i) \rightarrow \neg p'_j(\theta'_j)$ , where  $\theta = \theta'_j \cup \theta_i$  is the union of variable names occurring in  $\theta'_j$  and  $\theta_i$ . Entailing axioms are created when synonymy (e.g.  $\text{house} \rightarrow \text{home}$ ),

hyponymy (e.g.  $\text{sea} \rightarrow \text{water}$ ), adjectival similarity (e.g.  $\text{huge} \rightarrow \text{big}$ ), derivationally related forms (e.g.  $\text{accommodating} \rightarrow \text{accommodation}$ ), or inflection relations (e.g.  $\text{wooded} \rightarrow \text{wood}$ ) are found in WordNet<sup>1</sup>. Contradiction axioms are created solely when antonymy relations (e.g.  $\text{big} \rightarrow \neg\text{small}$ ) are found. Once these axioms are created, they are inserted in the theorem and the proof continues.

Note that in Figure 1, if axioms were created a priori before the proof takes place, an axiom of the form  $\forall x.\text{black}(x) \rightarrow \neg\text{white}(x)$  would have been created and a contradiction would be found in step 1 when proving the sub-goal  $g_2 : \text{white}(x_1)$ . We believe that the frequency of those cases increases with the length of sentences (or paragraphs) and the coverage of the external lexical resources.

Figure 2 shows our pipeline. Our software and Neo-Davidsonian semantic templates are open-sourced and publicly available at <https://github.com/mynlp/ccg2lambda>.

## 5 Experiments

### 5.1 Dataset

We use the SemEval-2014 version of the SICK dataset (Marelli et al., 2014), which is a dataset of English single-premise textual entailment problems annotated with three relations: *entailing* (yes), *contradicting* (no) or *unrelated* (unknown). The SICK dataset was originally developed to test approaches of compositional distributional semantics and it includes a variety of lexical, syntactic and semantic phenomena at the sentential level. With respect to FraCaS (Cooper et al., 1994), it contains less linguistically challenging problems but there is a higher need of lexical knowledge,

<sup>1</sup>To maximise coverage, we consider all possible senses for a given predicate (word).

Problem ID	T-H pairs	Entailment
1412	T: <i>Men are sawing logs .</i> H: <i>Men are cutting wood .</i>	Yes
4114	T: <i>There is no man eating food .</i> H: <i>A man is eating a pizza .</i>	No
718	T: <i>A few men in a competition are running outside .</i> H: <i>A few men are running competitions outside .</i>	Unknown

Table 1: Examples of entailment problems from the SICK dataset. Some problems require a mix of logical reasoning and external lexical knowledge.

making it suitable to test our mechanism. With respect to the RTE datasets from the PASCAL RTE challenges, SICK problems are much shorter (and easier to syntactically parse), thus making them affordable for our current semantic parser.

Note that, although the SICK dataset only contains single-premise problems, our method also applies to multi-premise problems out-of-the-box. The dataset contains 4,500 problems for training, 500 for trial and 4,927 for testing, with a ratio of yes/no/unk problems of .29/.15/.56 in all splits. There are almost 212,000 running words, an average premise and conclusion length of 10.6 and a vocabulary of 2,409 words. Typically, there were about 3.6 words in the conclusion that did not appear in the premise, and 3.8 vice versa. Corpus statistics were collected after sentences were tokenized with the Penn Treebank Project tokenizer<sup>2</sup>. Some examples of entailment problems for the SICK dataset are in Table 1.

## 5.2 Experimental setup

We parsed the tokenized sentences of the premises and hypotheses using the wide-coverage CCG parsers C&C (Clark and Curran, 2007) and EasyCCG (Lewis and Steedman, 2014). CCG derivation trees (parses) were converted into logical semantic representations using *ccg2lambda* (Martínez-Gómez et al., 2016) and our first-order Neo-Davidsonian event semantics. The validation of our version of semantic templates was carried out exclusively on the trial split of the SICK dataset.

We used Coq (Castéran and Bertot, 2004), an interactive natural deduction (Coquand and Huet, 1988) theorem prover that we run fully automatically with a number of built-in theorem-proving routines called *tactics*, which include first-order

<sup>2</sup><https://www.cis.upenn.edu/~treebank/tokenization.html>

logic, arithmetic and equational reasoning. The axiom injection mechanism presented here could also have been implemented as a tactic to achieve a higher proving efficiency. However, this enhancement was left out from this work as it is both technically involved and makes our system bound to this specific prover. Instead, we monitor the proving progress and detect unprovable sub-goals; if our module produces an axiom, then it is introduced in the theorem and the proof is restarted. We call this method **SPSA**, the selector of predicates with shared arguments.

We use two in-house baselines: **No axioms** is our system without axiom injection, where only the logic of the language is used to prove sentence-level entailment relations. **Naïve** is a naïve method where we search for a WordNet linguistic relation between any two words of the premise and conclusion. If such a relation is found, then an axiom is constructed. All axioms found in this way are introduced in the theorem at once, and then the proving is performed. In this naïve method and in SPSA, if two words have more than one WordNet linguistic relation, then we only consider one, in this order: inflections, derivationally related forms, synonyms, antonyms, hypernyms, adjectival similarity and hyponyms. Moreover, although WordNet also contains linguistic relations between phrases, we only consider word-to-word relations. Our plain-logic system, the naïve and the SPSA methods were all timed-out after 100 seconds, at which the entailment judgement “unknown” was produced. When a syntactic parse error occurs, our systems tend to judge the entailment relation as “unknown”. To gain robustness and following Abzianidze (2015), we use a multi-parsing strategy (unless stated otherwise), that is, we use both C&C and EasyCCG parsers, and output any of their judgements if they are different

from “unknown”<sup>3</sup>.

Out of more than 20 participating teams in SemEval 2014, we compare our system to the following representative state-of-the-art systems: **Illinois-LH** (Lai and Hockenmaier, 2014), **ECNU** (Zhao et al., 2014), **UNAL-NLP** (Jiménez et al., 2014), **SemantiKLUE** (Proisl et al., 2014) are systems that build statistical classifiers on shallow features such as word alignments, syntactic structures and distributional similarities. These systems are the top performing systems in SemEval-2014. **The Meaning Factory** (Bjerva et al., 2014) is a hybrid system that combines logic semantic representations derived from CCG trees, with model builders and a statistical classifier, whereas **LangPro** (Abzianidze, 2015) is a purely logic system that composes Lambda Logical Forms of Natural Logic from CCG derivations. **Nutcracker** is a first-order logic system, where the effectiveness of introducing WordNet (and PPDB) using conventional methods is evaluated in (Pavlick et al., 2015).

We also include Markov Logic Networks (MLN) as described by Beltagy et al. (2016), where **MLN** denotes their system with closed-world assumptions and coreferences; **MLN-WN-PPDB** is their system augmented with WordNet and PPDB lexical relations, some hand-coded rules, and C&C/EasyCCG multi-parsing; **MLN-eclassif** denotes Beltagy et al. (2016)’s system augmented with a statistical classifier to recognise phrasal entailment relations (hence, we add this system in the list of statistical systems).

As it is common in RTE for SICK, we use precision and recall, where a successful prediction is one where the gold entailment label is either “yes” or “no”, and the system correctly predicts it. The accuracy, instead, is computed as a 3-way classification task, where a successful prediction counts on any of the three labels.

### 5.3 Results

Table 2 shows the results of our experimentation. Our plain first-order logic system **No axioms** has the highest precision 98.90%, but the lowest recall (46.48%). However, its accuracy (76.65%) is well beyond the baseline accuracy (56.69%) based on the majority class.

<sup>3</sup>If the system using C&C parser judges “yes” and the other judges “no”, or vice versa, then the final output is “unknown”.

System	Prec.	Rec.	Acc.
MLN-eclassif	–	–	85.10
Illinois-LH	81.56	81.87	84.57
ECNU	84.37	74.37	83.64
UNAL-NLP	81.99	76.80	83.05
SemantiKLUE	85.40	69.63	82.32
The Meaning Factory	93.63	60.64	81.60
LangPro Hybrid-800	97.95	58.11	81.35
MLN-WN-PPDB	–	–	80.40
Nutcracker-WN-PPDB	–	–	78.60
Nutcracker-WN	–	–	77.50
Nutcracker	–	–	74.30
MLN	–	–	73.40
Baseline (majority)	–	–	56.69
SPSA-VerbOcean	97.04	63.64	83.13
SPSA	97.07	62.13	82.97
SPSA, only C&C	97.27	58.48	81.44
SPSA, only EasyCCG	97.73	58.71	81.59
Naïve	92.99	59.70	80.98
No axioms	98.90	46.48	76.65

Table 2: Results on the test split of SICK dataset, using precision, recall and accuracy.

The **Naïve** method produced an increase of 4.33% points in accuracy with respect to the pure logic system. As a comparison, Pavlick et al. (2015) reported that a naïve introduction of axioms from WordNet on **Nutcracker** (Bjerva et al., 2014) for SICK dataset leads to an increase of 3.2% points of accuracy (from 74.3% to 77.5%), whereas using WordNet and sophisticated classifiers on the Paraphrase Database (Ganitkevitch et al., 2013) lead to an increase of 4.3% points in accuracy.

When the **SPSA** component substitutes the **Naïve** method, there is a 6.32% increase in the accuracy (from 76.63% to 82.97%), the recall increases by 15.65% and the precision only decreases by 1.83% with respect to the **No axioms** baseline. This system had higher performance than the other two best logic systems **The Meaning Factory** and **LangPro** (82.97% vs. 81.60% and 81.35%), and makes the use of external linguistic knowledge more effective than that in Pavlick et al. (2015), even without the use of a larger paraphrase database such as PPDB. If we add VerbOcean, which is an “unrefined” list of 22,306 verb relations, the accuracy further improves up to 83.13%, ranking our system on the fourth position among the statistical methods, af-

Prob. ID	T-H pairs	Gold	System	Axioms needed
1412	T: <i>Men are sawing logs .</i> H: <i>Men are cutting wood .</i>	Yes	Yes	$\forall v.\text{saw}(v) \rightarrow \text{cut}(v)$ $\forall x.\text{log}(x) \rightarrow \text{wood}(x)$
2404	T: <i>The lady is slicing a tomato .</i> H: <i>There is no one cutting a tomato .</i>	No	No	$\forall v.\text{slice}(v) \rightarrow \text{cut}(v)$
530	T: <i>A biker is wearing gear which is black .</i> H: <i>A biker wearing black is breaking the gears .</i>	Unk	Yes	
1495	T: <i>A man is playing a guitar .</i> H: <i>A man is strumming a guitar .</i>	Yes	Unk	$\forall v.\text{play}(v) \rightarrow \text{strum}(v)$
1266	T: <i>A band is playing on a stage .</i> H: <i>A band is playing onstage .</i>	Yes	Unk	“on a stage” $\rightarrow$ “onstage”
2166	T: <i>A woman is sewing with a machine .</i> H: <i>A woman is using a machine made for sewing .</i>	Yes	Unk	“sewing with a machine” $\rightarrow$ “using a machine made for sewing”
384	T: <i>A white and tan dog is running through the tall and green grass .</i> H: <i>A white and tan dog is running through a field .</i>	Yes	Unk	“tall and green grass” $\rightarrow$ “field”

Table 3: Examples of successful and erroneous entailment predictions of our system, collected on the trial split of the SICK dataset.

ter **MLN-eclassif**, **Illinois-LH** and **ECNU**.

When limiting our semantic logical representations to those obtained only from the C&C parser (**SPSA, only C&C**), the recall was reduced by 3.65% and the accuracy by 1.53%, while the precision remained almost equal. Similar results were obtained with the EasyCCG parser. Although no single parser gives clearly a higher performance (in terms of recognising textual entailment), there are clear advantages to using both parsers, which is consistent with findings in Abzianidze (2015).

Regarding the proving time of the SPSA and the naïve methods, there were surprisingly no big differences. The proving time average, median and standard deviation per call to the theorem prover was 10 milliseconds, which was negligible when compared to the python overhead (the main language of our software). The SPSA method did an average of 10.7 calls to the theorem prover per RTE problem, whereas the naïve method did an average of 3.7. Note that these calls include the forward entailment and the contradiction proof attempts, both for C&C and EasyCCG parse trees. If lexical relations were found between the premise and conclusion, the naïve method would only do one more call (for each parser), whereas the SPSA method would do as many calls as axioms are potentially necessary. For that reason, the number of calls of the SPSA method is much larger.

#### 5.4 Positive Examples and Error analysis

Table 3 shows some positive and negative examples of performance of our system on the trial split of the SICK dataset. For the first two examples, our plain logic system (without axioms)

produces incorrect entailment judgements (“unknown”), while our system produces the correct label, due to the introduction of two and one axioms in their corresponding theorems, respectively. The first axiom  $\forall v.\text{saw}(v) \rightarrow \text{cut}(v)$  states that any event  $v$  of sawing is an event of cutting. Note that those predicates only have one argument event variable  $v$ , following Neo-Davidsonian event semantics. The second axiom  $\forall x.\text{log}(x) \rightarrow \text{wood}(x)$  states that any entity  $x$  that is a log is wood.

In the third example, the label of the gold and plain logic system is “unknown”. However, our axiom injection system produces the axiom  $\forall v.\text{wear}(v) \rightarrow \text{break}(v)$ , where the meaning of wear is that of “impairment resulting from long use” (taken from WordNet). These two predicates apply over the object gear, thus sharing the same variable instantiation and producing the error. However, these cases are rare.

In the rest of the examples, our mechanism displays a lack of coverage to create axioms. In the fourth example, play and strum are not direct synonyms, but sister terms (according to WordNet). Many sister terms have an entailment relation, but many others do not (e.g. stand and run). In the rest of the examples, an ideal axiom injection mechanism would need access to string similarity methods (i.e. “on a stage”  $\rightarrow$  “onstage”) and to a knowledge base to understand that a machine is something that can be used, or that “tall and green grass” is a “field”.

## 6 Discussion and Future Work

The axiom injection method presented in this paper is more sophisticated and precise than simply assessing the linguistic relation between any two words from  $T$  and  $H$  and substituting those words conveniently (or equivalently in our framework, to introduce an axiom). Moreover, the naïve method is bound to show gradually lower precision when the size of sentences or the coverage of lexical resources increases, since there are more chances to obtain out-of-context lexical relations. Our axiom injection methods showed larger numbers of calls to the theorem prover, but each call took an average of only 10 milliseconds to complete. The reason for these larger numbers of calls reside in the implementation of the mechanism, since a proof needs to be re-run every time a new axiom is found. A possible enhancement would be to implement our axiom construction and injection as a Coq *tactic* that proves a sub-goal if its predicate has an entailing linguistic relation with any subset of the predicates in the logical premises at a specific stage of a proof.

In order to assess the precision of our SPSA method, we used WordNet and VerbOcean as our databases of external linguistic knowledge, which are databases of high-precision relations. In this setup, we found that our method solves effectively the lack of linguistic knowledge while keeping the precision high. However, other databases such as the Paraphrase Database (Ganitkevitch et al., 2013) or statistical classifiers could further increase the coverage of our method.

On one hand, the SPSA method requires access to the currently active sub-goals (and pool of logical premises) during a proof. Although such information is typically available in logic system, our method might not be directly applicable to systems that rely on statistical classifiers to judge compositional entailment relations. On the other hand, our system is characterised by its very high precision, which is a desirable characteristic when considering system combinations. In such setup, our system could run first, and if no conclusive sentential entailment relation is found, a statistical system could judge the relation, possibly using our logical representations and axioms as features.

Our method cannot be applied yet to larger texts, because CCG derivations accumulate errors when parsing larger sentences, and our logic composition is sensitive to those errors. Thus, making

our method more robust against CCG errors is a natural step. One possible solution is to use N-best CCG trees, collect features from those trees and possibly their semantic logical interpretations, and perform reranking.

## 7 Conclusion

We have presented a simple and effective method that introduces linguistic axioms on-demand to recognise textual entailments. The strategy is to build logical semantic representation of  $T$  and  $H$ , monitor the proof of the theorem  $T \rightarrow H$ , find unprovable sub-goals that share arguments (variable instantiations) with logical predicates, retrieve linguistic knowledge from an external resource, and insert the corresponding axioms on-demand. This system proved more effective and precise than simply enumerating all possible relations between words in  $T$  and  $H$ .

As it is common in logic systems, our method does not need parameter tuning. Moreover, the semantic representations and axioms are highly interpretable, which makes our system predictable, easy to understand, and easily extensible to use other linguistic resources or classifiers.

Finally, our logics and axiom construction/injection system have a high precision, making it a good candidate either as a standalone system, or as part of larger systems that use our logical semantic interpretations and axioms.

# Learning to Predict Denotational Probabilities For Modeling Entailment

Alice Lai and Julia Hockenmaier

Department of Computer Science  
University of Illinois at Urbana-Champaign  
{aylai2, juliahmr}@illinois.edu

## Abstract

We propose a framework that captures the denotational probabilities of words and phrases by embedding them in a vector space, and present a method to induce such an embedding from a dataset of denotational probabilities. We show that our model successfully predicts denotational probabilities for unseen phrases, and that its predictions are useful for textual entailment datasets such as SICK and SNLI.

## 1 Introduction

In order to bridge the gap between vector-based distributional approaches to lexical semantics that are intended to capture which words occur in similar contexts, and logic-based approaches to compositional semantics that are intended to capture the truth conditions under which statements hold, Young et al. (2014) introduced the concept of “denotational similarity.” Denotational similarity is intended to measure the similarity of simple, declarative statements in terms of the similarity of their truth conditions.

From classical truth-conditional semantics, Young et al. borrowed the notion of the denotation of a declarative sentence  $s$ ,  $\llbracket s \rrbracket$ , as the set of possible worlds in which the sentence is true. Young et al. apply this concept to the domain of image descriptions by defining the *visual denotation* of a sentence  $s$  as the set of images that  $s$  describes. The denotational probability of  $s$ ,  $P_{\llbracket s \rrbracket}(s)$ , is the number of images in the visual denotation of  $s$  over the size of the corpus. Two sentences are denotationally similar if the sets of images (possible worlds) they describe have a large overlap. For example, “A woman is jogging on a beach” and “A woman is running on a sandy shore” can often be used to describe the same scenario, so they

will have a large image overlap that corresponds to high denotational similarity.

Given the above definitions, Young et al. estimate the denotational probabilities of phrases from FLICKR30K, a corpus of 30,000 images, each paired with five descriptive captions. Young et al. (2014) and Lai and Hockenmaier (2014) showed that these similarities are complementary to standard distributional similarities, and potentially more useful for semantic tasks that involve entailment. However, the systems presented in these papers were restricted to looking up the denotational similarities of frequent phrases in the training data. In this paper, we go beyond this prior work and define a model that can *predict* the denotational probabilities of novel phrases and sentences. Our experimental results indicate that these predicted denotational probabilities are useful for several textual entailment datasets.

## 2 Textual entailment in SICK and SNLI

The goal of textual entailment is to predict whether a hypothesis sentence is true, false, or neither based on the premise text (Dagan et al., 2013). Due in part to the Recognizing Textual Entailment (RTE) challenges (Dagan et al., 2006), the task of textual entailment recognition has received a lot of attention in recent years. Although full entailment recognition systems typically require a complete NLP pipeline, including coreference resolution, etc., this paper considers a simplified variant of this task in which the premise and hypothesis are each a single sentence. This simplified task allows us to ignore the complexities that arise in longer texts, and instead focus on the purely semantic problem of how to represent the meaning of sentences. This version of the textual entailment task has been popularized by two datasets, the Sentences Involving Compositional Knowl-

edge (SICK) dataset (Marelli et al., 2014) and the Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015), both of which involve a 3-way classification for textual entailment.

SICK was created for SemEval 2014 based on image caption data and video descriptions. The premises and hypotheses are automatically generated from the original captions and so contain some unintentional systematic patterns. Most approaches to SICK involve hand-engineered features (Lai and Hockenmaier, 2014) or large collections of entailment rules (Beltagy et al., 2015).

SNLI is the largest textual entailment dataset by several orders of magnitude. It was created with the goal of training neural network models for textual entailment. The premises in SNLI are captions from the FLICKR30K corpus (Young et al., 2014). The hypotheses (entailed, contradictory, or neutral in relation to the premise) were solicited from workers on Mechanical Turk. Bowman et al. (2015) initially illustrated the effectiveness of LSTMs (Hochreiter and Schmidhuber, 1997) on SNLI, and recent approaches have focused on improvements in neural network architectures. These include sentence embedding models (Liu et al., 2016; Munkhdalai and Yu, 2017a), neural attention models (Rocktäschel et al., 2016; Parikh et al., 2016), and neural tree-based models (Munkhdalai and Yu, 2017b; Chen et al., 2016). In contrast, in this paper we focus on using a different input representation, and demonstrate its effectiveness when added to a standard neural network model for textual entailment. We demonstrate that the results of the LSTM model of Bowman et al. (2015) can be improved by adding a single feature based on our predicted denotational probabilities. We expect to see similar improvements when our predicted probabilities are added to more complex neural network entailment models, but we leave those experiments for future work.

### 3 Vector space representations

Several related works have explored different approaches to learning vector space representations that express entailment more directly. Kruszewski et al. (2015) learn a mapping from an existing distributional vector representation to a structured Boolean vector representation that expresses entailment as feature inclusion. They evaluate the resulting representation on lexical entailment tasks and on sentence entailment in SICK, but they re-

strict SICK to a binary task and their sentence vectors result from simple composition functions (e.g. addition) over their word representations. Henderson and Popa (2016) learn a mapping from an existing distributional vector representation to an entailment-based vector representation that expresses whether information is known or unknown. However, they only evaluate on lexical semantic tasks such as hyponymy detection.

Other approaches explore the idea that it may be more appropriate to represent a word as a region in space instead of a single point. Erk (2009) presents a word vector representation in which the hyponyms of a word are mapped to vectors that exist within the boundaries of that word vector’s region. Vilnis and McCallum (2015) use Gaussian functions to map a word to a density over a latent space. Both papers evaluate their models only on lexical relationships.

## 4 Denotational similarities

In contrast to traditional distributional similarities, Young et al. (2014) introduced the concept of “denotational similarities” to capture which expressions can be used to describe similar situations. Young et al. first define the *visual denotation* of a sentence (or phrase)  $s$ ,  $\llbracket s \rrbracket$ , as the (sub)set of images that  $s$  can describe. They estimate the denotation of a phrase and the resulting similarities from FLICKR30K, a corpus of 30,000 images, each paired with five descriptive captions. In order to compute visual denotations from the corpus, they define a set of normalization and reduction rules (e.g. lemmatization, dropping modifiers, replacing nouns with their hypernyms, dropping PPs, extracting NPs) that augment the original FLICKR30K captions with a large number of shorter, more generic phrases that are each associated with a subset of the FLICKR30K images.

The result is a large subsumption hierarchy over phrases, which Young et al. call a denotation graph (see Figure 1). The structure of the denotation graph is similar to the idea of an entailment graph (Berant et al., 2012). Each node in the denotation graph corresponds to a phrase  $s$ , associated with its denotation  $\llbracket s \rrbracket$ , i.e. the set of images that correspond to the original captions from which this phrase could be derived. For example, the denotation of a phrase “*woman jog on beach*” is the set of images in the corpus that depict a woman jogging on a beach. Note that the deno-

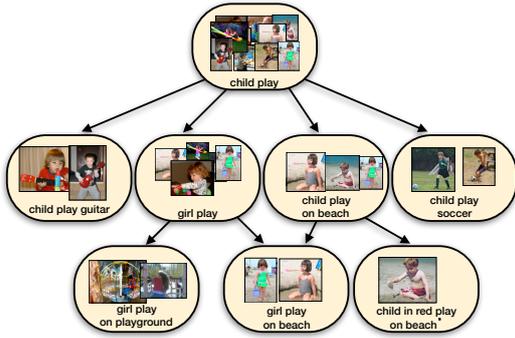

Figure 1: The denotation graph is a subsumption hierarchy over phrases associated with images.

tation of a node (e.g. “*woman jog on beach*”) is always a subset of the denotations of any of its ancestors (e.g. “*woman jog*”, “*person jog*”, “*jog on beach*”, or “*beach*”).

The denotational probability of a phrase  $s$ ,  $P_{\square}(s)$ , is a Bernoulli random variable that corresponds to the probability that a randomly drawn image can be described by  $s$ . Given a denotation graph over  $N$  images,  $P_{\square}(s) = \frac{\llbracket s \rrbracket}{N}$ . The joint denotational probability of two phrases  $x$  and  $y$ ,  $P_{\square}(x, y) = \frac{\llbracket x \cap y \rrbracket}{N}$ , indicates how likely it is that a situation can be described by both  $x$  and  $y$ . Young et al. propose to use pointwise mutual information scores (akin to traditional distributional similarities) and conditional probabilities  $P_{\square}(x|y) = \frac{\llbracket x \cap y \rrbracket}{\llbracket y \rrbracket}$  as so-called denotational similarities. In this paper, we will work with denotational conditional probabilities, as they are intended to capture entailment-like relations that hold due to commonsense knowledge, hyponymy, etc. (what is the probability that  $x$  is true, given that  $y$  can be said about this situation?). In an ideal scenario, if the premise  $p$  entails the hypothesis  $h$ , then the conditional probability  $P(h|p)$  is 1 (or close to 1). Conversely, if  $h$  contradicts  $p$ , then the conditional probability  $P(h|p)$  is close to 0. We therefore stipulate that learning to predict the conditional probability of one phrase  $h$  given another phrase  $p$  would be helpful in predicting textual entailment. We also note that by the definition of the denotation graph, if  $x$  is an ancestor of  $y$  in the graph, then  $y$  entails  $x$  and  $P_{\square}(x|y) = 1$ .

Young et al. (2014) and Lai and Hockenmaier (2014) show that denotational probabilities can be at least as useful as traditional distributional similarities for tasks that require semantic inference such as entailment or textual similarity recognition. However, their systems can only use deno-

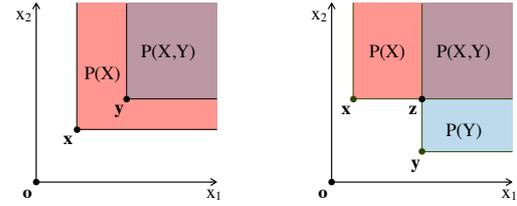

Figure 2: An embedding space that expresses the individual probability of events  $X$  and  $Y$  and the joint probability  $P(X, Y)$ .

tational probabilities between phrases that already exist in the denotation graph (i.e. phrases that can be derived from the original FLICKR30K captions).

Here, we present a model that learns to predict denotational probabilities  $P_{\square}(x)$  and  $P_{\square}(x|y)$  even for phrases it has not seen during training. Our model is inspired by Vendrov et al. (2016), who observed that a partial ordering  $\preceq$  over the vector representations of phrases can be used to express an entailment relationship. They induce a so-called order embedding for words and phrases such that the vector  $\mathbf{x}$  corresponding to phrase  $x$  is smaller than the vector  $\mathbf{y}$ , i.e.  $\mathbf{x} \preceq \mathbf{y}$ , for phrases  $y$  that are entailed by  $x$ , where  $\preceq$  corresponds to the reversed product order on  $\mathbb{R}_+^N$  ( $\mathbf{x} \preceq \mathbf{y} \Leftrightarrow x_i \geq y_i \forall i$ ). They use their model to predict entailment labels between pairs of sentences, but it is only capable of making a binary entailment decision.

## 5 An order embedding for probabilities

We generalize this idea to learn an embedding space that expresses not only the binary relation that phrase  $x$  is entailed by phrase  $y$ , but also the probability that phrase  $x$  is true given phrase  $y$ . Specifically, we learn a mapping from a phrase  $x$  to an  $N$ -dimensional vector  $\mathbf{x} \in \mathbb{R}_+^N$  such that the vector  $\mathbf{x} = (x_1, \dots, x_N)$  defines the denotational probability of  $x$  as  $P_{\square}(x) = \exp(-\sum_i x_i)$ . The origin (the zero vector) therefore has probability  $\exp(0) = 1$ . Any other vector  $\mathbf{x}$  that does not lie on the origin (i.e.  $\exists_i x_i > 0$ ) has probability less than 1, and a vector  $\mathbf{x}$  that is farther from the origin than a vector  $\mathbf{y}$  represents a phrase  $x$  that has a smaller denotational probability than phrase  $y$ . We can visualize this as each phrase vector occupying a region in the embedding space that is proportional to the denotational probability of the phrase. Figure 2 illustrates this in two dimensions. The zero vector at the origin has a probability pro-

portional to the entire region of the positive orthant, while other points in the space correspond to smaller regions and thus probabilities less than 1.

The joint probability  $P_{\square}(x, y)$  in this embedding space should be proportional to the size of the intersection of the regions of  $\mathbf{x}$  and  $\mathbf{y}$ . Therefore, we define the joint probability of two phrases  $x$  and  $y$  to correspond to the vector  $\mathbf{z}$  that is the element-wise maximum of  $\mathbf{x}$  and  $\mathbf{y}$ :  $z_i = \max(x_i, y_i)$ . This allows us to compute the conditional probability  $P_{\square}(x|y)$  as follows:

$$\begin{aligned} P_{\square}(x|y) &= \frac{P_{\square}(x, y)}{P_{\square}(y)} \\ &= \frac{\exp(-\sum_i z_i)}{\exp(-\sum_i y_i)} \\ &= \exp(\sum_i y_i - \sum_i z_i) \end{aligned}$$

**Shortcomings** We note that this embedding does not allow us to represent the negation of  $x$  as a vector. We also cannot represent two phrases that have completely disjoint denotations: in Figure 2, the  $P(X)$  and  $P(Y)$  regions will always intersect and therefore the  $P(X, Y)$  region will always have an area greater than 0. In fact, in our embedding space, the joint probability represented by the vector  $\mathbf{z}$  will always be greater than or equal to the product of the probabilities represented by the vectors  $\mathbf{x}$  and  $\mathbf{y}$ . For any pair  $\mathbf{x} = (x_1, \dots, x_N)$  and  $\mathbf{y} = (y_1, \dots, y_N)$ ,  $P_{\square}(X, Y) \geq P_{\square}(X)P_{\square}(Y)$ :

$$\begin{aligned} P_{\square}(X, Y) &= \exp\left(-\sum_i \max(x_i, y_i)\right) \\ &\geq \exp\left(-\sum_i x_i - \sum_i y_i\right) \\ &= P_{\square}(X)P_{\square}(Y) \end{aligned}$$

(Equality holds when  $\mathbf{x}$  and  $\mathbf{y}$  are orthogonal, and thus  $\sum_i x_i + \sum_i y_i = \sum_i \max(x_i, y_i)$ ). Therefore, the best we can do for disjoint phrases is learn an embedding that assumes the phrases are independent. In other words, we can map the disjoint phrases to two vectors whose computed joint probability is the product of the individual phrase probabilities.

Although our model cannot represent two events with completely disjoint denotations, we will see below that it is able to learn that some phrase pairs have very low denotational conditional probabilities. We note also that our model

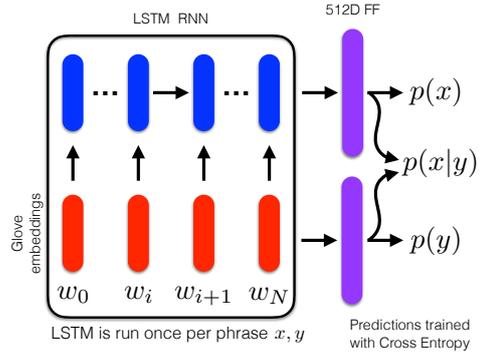

Figure 3: Our probability model architecture. Each phrase is a sequence of word embeddings that is passed through an LSTM to produce a 512d vector representation for the premise and the hypothesis. Both vectors are used to compute the predicted conditional probability and calculate the loss.

cannot express  $P(X) = 0$  exactly, but can get arbitrarily close in order to represent the probability of a phrase that is extremely unlikely.

## 6 Our model for $P_{\square}(x)$ and $P_{\square}(x, y)$

We train a neural network model to predict  $P_{\square}(x)$ ,  $P_{\square}(y)$ , and  $P_{\square}(x|y)$  for phrases  $x$  and  $y$ . This model consists of an LSTM that outputs a 512d vector which is passed through an additional 512d layer. We use 300d GloVe vectors (Pennington et al., 2014) trained on 840B tokens as the word embedding input to the LSTM. We use the same model to represent both  $x$  and  $y$  regardless of which phrase is the premise or the hypothesis. Thus, we pass the sequence of word embeddings for phrase  $x$  through the model to get  $\mathbf{x}$ , and we do the same for phrase  $y$  to get  $\mathbf{y}$ . As previously described, we sum the elements of  $\mathbf{x}$  and  $\mathbf{y}$  to get the predicted denotational probabilities  $P_{\square}(x)$  and  $P_{\square}(y)$ . From  $\mathbf{x}$  and  $\mathbf{y}$ , we find the joint vector  $\mathbf{z}$ , which we use to compute the predicted denotational conditional probability  $P_{\square}(x|y)$  according to the equation in Section 5. Figure 3 illustrates the structure of our model.

Our training data consists of ordered phrase pairs  $\langle x, y \rangle$ . We train our model to predict the denotational probabilities of each phrase ( $P_{\square}(x)$  and  $P_{\square}(y)$ ) as well as the conditional probability  $P_{\square}(x|y)$ . Typically the pair  $\langle y, x \rangle$  will also appear in the training data.

Our per-example loss is the sum of the cross entropy losses for  $P_{\square}(x)$ ,  $P_{\square}(y)$ , and  $P_{\square}(x|y)$ :

$$L = -[P_{\square}(x) \log Q(x) + (1 - P_{\square}(x)) \log(1 - Q(x))] \\ - [P_{\square}(y) \log Q(y) + (1 - P_{\square}(y)) \log(1 - Q(y))] \\ - [P_{\square}(x|y) \log Q(x|y) + (1 - P_{\square}(x|y)) \log(1 - Q(x|y))]$$

We use the Adam optimizer with a learning rate of 0.001, and a dropout rate of 0.5. These parameters were tuned on the development data.

**Numerical issues** In Section 5, we described the probability vectors  $\mathbf{x}$  as being in the positive orthant. However, in our implementation, we use unnormalized log probabilities. This puts all of our vectors in the negative orthant instead, but it prevents the gradients from becoming too small during training. To ensure that the vectors are in  $\mathbb{R}_-^N$ , we clip the values of the elements of  $\mathbf{x}$  so that  $x_i \leq 0$ . To compute  $\log P_{\square}(x)$ , we sum the elements of  $\mathbf{x}$  and clip the sum to the range  $(\log(10^{-10}), -0.0001)$  in order to avoid errors caused by passing  $\log(0)$  values to the loss function. The conditional log probability is simply  $\log P_{\square}(x|y) = \log P_{\square}(x, y) - \log P_{\square}(y)$ , where  $\log P_{\square}(x, y)$  is now the element-wise minimum:

$$\log P_{\square}(x, y) = \sum_i \min(x_i, y_i)$$

This element-wise minimum is a standard pooling operation (we take the minimum instead of the more common max pooling). Note that if  $x_i > y_i$ , neither element  $x_i$  nor  $y_i$  is updated with respect to the  $P_{\square}(x|y)$  loss. Both  $x_i$  and  $y_i$  will always be updated with respect to the  $P_{\square}(x)$  and  $P_{\square}(y)$  components of the loss.

## 6.1 Training regime

To train our model, we use phrase pairs  $\langle x, y \rangle$  from the denotation graph generated on the training split of the FLICKR30K corpus (Young et al., 2014). We consider all 271,062 phrases that occur with at least 10 images in the training split of the graph, to ensure that the phrases are frequent enough that their computed denotational probabilities are reliable. Since the FLICKR30K captions are lemmatized in order to construct the denotation graph, all the phrases in the dataset described in this section are lemmatized as well.

We include all phrase pairs where the two phrases have at least one image in common. These constitute 45 million phrase pairs  $\langle x, y \rangle$  with  $P_{\square}(x|y) > 0$ . To train our model to predict

$P_{\square}(x|y) = 0$ , we include phrase pairs  $\langle x, y \rangle$  that have no images in common if  $N \times P_{\square}(x)P_{\square}(y) \geq N^{-1}$  ( $N$  is the total number of images), meaning that  $x$  and  $y$  occur frequently enough that we would expect them to co-occur at least once in the data. This yields 2 million pairs where  $P_{\square}(x|y) = 0$ . For additional examples of  $P_{\square}(x|y) = 1$ , we include phrase pairs that have an ancestor-descendant relationship in the denotation graph. We include all ancestor-descendant pairs where each phrase occurs with at least 2 images, for an additional 3 million phrase pairs.

For evaluation purposes, we first assign 5% of the phrases to the development pool and 5% to the test pool. The actual test data then consists of all phrase pairs where at least one of the two phrases comes from the test pool. The resulting test data contains 10.6% unseen phrases by type and 51.2% unseen phrases by token. All phrase pairs in the test data contain at least one phrase that was unseen in the training or development data. The development data was created the same way.

This dataset is available to download at <http://nlp.cs.illinois.edu/HockenmaierGroup/data.html>.

We train our model on the training data (42 million phrase pairs) with batch size 512 for 10 epochs, and use the mean KL divergence on the conditional probabilities in the development data to select the best model. Since  $P_{\square}(x|y)$  is a Bernoulli distribution, we compute the KL divergence for each phrase pair  $\langle x, y \rangle$  as

$$D_{KL}(P||Q) = P_{\square}(x|y) \log \frac{P_{\square}(x|y)}{Q(x|y)} \\ + (1 - P_{\square}(x|y)) \log \frac{1 - P_{\square}(x|y)}{1 - Q(x|y)}$$

where  $Q(x|y)$  is the conditional probability predicted by our model.

## 7 Predicting denotational probabilities

### 7.1 Prediction on new phrase pairs

We evaluate our model using 1) the KL divergences  $D_{KL}(P||Q)$  of the gold individual and conditional probabilities  $P_{\square}(x)$  and  $P_{\square}(x|y)$  against the corresponding predicted probabilities  $Q$ , and 2) the Pearson correlation  $r$ , which expresses the correlation between two variables (the per-item gold and predicted probabilities) as a value between  $-1$  (total negative correlation) and

	$P(x)$		$P(x y)$	
	KL	$r$	KL	$r$
Training data	0.0003	0.998	0.017	0.974
Full test data	0.001	0.979	0.031	0.949
Unseen pairs	0.002	0.837	0.048	0.920
Unseen words	0.016	0.906	0.127	0.696

Table 1: Our model predicts the probability of unseen phrase pairs with high correlation to the gold probabilities.

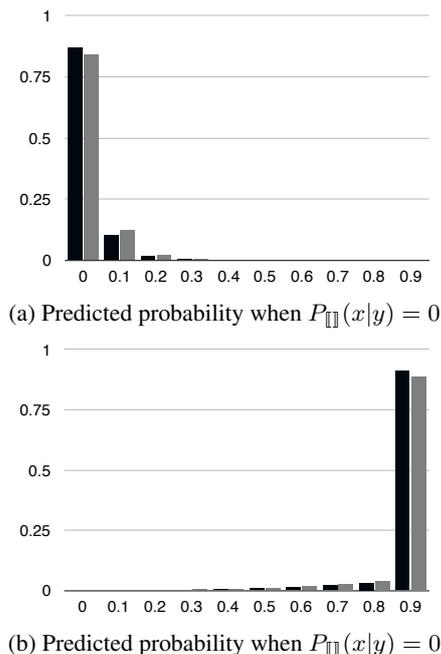

Figure 4: Predicted probabilities on denotational phrase test data when  $P_{\square}(x|y) = 0$  is 0 or 1. Black is the full test data and gray is the subset of pairs where both phrases are unseen. Frequency is represented as a percentage of the size of the data.

1 (total positive correlation). As described above, we compute the KL divergence on a per-item basis, and report the mean over all items in the test set.

Table 1 shows the performance of our trained model on unseen test data. The full test data consists of 4.6 million phrase pairs, all of which contain at least one phrase that was not observed in either the training or development data. Our model does reasonably well at predicting these conditional probabilities, reaching a correlation of  $r = 0.949$  with  $P_{\square}(x|y)$  on the complete test data. On the subset of 123,000 test phrase pairs where both phrases are previously unseen, the model’s predictions are almost as good at  $r = 0.920$ .

On the subset of 3,100 test phrase pairs where at

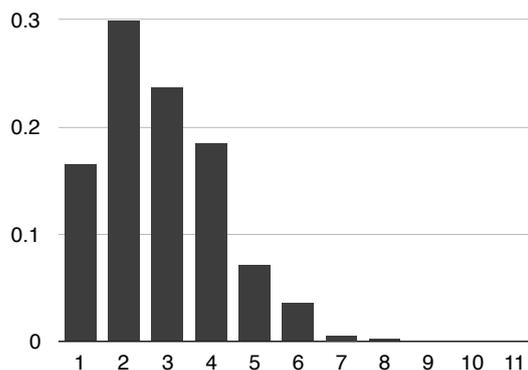

Figure 5: Distribution of phrase lengths as a fraction of the data size on the denotation graph phrase training data.

least one word was unseen in training, the model’s predictions are worse, predicting  $P_{\square}(x|y)$  with a correlation of  $r = 0.696$ . On the remaining test pairs, the model predicts  $P_{\square}(x|y)$  with a correlation of  $r = 0.949$ .

We also analyze our model’s accuracy on phrase pairs where the gold  $P_{\square}(x|y)$  is either 0 or 1. The latter case reflects an important property of the denotation graph, since  $P_{\square}(x|y) = 1$  when  $x$  is an ancestor of  $y$ . More generally, we can interpret  $P_{\square}(h|p) = 1$  as a confident prediction of entailment, and  $P_{\square}(h|p) = 0$  as a confident prediction of contradiction. Figure 4 shows the distribution of predicted conditional probabilities for phrase pairs where gold  $P_{\square}(h|p) = 0$  (top) and gold  $P_{\square}(h|p) = 1$  (bottom). Our model’s predictions on unseen phrase pairs (gray bars) are nearly as accurate as its predictions on the full test data (black bars).

## 7.2 Prediction on longer sentences

Our model up to this point has only been trained on short phrases, since conditional probabilities in the denotation graph are only reliable for phrases that occur with multiple images (see Figure 5 for the distribution of phrase lengths in the training data). To improve our model’s performance on longer sentences, we add the SNLI training data (which has a mean sentence length of 11 words) to our training data. We train a new model from scratch on a corpus consisting of the previously described 42 million phrase pairs and the 550,000 SNLI training sentence pairs (lemmatized to match our phrase pairs). We do not train on SICK because the corpus is much smaller and has a different distribution of phenomena, including

explicit negation. We augment the SNLI data with approximate gold denotational probabilities by assigning a probability  $P_{\square}(S) = s/N$  to a sentence  $S$  that occurs  $s$  times in the  $N$  training sentences. We assign approximate gold conditional probabilities for each sentence pair  $\langle p, h \rangle$  according to the entailment label: if  $p$  entails  $h$ , then  $P(h|p) = 0.9$ . If  $p$  contradicts  $h$ , then  $P(h|p) = 0.001$ . Otherwise,  $P(h|p) = 0.5$ .

Figure 6 shows the predicted probabilities on the SNLI test data when our model is trained on different distributions of data. The top row shows the predictions of our model when trained only on short phrases from the denotation graph. We observe that the median probabilities increase from contradiction to neutral to entailment, even though this model was only trained on short phrases with a limited vocabulary. Given the training data, we did not expect these probabilities to align cleanly with the entailment labels, but even so, there is already some information here to distinguish between entailment classes.

The bottom row shows that when our model is trained on both denotational phrases and SNLI sentence pairs with approximate conditional probabilities, its probability predictions for longer sentences improve. This model’s predicted conditional probabilities align much more closely with the entailment class labels. Entailing sentence pairs have high conditional probabilities (median 0.72), neutral sentence pairs have mid-range conditional probabilities (median 0.46), and contradictory sentence pairs have conditional probabilities approaching 0 (median 0.19).

## 8 Predicting textual entailment

In Section 7.2, we trained our probability model on both short phrase pairs for which we had gold probabilities and longer SNLI sentence pairs for which we estimated probabilities. We now evaluate the effectiveness of this model for textual entailment, and demonstrate that these predicted probabilities are informative features for predicting entailment on both SICK and SNLI.

**Model** We first train an LSTM similar to the 100d LSTM that achieved the best accuracy of the neural models in Bowman et al. (2015). It takes GloVe word vectors as input and produces 100d sentence vectors for the premise and hypothesis. The concatenated 200d sentence pair representation from the LSTM passes through three

Model	Test Acc.
Our LSTM	77.2
Our LSTM + CPR	<b>78.2</b>
Bowman et al. (2015) LSTM	77.2

Table 2: Entailment accuracy on SNLI (test).

Model	Test Acc.
Our LSTM	81.5
Our LSTM + CPR	<b>82.7</b>
Bowman et al. (2015) transfer	80.8

Table 3: Entailment accuracy on SICK (test).

200d tanh layers and a softmax layer for 3-class entailment classification. We train the LSTM on the SNLI training data with batch size 512 for 10 epochs. We use the Adam optimizer with a learning rate of 0.001 and a dropout rate of 0.85, and use the development data to select the best model.

Next, we take the output vector produced by the LSTM for each sentence pair and append our predicted  $P_{\square}(h|p)$  value (the probability of the hypothesis given the premise). We train another classifier that passes this 201d vector through two tanh layers with a dropout rate of 0.5 and a final 3-class softmax classification layer. Holding the parameters of the LSTM fixed, we train this model for 10 epochs on the SNLI training data with batch size 512.

**Results** Table 2 contains our results on SNLI. Our baseline LSTM achieves the same 77.2% accuracy reported by Bowman et al. (2015), whereas a classifier that combines the output of this LSTM with only a single feature from the output of our probability model improves to 78.2% accuracy.

We use the same approach to evaluate the effectiveness of our predictions on SICK (Table 3). SICK does not have enough data to train an LSTM, so we combine the SICK and SNLI training data to train both the LSTM and the final model. When we add the predicted conditional probability as a single feature for each SICK sentence pair, performance increases from 81.5% to 82.7% accuracy. This approach outperforms the transfer learning approach of Bowman et al. (2015), which was also trained on both SICK and SNLI.

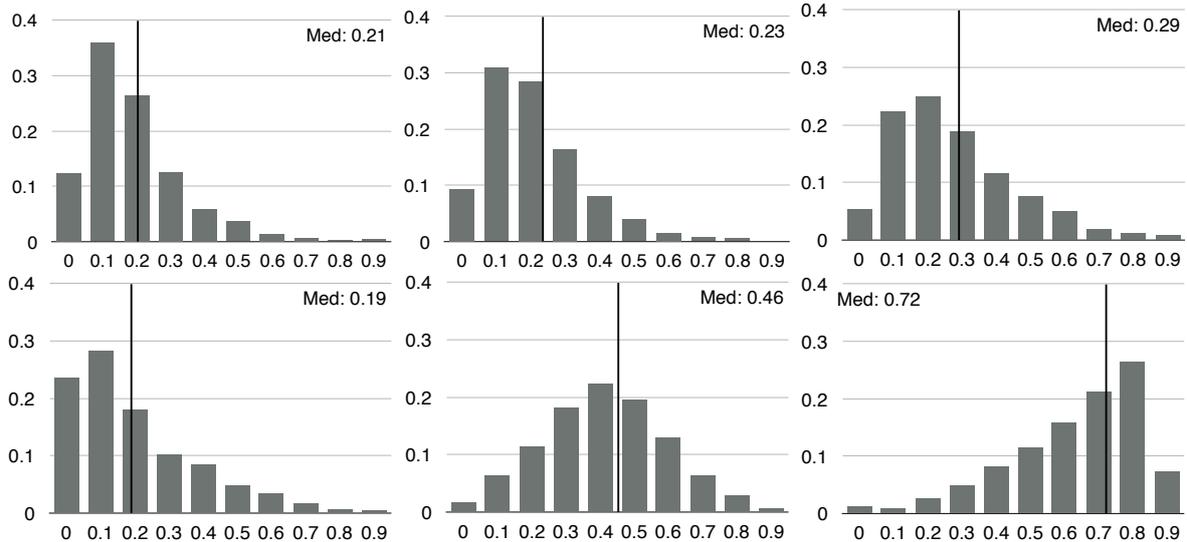

Figure 6: Predicted conditional probabilities  $P(h|p)$  for SNLI sentence pairs (test) by entailment label, as a percentage of pairs with that label. Top: predictions from the model trained only on short denotational phrases. Bottom: predictions from the model trained on both short denotational phrases and SNLI.

Premise	Hypothesis	G	P
1 person walk on trail in woods	in forest	1.0	1.0
2 group of person bike	group of person ride	0.9	0.8
3 adult sing while play instrument	adult play guitar	0.8	0.8

11 sit at bench	adult read book	0.1	0.1
12 person leap into air	jump over obstacle	0.0	0.0
13 person talk on phone	man ride skateboard	0.0	0.0

Table 4: Gold and predicted conditional probabilities from the denotational phrase development data.

## 9 Discussion

Section 7 has demonstrated that we can successfully learn to predict denotational probabilities for phrases that we have not encountered during training and for longer sentences. Section 8 has illustrated the utility of these probabilities by showing that a single feature based on our model’s predicted conditional denotational probabilities improves the accuracy of an LSTM on SICK and SNLI by 1 percentage point or more. Although we were not able to evaluate the impact on more complex, recently proposed neural network models,

Premise	Hypothesis	Gold	Pred
skier on snowy hill	athlete	1.00	0.99
pitcher throw ball	mound	0.53	0.84
golf ball	athlete	0.53	0.66
person point	man point	0.48	0.41
in front of computer	person look	0.36	0.21

Table 5: Gold and predicted conditional probabilities from unseen pairs in the denotational phrase development data.

this improvement is quite encouraging. We note in particular that we only have accurate denotational probabilities for the short phrases from the denotation graph (mostly 6 words or fewer), which have a limited vocabulary compared to the full SNLI data (there are 5263 word types in the denotation graph training data, while the lemmatized SNLI training data has a vocabulary of 31,739 word types).

We examine examples of predicted conditional probabilities for phrase and sentence pairs to analyze our model’s strengths and weaknesses. Table 4 has example predictions from the denotation phrase development data. Our model correctly predicts high conditional probability for entailed phrase pairs even when there is no direct hypernym involved, as in example 2, and for closely related phrases that are not strictly entailing, as in example 3. Our model also predicts reasonable probabilities for events that frequently co-occur but are not required to do so, such as example 7.

	Premise	Hypothesis	CPR
Entailment	1 A person rides his bicycle in the sand beside the ocean.	A person is on a beach.	0.88
	2 Two women having drinks and smoking cigarettes at the bar.	Two women are at a bar.	0.86
	3 A senior is waiting at the window of a restaurant that serves sandwiches.	A person waits to be served his food.	0.61
	4 A man with a shopping cart is studying the shelves in a supermarket aisle.	There is a man inside a supermarket.	0.47
	5 The two farmers are working on a piece of John Deere equipment.	John Deere equipment is being worked on by two farmers.	0.16
Neutral	6 A group of young people with instruments are on stage.	People are playing music.	0.86
	7 Two doctors perform surgery on patient.	Two doctors are performing surgery on a man.	0.56
	8 Two young boys of opposing teams play football, while wearing full protection uniforms and helmets.	Boys scoring a touchdown.	0.30
	9 Two men on bicycles competing in a race.	Men are riding bicycles on the street.	0.24
Contradiction	10 Two women having drinks and smoking cigarettes at the bar.	Three women are at a bar.	0.79
	11 A man in a black shirt is playing a guitar.	The man is wearing a blue shirt.	0.47
	12 An Asian woman sitting outside an outdoor market stall.	A woman sitting in an indoor market.	0.22
	13 A white dog with long hair jumps to catch a red and green toy.	A white dog with long hair is swimming underwater.	0.09
	14 Two women are embracing while holding to go packages.	The men are fighting outside a deli.	0.06

Table 6: Predicted conditional probabilities for sentence pairs from the SNLI development data.

In examples 10 and 11, our model predicts low probabilities for occasionally co-occurring events, which are still more likely than the improbable co-occurrence in example 13. Table 5 demonstrates similar patterns for pairs where both phrases were unseen.

Table 6 has examples of predicted conditional probabilities for sentence pairs from the SNLI development data. Some cases of entailment are straightforward, so predicting high conditional probability is relatively easy. This is the case with example 2, which simply involves dropping words from the premise to reach the hypothesis. In other cases, our model correctly predicts high conditional probability for an entailed hypothesis that does not have such obvious word-to-word correspondence with the premise, such as example 1. Our model’s predictions are less accurate when the sentence structure differs substantially between premise and hypothesis, or when there are many unknown words, as in example 5. For neutral pairs, our model usually predicts mid-range probabilities, but there are some exceptions. In example 6, it is not certain that the people are playing music, but it is a reasonable assumption from the premise. It makes sense that in this case, our model assigns this hypothesis a higher conditional probability given the premise than for most neutral sentence pairs. In example 7, we might guess that the patient is a man with 50% probability, so the predicted conditional probability of our model seems reasonable. Our model cannot reason about numbers and quantities, as example

10 shows. It also fails to predict in example 11 that a man wearing a black shirt is probably not wearing a blue shirt as well. However, our model does correctly predict low probabilities for some contradictory examples that have reasonably high word overlap, as in example 13. Finally, example 14 shows that our model can correctly predict very low conditional probability for sentences that share no common subject matter.

## 10 Conclusion

We have presented a framework for representing denotational probabilities in a vector space, and demonstrated that we can successfully train a neural network model to predict these probabilities for new phrases. We have shown that when also trained on longer sentences with approximate probabilities, our model can learn reasonable representations for these longer sentences. We have also shown that our model’s predicted probabilities are useful for textual entailment, and provide additional gains in performance when added to existing competitive textual entailment classifiers. Future work will examine whether the embeddings our model learns can be used directly by these classifiers, and explore how to incorporate negation into our model.

## Abstract

To find out how users' social media behaviour and language are related to their ethical practices, the paper investigates applying Schwartz' psycholinguistic model of societal sentiment to social media text. The analysis is based on corpora collected from user essays as well as social media (Facebook and Twitter). Several experiments were carried out on the corpora to classify the ethical values of users, incorporating Linguistic Inquiry Word Count analysis, n-grams, topic models, psycholinguistic lexica, speech-acts, and non-linguistic information, while applying a range of machine learners (Support Vector Machines, Logistic Regression, and Random Forests) to identify the best linguistic and non-linguistic features for automatic classification of values and ethics.

## 1 Introduction

In the recent years, there have been significant efforts on determining the opinion/sentiment/emotion about a specific topic held by the author of a piece of text, and on automatic sentiment strength analysis of text, classifying it into either one of the classes positive, negative or neutral, or into Ekman's classes of happy, sad, anger, fear, surprise, and disgust. However, the intrinsic value of the lives we lead reflects the strength of our values and ethics which guide our social practices, attitude and behaviour. This paper reports work on investigating

a psycholinguistic model, the Schwartz model (Schwartz and Bilsky, 1990; Schwartz, 2012), and applying it to social media text. It will here be referred to as a societal sentiment model, since societal values grow from the interactions, and the views and sentiment of the society are key to ethical practices. No computational model for Schwartz' Values has been tested or examined before as such, but there has been a growing interest in the scientific community on doing automatic personality recognition, commonly using the Big 5 factor model (Goldberg, 1990) that defines personality traits such as openness, conscientiousness, extraversion, agreeableness, and neuroticism.

The Schwartz values model defines ten distinct ethical values (henceforth only values), that respectively are: *Achievement* sets goals and achieves them; *Benevolence* seeks to help others and provide general welfare; *Conformity* obeys clear rules, laws and structures; *Hedonism* seeks pleasure and enjoyment; *Power* controls and dominates others, controls resources; *Security* seeks health and safety; *Self-direction* wants to be free and independent; *Stimulation* seeks excitement and thrills; *Tradition* does things blindly because they are customary; *Universalism* seeks peace, social justice and tolerance for all.

Deeper understanding of human beliefs, attitudes, ethics, and values has been a key research agenda in Psychology and Social Science research for several decades. One of the most accepted and widely used frameworks is Schwartz 10-Values model, has seen great success in psychological research as well as in other fields. The ten basic values are related to various outcomes and ef-

\* The two first authors contributed equally.

fects of a person's role in a society (Argandoña, 2003; Agle and Caldwell, 1999; Hofstede et al., 1991; Rokeach, 1973). Schwartz values have also proved to provide an important and powerful explanation of consumer behaviour and how they influence it (Kahle et al., 1986; Clawson and Vinson, 1978). Moreover, there are results that indicate how values of workforce and ethical practice in organisations are directly related to transformational and transactional leadership (Hood, 2003).

We believe that these kind of models may become extremely useful in the future for various purposes like Internet advertising (specifically social media advertising), community detection, computational psychology, recommendation systems, sociological analysis (for example East vs West cultural analysis) over social media.

In order to experiment with this, three corpora have been collected and annotated with Schwartz values. Two of the corpora come from popular social media platforms, Facebook and Twitter, while the third corpus consists of essays. A range of machine learning techniques has then been utilized to classify an individual's ethical practices into Schwartz' classes by analyzing the user's language usage and behaviour in social media. In addition to identifying the ten basic values, Schwartz' theory also explains how the values are interconnected and influence each other, since the pursuit of any of the values results in either an accordance with one another (e.g., Conformity and Security) or a conflict with at least one other value (e.g., Benevolence and Power). The borders between the motivators are artificial and one value flows into another. Such overlapping and fuzzy borders between values make the computational classification problem more challenging.

The paper is organized as follows. Section 2 introduces related work in the area. Details of the corpora collection and annotation are given in Section 3. Section 4 reports various experiments on automatic value detection, while Section 5 discusses the performance of the psycholinguistic experiments and mentions possible future directions.

## 2 Related Work

State-of-the-art sentiment analysis (SA) systems look at a fragment of text in isolation. However, in order to design a Schwartz model classifier, we require a psycholinguistic analysis. Therefore, textual features and techniques proposed and dis-

cussed for SA are quite different from our current research needs. Hence, we will here focus only on previous research efforts in automatic personality analysis that closely relate to our research work. Personality models can be seen as an augmentation to the basic definition of SA, where the aim is to understand sentiment/personality at person level rather than only at message level.

In recent years, there has been a lot of research on automated identification of various personality traits of an individual from their language usage and behaviour in social media. A milestone in this area was the 2013 Workshop and Shared Task on Computational Personality Recognition (Celli et al., 2013), repeated in 2014 (Celli et al., 2014). Two corpora were released for the 2013 task. One was a Facebook corpus, consisting of about 10,000 Facebook status updates of 250 users, plus their Facebook network properties, labelled with personality traits. The other corpus comprised 2,400 essays written by several participants labelled with the personalities. Eight teams participated in the shared task. The highest result was achieved by Markovikj et al. (2013) with an F-score of 0.73 (average for all the traits). The main methods and features (linguistic as well as non-linguistic) used by the participant groups were as follows.

**Linguistic Features:** The participating teams tested several linguistic features. Since n-grams are known to be useful for any kind of textual classification, all the teams tested various lengths of n-grams (uni, bi, and tri-grams). Categorical features like part-of-speech (POS), word level features like capital letters, repeated words were also used. Linguistic Inquiry Word Count (LIWC) features were used by all the teams as their baselines. LIWC (Pennebaker et al., 2015) is a hand-crafted lexicon specifically designed for psycholinguistic experiments. Another psycholinguistic lexicon called MRC (Wilson, 1988) was also used by a few teams, as well as lexica such as SentiWordNet (Baccianella et al., 2010) and WordNet Affect (Strapparava and Valitutti, 2004). Two more important textual features were discussed by the participating teams. Linguistic nuances, introduced by Tomlinson et al. (2013), is the depth of the verbs in the Wordnet troponymy hierarchy. Speech act features were utilized by Appling et al. (2013): the authors manually annotated the given Facebook corpus with speech acts and reported their correlation with the personality traits.

Here we briefly describe some people. Please read each description and think about how much each person is or is not like you. Tick the box to the right that shows how much the person in the description is like you.

		HOW MUCH LIKE YOU IS THIS PERSON?					
		Very much like me	Like me	Some- what like me	A little like me	Not like me	Not like me at all
1.	Thinking up new ideas and being creative is important to her. She likes to do things in her original way. <b>SD</b>	6	5	4	3	2	1
2.	It is important to her to be rich. She wants to have a lot of money and expensive things. <b>PO</b>	6	5	4	3	2	1
3.	She thinks it is important that every person in the world be treated equally. She believes everyone should have equal opportunities in life. <b>UN</b>	6	5	4	3	2	1
4.	Its important to her to show her abilities. She wants people to admire what she does. <b>AC</b>	6	5	4	3	2	1
5.	It is important to her to live in secure surroundings. She avoids anything that might endanger her safety. <b>SE</b>	6	5	4	3	2	1

Table 1: Instructions and format of the Portrait Values Questionnaire. For each statement, the respondents should answer the question "How much like you is this person?" by checking one of the six boxes.

**Non-Linguistic Features:** All teams used Facebook network properties including network size, betweenness centrality, density and transitivity, provided as a part of the released dataset.

### 3 Corpus Acquisition

To start with, we ask a very fundamental question: *whether social media is a good proxy of the original (real life) society or not*. Back et al. (2010) and Golbeck et al. (2011) provide empirical answers to this question. Their results respectively indicate that, in general, people do not use virtual desired/bluffed social media profiles to promote an idealized-virtual-identity and that a user's personality can be predicted from his/her social media profile. This does not mean that there are no outliers, but our corpus collection was grounded on the assumption that it is true for a major portion of the population that social media behaviour to a large extent mirror that of the actual human society. Two of the most popular social media platforms, Twitter and Facebook, were chosen as sources for the corpora to validate this assumption. In addition, an essay corpus was collected. These three diverse corpora were then used for training and testing Schwartz values analysis methods.

#### 3.1 Questionnaire for Self-Assessment

A standard method of psychological data collection is through self-assessment tests, popularly known as psychometric tests. In our experiments, self-assessments were obtained using male/female versions of PVQ, the Portrait Values Questionnaire (Schwartz et al., 2001). The participants

were asked to answer each question on a 1–6 Likert rating scale.<sup>1</sup> A rating of 1 means "not like me at all" and 6 means "very much like me". An example question is "He likes to take risks. He is always looking for adventures." where the user should answer while putting himself in the shoes of "He" in the question. A few exemplary items as well as the instructions and format of the written form of the PVQ are presented in Table 1.

The standard practice is to ask a fixed number of questions per psychological dimension. Here there are five questions for each of the ten Values classes, resulting in a 50 item questionnaire. Once all the questions in the PVQ have been answered, for each user and for each Values class, a score is generated by averaging all the scores (i.e., user responses) corresponding to the questions in that class, as described by Schwartz (2012). Further, the rescaling strategy proposed by Schwartz (2012) was used to eliminate randomness from each response given by a user as follows: For each user, the mean response score was first calculated considering all the responses s/he provided, and then the mean score from each response was subtracted. See Schwartz (2012) for more details on PVQ and the score computation mechanism.

The ranges of scores obtained from the previous rescaling method may vary across different Values classes. For instance, the ranges of the rescaled scores for the Essay corpus are as follows: Achievement [−4.12, 3.36], Benevolence [−1.56, 3.39], Conformity [−3.35, 3.01], Hedo-

<sup>1</sup><http://www.simplypsychology.org/likert-scale.html>

nism  $[-5.18, 4.35]$ , Power  $[-6.0, 2.27]$ , Security  $[-2.60, 2.40]$ , Self-Direction  $[-1.61, 3.40]$ , Stimulation  $[-5.0, 2.63]$ , Tradition  $[-4.49, 3.35]$ , and Universalism  $[-3.33, 3.30]$ .<sup>2</sup>

Hence the standard normalisation formula was applied to move the ranges of the different Values classes to the  $[-1, 1]$  interval:

$$x_{scaled} = \frac{2 * (x - x_{min})}{x_{max} - x_{min}} - 1$$

A ‘Yes’ or ‘No’ binary value was assigned to each Values class: if the score was less than 0, the class was considered to be negative, indicating absence of that Values trait for the particular user; while scores  $\geq 0$  were considered to be positive, indicating the presence of that trait for the user. We will use the real scores ranging  $[-1, 1]$  for the regression experiments mentioned in Section 4.

Reports of psychological analysis always depend on how the target population is chosen. Therefore while we are hypothesising that a few people are more Power oriented, an open question that remains unanswered is whom they are more Power oriented than. For example, if we (hypothetically) choose parliamentarians / politicians as participants in an experiment, then the entire examined population will likely turn out to be Power oriented. Therefore, it makes sense to normalise the obtained data into two groups  $[-1, 0)$  and  $[0, 1]$  and proclaim that people with  $[0, 1]$  range scores are relatively more Power (or any other Value) oriented than the people having score ranging  $[-1, 0)$ .

The same normalisation mechanism was applied to all the corpora, but also after normalisation the different Values distributions were imbalanced (with the Facebook data being the most imbalanced). One possible reason behind such imbalanced distributions is that the portion of the real population using social media is slightly biased towards some Values types due to several societal reasons such as educational/family background, age group, occupation, etc. Another reason could be that the divisions between different value types simply never are balanced in any population. However, analysing such societal traits is a separate research direction altogether and out of the scope of the current study.

<sup>2</sup>The distribution of value types over a corpus was analysed using the Bienaymé-Chebyshev Inequality (Bienaymé, 1853; Tchébichef, 1867), showing that, e.g, most Achievement instances (89%) were in the range  $[-2.96, 2.84]$ .

The PVQ questionnaire setting described above was used to separately collect textual user data separately for the Essay, Facebook, and Twitter corpora, as discussed in the rest of this section.

### 3.2 Essay Corpus

The Essay corpus was collected using the Amazon Mechanical Turk (AMT)<sup>3</sup> crowd-sourcing service. The turkers (users providing responses on AMT) were asked to compose an essay on the most important values and ethics guiding their lives, and to answer the PVQ questionnaire. A total of 981 users participated in the essay writing. However, not all the responses were useful for the analysis, since some participants did not answer all the questions and some did not write the essay carefully. For example, one user wrote: *“I don’t really have a guide in life. I go by what sounds and feels good. that means what makes me happy rather that effects others or not.”* Filtering out such users, data from 767 respondents was retained.

### 3.3 Twitter Corpus

In the first quarter of 2016, the micro blogging service Twitter averaged 310 million monthly active users,<sup>4</sup> with around 6,000 tweets being posted every second. Therefore, Twitter came as the second natural choice as data source. The data collection was crowd-sourced using Amazon Mechanical Turk, while ensuring that the participants came from various cultures and ethnic backgrounds: the participants were equally distributed, and consisted of Americans (Caucasian, Latino, African-American), Indians (East, West, North, South), and a few East-Asians (Singaporeans, Malaysian, Japanese, Chinese). The selected Asians were checked to be mostly English speaking.

The participants were requested to answer the PVQ questionnaire and to provide their Twitter IDs, so that their tweets could be crawled. However, several challenges have to be addressed when working with Twitter, and a number of iterations, human interventions and personal communications were necessary. For example, several users had protected Twitter accounts, so that their tweets were not accessible when using the Twitter API. In addition, many users had to be discarded since they had published less than 100 tweets, making

Table 3: Fuzzy distributions of Schwartz’ ten personality value types in the Twitter corpus.

them uninteresting for statistical analysis. In addition, some extreme cases when users mentioned someone else’s (some celebrity’s) Twitter account, had to be discarded. The open source free Twitter API: Twitter4J<sup>5</sup> also has a limit of accessing only the current 3,200 tweets from any user. To resolve this issue, an open source Java application (Henrique, 2015) was used.

At the end of the data collection process, data from 367 unique users had been gathered. The highest number of tweets for one user was 15K, while the lowest number of tweets for a user was a mere 100; the average number of messages per user in the Twitter corpus was found to be 1,608.

### 3.4 Facebook Corpus

Facebook (FB) is the most popular social networking site in the world, with 1.65 billion monthly active users during the first quarter of 2016.<sup>6</sup> Therefore, Facebook was a natural first choice for corpus collection, but since the privacy policy of Facebook is very stringent, accessing Facebook data is challenging. To collect the corpus, a Facebook Canvas web-application was developed using Facebook Graph API and Facebook SDK v5 for PHP library. Undergraduate students of two Indian institutes (NIT, Agartala, Tripura and IIIT, Sri City, Andhra Pradesh) were contacted for the data

collection. The application was circulated among the students and they were requested to take part in the PVQ survey and to donate their FB Timeline data and friend list data. Timeline data includes their own posts and all the posts they are tagged in, and posts other people made on their Timeline.

So far, data from 114 unique users has been collected, but the data is highly imbalanced (for some value types the distributions of ‘Yes’ and ‘No’ classes were in 90:10 ratio). Crowd-sourcing is a cheap and fast way to collect data, but unfortunately some annotators chose random labels to minimize their cognitive thinking load. These annotators can be considered as spammers and make aggregation of crowd-sourced data a challenging problem, as discussed in detail by Hovy et al. (2013). To filter out spammers, the MACE (Hovy et al., 2013) tool was used and data from 54 users discarded, so the final dataset includes only 60 participants. The average number of messages per user in the Facebook corpus is 681.

### 3.5 Corpus Statistics

Categorical flat distributions are reported in Table 2. Schwartz’ model defines fuzzy membership, which means that anyone having a Power orientation can have the Achievement orientation as well. To understand this notion vividly, we have reported the fuzzy membership statistics from the Twitter data in Table 3 (due to space limitations, statistics for the other corpora are not reported).

<sup>5</sup><http://twitter4j.org/>

<sup>6</sup><http://www.statista.com/statistics/264810/number-of-monthly-active-facebook-users-worldwide/>

Feature Ablation	AC	BE	CO	HE	PO	SE	SD	ST	TR	UN
Before Ablation	65.84	56.06	64.02	58.02	58.80	53.06	60.89	56.58	64.28	65.58
After Ablation	65.84	58.54	64.80	58.93	59.58	55.80	61.53	56.84	65.06	66.10

Table 4: Best LIWC feature selection (by accuracy) for each of Schwartz’ ten personality value types. The values in the ‘Before Feature Ablation’ row are based on the full feature set (69 features).

The statistics in Table 3 show how the ten values are interconnected and influence each other, supporting the basic assumption of the Schwartz model that the borders between value classes are artificial and that one value flows into the next.

#### 4 Automatic Identification Experiments

Several experiments were performed to get a better understanding of the most appropriate linguistic and non-linguistic features for the problem domain. The experiments were designed as a single label classification task (each input corresponds to one target label) with 20 classes, with ‘Yes’ and ‘No’ classes for each of the ten Schwartz values. Ten different classifiers were trained, each for a particular value type. Each classifier predicts whether the person concerned is positively or negatively inclined towards the given Schwartz value.

The versions implemented in WEKA (Witten and Frank, 2005) of three different machine learning algorithms were used in the experiments: Sequential Minimal Optimization (SMO; a version of Support Vector Machines, SVM), Simple Logistic Regression (LR), and Random Forests (RF). In all the mentioned experiments the corpora were pre-processed, i.e., tokenized by the CMU tokenizer (Gimpel et al., 2011) and stemmed by the Porter Stemmer (Porter, 1980). All the lexica were also stemmed in the same way before usage and all results reported below were obtained using 10-fold cross validation on each of the corpora.

##### 4.1 Linguistic Features

**LIWC Analysis:** LIWC (Pennebaker et al., 2015) is a well developed hand-crafted lexicon. It has 69 different categories (emotions, psychology, affection, social processes, etc.) and almost 6,000 distinct words. The 69 categorical features were extracted as user-wise categorical word frequencies. As the text length (for the Essay corpus) or number of messages (Twitter and FB corpora) varies from person to person, Z-score normalization (or standardization) was applied using

the equation:  $\hat{x} = (x - \mu)/\sigma$ , where  $x$  is the ‘raw frequency count’,  $\mu$  and  $\sigma$  are respectively the mean and standard deviation of a particular feature. After normalizing, each feature vector value is centered around  $\sigma = (0, 1)$ . This normalization led to an increase in the accuracy figures in many of the cases.

To investigate how each LIWC feature contributes, feature ablation was performed and the Pearson correlations of LIWC features vs value types were analysed. The final classifiers were trained using only the features that were contributing for a particular value type. This resulted in a performance boost and also gave reduced time complexity (both model training and testing times). Table 4 contains detailed categorical features for each value type for the SMO model, and, e.g., shows that the same accuracy (65.84%) for the Achievement class as obtained by using the full 69 feature set also can be obtained by using only 52 LIWC features. Moreover, the lowest obtained accuracy 53.06% for the Security class increased to 55.80% when considering only 47 features. Clearly, the details of which features actually contribute to each class cannot be included here (for space reasons), but the important lesson is that it is possible to reduce the feature set and increase performance in this way.

**n-grams:** In line with the systems discussed in Section 2, n-gram features were added to the LIWC baseline. In a first run, the top 20% of the most frequent uni-grams from the Essay corpus were included as new features, resulting in a 1452+69 feature set. Unexpectedly, SMO’s accuracy dropped by an average of 8.60%. The Achievement and Conformity values suffered the maximum performance drop, whereas Security and Hedonism had a slight increase in accuracy. Random Forests performed well in many of cases, except for the Security and Benevolence classes.

In a second iteration, categorical (value wise) n-grams features were selected and used. The resulting feature set sizes differ for each of the ten

values, ranging from the lowest number 886+69 for Power to the highest 1176+69 for Universalism. Marginally better performance was recorded.

*n*-grams (word grams) with various sizes of *n*, ranging from 2, 3, 4, 5, and so on, have different impact on performance on different kinds of applications. Commonly, bi-grams are better features for many text classification tasks. So, in a third iteration we tested system performance using bi-grams as added features with LIWC. As the total possible combinations of bi-grams are quite high, only the top 2,000 frequent bi-grams were included, resulting in 2000+69 features. There was no significant performance gain in this experiment on the Essay corpus, so this feature was not tested for the other two corpora.

**Topic Modeling:** In order to find out the bag-of-words features for each value type, i.e., the vocabulary that a person uses more frequently, the MALLET (McCallum, 2002)<sup>7</sup> topic modelling toolkit was used to extract a number of topics. MALLET uses Gibbs Sampling and Latent Dirichlet Allocation (LDA). In a pre-processing stage, stop words were removed and case was preserved. For the Essay corpus, we tested with different number of topic clusters of sizes 10, 20, 50, 75, and 100, and observed that 50 was the most suitable number. Each of the 50 topics contained an average of 19 words (the topic key words identified by MALLET), each with a specific weight attached. The top 5 topics were chosen for each value type, according to these weights, and the words of these topics were added as a new feature set along with the LIWC baseline features.

It was also observed that the rankings of the top 5 topics were almost similar for each Schwartz value. The accuracies obtained were almost similar to the accuracies obtained in the previous experiments; however, this time, since the dimension of the feature set is much smaller, the time complexity decreased by almost a factor of 10. Hence the topic modelling was repeated for the social media corpora from Facebook and Twitter, but resulting in a different number of topic clusters, namely 89. Added to the 69 LIWC features this thus resulted in a total of 158 features.

**Psycholinguistic Lexica:** In addition to the base feature set from LIWC, two other psycholinguistic lexica were added: the Harvard General Inquirer

(Stone et al., 1966) and the MRC psycholinguistic database (Wilson, 1988). The Harvard General Inquirer lexicon contains 182 categories, including two large valence categories positive and negative; other psycholinguistic categories such as words of pleasure, pain, virtue and vice; words indicating overstatement and understatement, often reflecting presence or lack of emotional expressiveness, etc. 14 features from the MRC Psycholinguistic lexicon were included, namely, number of letters, phonemes and syllables; Kucera-Francis frequency, number of categories, and number of samples; Thorndike-Lorge frequency; Brown verbal frequency; ratings of Familiarity, Concreteness, Imagability and Age of acquisition; and meaningfulness measures using Colorado Norms and Pavio Norms. In order to get these MRC features a machine readable version of it has been used.<sup>8</sup> Feature ranking was done by evaluating the contribution of each feature in an SMO classifier.

In addition, the sensorial lexicon Sensicon (Tekiroğlu et al., 2014) was used. It contains words with sense association scores for the five basic senses: Sight, Hearing, Taste, Smell, and Touch. For example, when the word 'apple' is uttered, the average human mind will visualize the appearance of an apple, stimulating the eye-sight, feel the smell and taste of the apple, making use of the nose and tongue as senses, respectively. Sensicon provides a numerical mapping which indicates the extent to which each of the five senses is used to perceive a word in the lexicon. Again, feature ablation was performed and the (Pearson) correlations of lexicon features vs values analysed. Finally, classifiers were trained using only contributing features for a particular value.

**Speech Act Features:** The way people communicate, whether it is verbally, visually, or via text, is indicative of Personality/Values traits. In social media, profile status updates are used by individuals to broadcast their mood and news to their peers. In doing so, individuals utilize various kinds of speech acts that, while primarily communicating their content, also leave traces of their values/ethical dimensions behind. Following the hypothesis of Appling et al. (2013), speech act features were applied in order to classify personalities/values. However, for this experiment the speech act classes were restricted to 11 major categories: Statement Non-Opinion (SNO), Wh

<sup>7</sup><http://mallet.cs.umass.edu>

<sup>8</sup><http://ota.oucs.ox.ac.uk/headers/1054.xml>

Speech Act	SNO	Wh	YN	SO	AD	YA	T	AP	RA	A	O	Avg.
Distribution	33.37	11.45	15.45	5.16	6.88	15.08	0.41	3.26	0.71	0.07	14.59	0.69
F <sub>1</sub> -score	0.45	0.88	0.88	0.72	0.45	0.60	0.72	0.60	0.12	0.77	0.12

Question (Wh), Yes-No Question (YN), Statement Opinion (SO), Action Directive (AD), Yes Answers (YA), Thanking (T), Appreciation (AP), Response Acknowledgement (RA), Apology (A) and others (O), hence avoiding having 43 fine-grained speech act classes.<sup>9</sup>

A corpus containing 7K utterances was collected from Facebook and Quora pages, and annotated manually. Motivated by the work by Li et al. (2014), this corpus was used to develop an SVM-based speech act classifier using the following features: bag-of-words (top 20% bigrams), presence of “wh” words, presence of question marks, occurrence of “thanks/thanking” words, POS tags distributions, and sentiment lexica such as the NRC lexicon (Mohammad et al., 2013), SentiWordNet (Baccianella et al., 2010), and WordNet Affect (Strapparava and Valitutti, 2004).

The categorical corpus distribution and the performance of the final classifier are reported in Table 5, showing an average F<sub>1</sub>-score of 0.69 in 10-fold cross validation. Automatic speech act classification of social media conversations is a separate research problem, which is out of the scope of the current study. However, although the speech act classifier was not highly accurate in itself, the user specific speech act distributions (in %) could be used as features for the psycholinguistic classifiers (resulting in 11 additional features). Experiment on the Essay and Facebook corpora showed only 1.15% and 1% performance gain, respectively, whereas on the Twitter Corpus, a noticeable performance improvement of 6.12% (F-measure) was obtained. This indicates that speech acts are important signals of psychological behaviour, so even though the speech act classifier performs poorly, the extracted information is relevant.

## 4.2 Non-Linguistic Features

Social network structure is very useful to predict any person’s intrinsic value. For each user in the Twitter corpus, the total number of tweets or messages, total number of likes, average time differ-

ence between two tweets/messages, total number of favourites and re-tweets, and their in-degree and out-degree centrality scores on network of friends and followers were used as features adding to a total of 7 features along with the feature set used in the Topic Modelling experiment (69 LIWC + 89 Topic Modeling words from the Essay Corpus) after observation of the structure of tweets and the previously done linguistic feature experiments. The degree centrality was calculated as of a vertex  $v$ , for a given graph  $G(V,E)$  with  $|V|$  vertices and  $|E|$  edges, is defined as:  $\{C_D = deg(v)\}$ .

The results of all the experiments after 10-fold cross-validation are summarized in Table 6 below.

## 5 Discussion and Conclusion

The main contributions of this paper are the introduction of a computational Schwartz values model, development of three different corpora annotated with Schwartz’ value, and experiments with features for automatic value classification. Table 6 reports that our models outperformed the majority baselines by significant margins of **+5.05**, **+7.20**, **+9.83** respectively on the Essay, Twitter and Facebook corpora. From the results it could be inferred that a few Schwartz values such as Self-Direction and Security are relatively difficult to identify, while on the other hand the accuracies for certain value types such as Power and Tradition are persistent and seem to be more salient.

The results also indicate that social media text is difficult for automatic classification, which is obvious from its terse nature. However, it is striking that the social media postings correlate far stronger than the essays with the psychometric data. This is probably since the size of the Twitter data is much larger than someones essay, and since when asked to write something, people become cautious; however, users behave more naturally when communicating in social media, making the data more insightful.

Another major implication from the experiments is that popular text classification features such as n-grams and topic-modelling were not performing well in this domain, indicating that this

<sup>9</sup>See for Fine-Gained Speech-Act classes <http://compprag.christopherpotts.net/swda.html>.

Table 6: Automatic Schwartz value classification (accuracy) on the Essay, Twitter and Facebook corpora. Details of feature ablation and class wise performance.

is not yet another text classification problem, but that rather further deeper psycholinguistic analysis is required to find out hidden clues and the nature of language vs ethical practices. Here, it is worth noting the research by Pennebaker (2011), which indicates that, surprisingly, non-content words like pronoun, prepositions, particles, and even symbols are more salient indicators of our personality.

For the machine learners, closer analysis revealed that SMO’s performance was somehow irregular and random, which might be an indication of over-fitting. For example, the performance for some Schwartz values greatly decreased when adding n-grams as new features with LIWC, whereas some values showed the opposite behaviour, implying that each value type has its own set of distinct clues, but also high overlap. On the other hand, the performance of the Random Forests classifier increased when the number of features was increased, resulting in a larger forest and hence for most value types it performed better than the other two classifiers with less over-fitting.

A major limitation of the work is that the collected social network corpus is skewed. Reports of

psychological analysis on any community always depend on how the target population is chosen. It is absolutely impossible to get precisely balanced data from any real community. For example, it is rather impossible to have 150+ absolute power oriented people in a corpus of size 367 users data. The only solution to this problem is having more data, which we currently are collecting.

The data will be publicly released to the research community soon. We are also very keen on the applied side of this kind of models. Presently we are analysing the community detection problem in social media in relation to values. Another interesting application could be comparative societal analysis between the Eastern and Western regions of the world. Relations among personality and ethics could also be explored.

## Abstract

Americans spend about a third of their time online, with many participating in online conversations on social and political issues. We hypothesize that social media arguments on such issues may be more engaging and persuasive than traditional media summaries, and that particular types of people may be more or less convinced by particular styles of argument, e.g. emotional arguments may resonate with some personalities while factual arguments resonate with others. We report a set of experiments testing at large scale how audience variables interact with argument style to affect the persuasiveness of an argument, an under-researched topic within natural language processing. We show that belief change is affected by personality factors, with conscientious, open and agreeable people being more convinced by emotional arguments.

## 1 Introduction

Americans spend a third of their online time on social media, with many participating in online conversations about education, public policy, or other social and political issues. Our hypothesis is that online dialogs have important properties that may make them a useful resource for educating the public about such issues. For example, user-generated content might be more engaging and persuasive than traditional media, due to the prevalence of emotional language, social affiliation, conversational argument structure and audience involvement. Moreover, particular types of people may be more or less convinced by particular styles of argument, e.g. emotional arguments

may resonate with some personalities while factual arguments resonate with others.

Factual: Death Penalty	
Q1:	I'm sure there have been more repeat murderers than innocent people put to death. As far as the cost goes, is that really an issue? Execution Room = \$10,000. Stainless Steel Table = \$2,000. Leather Straps = \$200. Lethal Injection Chemicals = \$5,000. Knowing this person will never possibly be able to kill again = PRICELESS
R1:	Actually the room, straps, and table are all multi-use. And the drugs only cost Texas \$86.08 per execution as of 2002.
Emotional: Death Penalty	
Q2:	You mean, the perpetrator is convicted and the defender acquitted? Yes, that's the rule and not the exception. Notice here how no-one ended up dead, or even particularly seriously injured. Additionally the circumstances described are incredibly rare, that's why it makes the news.
R2:	The defender shouldn't even have been brought to trial in the first place. That doesn't make it any better. Somebody breaks into your home and threatens your family with rape and murder, they deserve serious injury at the very least.

Table 1: Factual vs. Emotional dialog exchanges 4forums.com. Q = Quote, R = Response.

For example, contrast the two informal dialogic exchanges about the death penalty in Table 1 with the traditional media professional summary in Table 2. We might expect the argument in Table 2 to be more convincing, because it is carefully written to be balanced and exhaustive (Reed and Rowe, 2004). On the other hand, it seems possible that people find dialogic arguments such as those in Table 1 more engaging and learn more from them. And indeed, about 90% of the people in online forums are so-called lurkers (Whittaker, 1996; Nonnecke and Preece, 2000; Preece et al., 2004), and do not post, suggesting that they are in fact **reading** opinionated dialogs such as those in Table 1 for interest or entertainment.

Research in social psychology identifies three

Curated Summary: Death Penalty	
<b>PRO:</b>	Proponents of the death penalty say it is an important tool for preserving law and order, deters crime, and costs less than life imprisonment. They argue that retribution or "an eye for an eye" honors the victim, helps console grieving families, and ensures that the perpetrators of heinous crimes never have an opportunity to cause future tragedy.
<b>CON:</b>	Opponents of capital punishment say it has no deterrent effect on crime, wrongly gives governments the power to take human life, and perpetuates social injustices by disproportionately targeting people of color (racist) and people who cannot afford good attorneys (classist). They say lifetime jail sentences are a more severe and less expensive punishment than death.

Table 2: Traditional balanced summary of the death penalty issue from [ProCon.org](http://ProCon.org).

factors that affect argument persuasiveness (Petty and Cacioppo, 1986; Petty and Cacioppo, 1988).

- the ARGUMENT itself
- the AUDIENCE
- the SOURCE of the argument

The ARGUMENT includes the content and its presentation, e.g. whether it is a monolog or a dialog, or whether it is factual or emotional as illustrated in Table 1 and Table 2. The AUDIENCE factor models people's prior beliefs and social affiliations as well as innate individual differences that affect their susceptibility to particular arguments or types of arguments (Anderson, 1971; Davies, 1998; Devine et al., 2000; Petty et al., 1981). Behavioral economics research shows that the cognitive style of the audience interacts with the argument's emotional appeal: emphasizing personal losses is more persuasive for neurotics, whereas gains are effective for extraverts (Carver et al., 2000; Mann et al., 2004). The SOURCE is the speaker, whose influence may depend on factors such as attractiveness, expertise, trustworthiness or group identification or homophily (Eagly and Chaiken, 1975; Kelman, 1961; Bender et al., 2011; Luchok and McCroskey, 1978; Ludford et al., 2004; McPherson et al., 2001).

We present experiments evaluating how properties of social media arguments interact with audience factors to affect belief change. We compare the effects of two aspects of the ARGUMENT: whether it is monologic or dialogic, and whether it is factual or emotional. We also examine how these factors interact with properties of the AUDIENCE. We profile audience **prior beliefs** to test if

more neutral people are swayed by different types of arguments than people with entrenched beliefs. We also profile the audience for Big Five personality traits to see whether **different personality types** are more open to different types of arguments, e.g., we hypothesize that people who are highly agreeable (A) might be more affected by the combative style of emotional arguments. We provide a new corpus for the research community of audience personality profiles, arguments, and belief change measurements.<sup>1</sup>

Audience factors have been explored in social psychological work on persuasion, but have been neglected in computational work, which has largely drawn from sentiment, rhetorical, or argument structure models (Habernal and Gurevych, 2016b; Conrad et al., 2012; Boltuzic and Šnajder, 2014; Choi and Cardie, 2008). We demonstrate that, indeed, undecided people respond differently to arguments than entrenched people, and that the responses of undecided people correlate with personality. We show that this holds across an array of different arguments. Our research questions are:

- Can we mine social media to find arguments that change people's beliefs?
- Do different argument types have different effects on belief change?
- Do personality and prior beliefs affect belief change?
- Are different personality types differently affected by factual vs. emotional arguments?

Our results show a small but highly reliable effect that short arguments derived from online dialogs do lead people to change their minds about topics such as abortion, gun control, gay marriage, evolution, the death penalty and climate change. As expected, opinion change is greater for people who are initially more neutral about a topic, than those who are entrenched. However personality variables also have a clear effect on opinion change: neutral, balanced arguments are more successful with all personality types, but conscientious people are more convinced by dialogic emotional arguments, and agreeable people are more persuaded by dialogic factual arguments. We describe how we use plan these findings to select and repurpose social media arguments to adapt them to people's individual differences and thus maximize their educational impact.

## 2 Related Work

Previous work on belief change has primarily focused on single, experimentally crafted, persuasive messages, rather than exploring whether user-generated dialogic arguments can be repurposed to persuade. Recently however several papers have begun to investigate two challenges in argument mining: (1) understanding the structure of an argument and extracting argument components (Lippi and Torroni, 2015; Nguyen and Litman, 2015; Stab and Gurevych, 2014; Lippi and Torroni, 2015; Biran and Rambow, 2011); and (2) understanding what predicts the persuasiveness of web-sourced argumentative content (Habernal and Gurevych, 2016b; Fang et al., 2016; Wachsmuth et al., 2016; Habernal and Gurevych, 2016a; Tan et al., 2016).

Tan et al. (2016) study belief change in the Reddit `/r/ChangeMyView` subreddit (CMV), in which an original poster (OP) challenges others to change his/her opinion. They build logistic regression models to predict argument success, identifying two conversational dynamic factors: a) early potential persuaders are more successful and b) after 4 exchanges, the chance of persuasion drops virtually to zero. Linguistic factors of persuasive posts include: a) dissimilar content words to the OP, b) similar stop words, c) being lengthy (in words, sentences, and paragraphs), d) italics and bullets. Finally, susceptibility to persuasion is correlated with singular vs. plural first person pronouns, which the authors relate to the personality trait of Openness to Experience. The CMV reddit offers a unique window into how persuasion of self-declared open-minded people occurs online. However, while Tan et al. find potential proxies for personality traits, they cannot examine traits directly because they do not have personality profiles as we do here. They also do not examine the effect of argument style as we do.

Recent work (Habernal and Gurevych, 2016b; Habernal and Gurevych, 2016a) also examines what makes an informal social media argument convincing. They have created a new dataset of pairs of arguments annotated for which argument is more convincing, along with the reasons given by annotators for its convincingness. They test several models for predicting convincingness comparing an SVM with engineered linguistic features to a BLSTM, with both models performing similarly. In contrast to our experiments, they do

not explore factors of the audience or explicitly vary the style of the argument.

Previous work also tests the hypothesis that dialogic exchanges might be more engaging, in the context of expository or car sales dialog (André et al., 2000; Lee, 2010; Craig et al., 2006; Stoyanchev and Piwek, 2010). Work comparing monologic vs. dialogic modes of providing information suggest that dialogs: (1) are more memorable and engaging, (2) stimulate the audience to formulate their own questions, and (3) allow audiences to be more successful at following communication (Lee et al., 1998; Fox Tree, 1999; Suzuki and Yamada, 2004; Driscoll et al., 2003; Fox Tree and Mayer, 2008; Fox Tree, 1999; Liu and Fox Tree, 2011).

Other work (Vydiswaran et al., 2012) explores how user-interface factors (e.g., number and order of argument presentation, whether and how arguments are rated) affect how readers process arguments. Several factors increased the number of passages read, including explicitly presenting contrasting viewpoints simultaneously. This exercise caused people with strong beliefs (about the healthiness of milk) to moderate their views after 20-30 minutes of concentrated study. We do not concentrate on interface factors, instead exploring how persuasiveness relates to audience factors and argumentative style. Also our experiments are run online with hundreds of users, rather than as a controlled study in the lab.

## 3 Experimental Method

Our experimental method consists of the following steps:

- Select user-generated dialogs with persuasive argument features from an online corpus of socio-political debates, exploring the role of **affect** (Sec. 3.1).
- Profile subjects for **personality traits** and **prior beliefs** about socio-political issues (Sec. 3.2).
- Expose subjects to user-generated, factual vs. emotional dialogic exchanges and compare the effects on belief change to balanced, curated arguments (Sec. 3.3).
- Conduct experiments to predict the degree of belief change as a function of prior belief, personality and type of argument.

The participants were pre-qualified using a reading comprehension task that checked their re-

sponses against a gold standard to ensure that they read the arguments carefully. Because we make many comparisons, and our experiments are conducted at large scale, all of our results incorporate Bonferroni corrections.

### 3.1 Dialog Selection: Identifying Socio-Emotional Arguments

Our work requires a new experimental corpus that is sensitive to readers' prior beliefs and personalities. We utilize online dialogs from 4forums.com downloaded from The Internet Argument Corpus (IAC) (Walker et al., 2012c). The IAC contains quote/response pairs of targeted arguments between two people (Table 1) on topics such as: death penalty, gay marriage, climate change, abortion, evolution and gun control. Each argument is annotated to distinguish arguments making strong appeals to emotional factors versus straightforwardly factual arguments.

We selected a subset of extreme exemplars of factual (FACT) versus emotional (EMOT) arguments, defined as Q/R pairs reliably annotated to be at the extreme ends of the fact/emotion scale, i.e. responses with an average  $\geq 4$  annotation were considered factual, and those whose annotation averaged  $\leq -4$  were considered emotional on a scale of -5 to 5. Table 1 illustrates both factual (R1) and emotional (R2) arguments, with additional examples for other topics in Table 3.

In the IAC, 95% of the Q-R pairs are disagreements, the FACT and EMOT datasets were selected to contain a similar proportion. There was no correlation between agreement/disagreement and emotionality ( $r = 0.07$ , ns).

### 3.2 Personality

Personality is usually measured with a standardized survey that calculates a scalar value for the five OCEAN traits: openness to experience O, conscientiousness C, extraversion E, agreeableness A, and neuroticism N (Goldberg, 1990; Norman, 1963) We first conducted an experiment to profile the Big Five personality traits of 637 Turkers using the Ten Item Personality Inventory (TIPI) (Gosling et al., 2003). The TIPI instrument defines each person on a scale from 1 to 7 with 0.5 precision. In order to guarantee reliability of our results, we then verified that our pre-qualified Turkers are representative of the population as a whole, by comparing the means and standard deviations of our sample of 637 Turkers with the na-

Factual: Abortion	
<b>Q3:</b>	Not only that, to suggest that untold numbers of women would seek illegal abortions is a question-begging claim that has no grounding in history, logic, or reason. It is an unfounded, unproven claim. It is a betrayal to sound judgment to make decisions based upon unfounded predictions into the future.
<b>R3:</b>	But it is based on history. There is plenty of history showing that women had illegal abortions.
Factual: Climate Change	
<b>Q4:</b>	This is where the looney left gets lost. Their mantra is atmospheric CO2 levels are escalating and this is unquestionably causing earth's temperature rise. But ask yourself – if global temperatures are experiencing the biggest sustained drop in decades, while CO2 levels continue to rise – how can it be true?
<b>R4:</b>	Because internal variability from the likes of ENSO, which can cause short term swings of a full degree C, easily swamp the smaller increase we'd expect from CO2 forcing. Easy.
Emotional: Abortion	
<b>Q5:</b>	Undesired first pregnancy is an acute problem for many girls who choose to go under the surgical knife, even though that often ends up with infertility, broken life etc. Dry fasting is an alternative to first pregnancy abortion. If applied, up to 2-3 months old embryo gets dissolved after 15-16 days of the fast. Plus, there is no 'christian' sin.
<b>R5:</b>	No Christian sin??? Other then the intent to kill and then doing so:p
Emotional: Gay Marriage	
<b>Q6:</b>	Did anyone else expect anything less? These evil fundie christianists can have affairs, 2, 3, 4, or even 5 marriages yet gay people are a threat to marriage by wanting to get married.
<b>R6:</b>	You hear that cry...allowing gays to marry will cause the downfall of civilization...but you never hear 'how' or 'why'? More Chicken Little #####.

Table 3: Factual vs. Emotional dialog exchanges. Q = Quote, R = Response.

tional standards given in Gosling et. al (2003). Table 4 shows that our survey means and standard deviations are very close to the national norms, suggesting our sample is representative of the public in general, and hence can be used to validate whether social media arguments could fruitfully be used to educate the public.

	E	A	C	N	O
Our survey	4.30	5.19	5.50	4.82	5.53
Norms	4.44	5.23	5.4	4.83	5.38
Our survey $\sigma$	1.45	1.11	1.32	1.42	1.07
Norms $\sigma$	1.44	1.24	1.24	1.41	1.14

Table 4: TIPI  $\sigma$  and mean from our personality survey compared to the normal distribution

### 3.3 Prior Beliefs and Belief Change

Previous research suggests that people who are entrenched about an issue are unlikely to change their mind (Anderson, 1971; Davies, 1998; Devine et al., 2000), so we wanted to establish the baseline beliefs of our pre-qualified Turkers before they had been exposed to any arguments about a topic. We therefore collected each Turker’s initial stance on a topic, by asking them to answer a simple **stance question** with no context, for example: *Should the death penalty be allowed?*. Likert responses were recorded on a -5 to 5 slider scale with 0.01 degrees of precision, with labels on the slider of “Yes”, “No”, or “Neutral”.

Curated Summary: Abortion	
<b>PRO:</b>	Proponents, identifying themselves as pro-choice, contend that abortion is a right that should not be limited by governmental or religious authority, and which outweighs any right claimed for an embryo or fetus. They argue that pregnant women will resort to unsafe illegal abortions if there is no legal option.
<b>CON:</b>	Opponents, identifying themselves as pro-life, assert that personhood begins at conception, and therefore abortion is the immoral killing of an innocent human being. They say abortion inflicts suffering on the unborn child, and that it is unfair to allow abortion when couples who cannot biologically conceive are waiting to adopt.

Table 5: Traditional balanced summary of “Should abortion be legal?” from ProCon.org.

Our goal is to compare the belief change that results from social-media dialogs with the belief change from professionally-curated monologs. We selected the balanced, monologic, argument summaries from the website ProCon.org (in Table 2 with an additional example in Table 5). The arguments from ProCon.org are very high quality, and produced by domain experts.

After probing initial beliefs, we presented participants with one of the three different argument types to test their affect on belief change: a Curated Monolog (MONO) (Table 2), an emotional argument (EMOT) (R2 in Table 1), or a factual argument (FACT) (R1 in Table 1). After each person read one of these three types of arguments, we retested their reactions to the original stance question, while viewing the argument. Responses were again recorded on a -5 to 5 slider scale with 0.01 degrees of precision, with labels on the slider of “Yes”, “No”, or “Neutral”. We computed belief change by measuring differences in stance be-

	N	Mean change	$\sigma$ change
MONO entrenched	1826	0.50	1.09
MONO neutral	1359	0.62	0.71
FACT entrenched	258	0.27	0.79
FACT neutral	202	0.39	0.55
EMOT entrenched	213	0.35	0.87
EMOT neutral	187	0.37	0.54
ALL entrenched	2951	0.43	1.00
ALL neutral	2234	0.51	0.65

Table 6: Means and  $\sigma$  for belief change for neutral and entrenched participants presented with MONO, FACT, or EMOT argument types. Neutrals show more belief change, and all argument types significantly affect beliefs

fore and after reading each argument. We created 20 HITs on Mechanical Turk for this task, with 5 items per hit.

## 4 Experimental Corpus Results

### 4.1 Entrenchment and Belief Change

Our first question is whether our method changed participant’s beliefs. Table 6 shows belief change as a function of argument type: monologs (MONO), factual (FACT) and emotional (EMOT). Belief change occurred for all argument types: and the change was statistically significant as measured by paired t-tests ( $t_{(5184)} = 38.31$ ,  $p < 0.0001$ ). This confirms our hypothesis that social media can be mined for persuasive materials. In addition, all three types of arguments independently led to significant changes in belief.<sup>2</sup>

One of the strongest theoretical predictions is that people with entrenched beliefs about an issue are less likely to change their mind when provided new information about that issue. Table 6 shows the relationship between initial beliefs and extent of belief change. We defined people as having more entrenched initial beliefs if their response to the initial stance question was within 0.5 points of the two ends of the scale, i.e. (1.0-1.5) or (4.5-5.0), indicating an extreme initial view.

We tested whether people who were more entrenched initially showed less change than those who were initially more neutral. We conducted a 2 Initial Belief (Entrenched/Neutral) X 3 Argument Type (MONO/EMOT/FACT) ANOVA, with Belief Change as the dependent variable, and Initial Belief and Argument Type as between subjects factors. Again, as expected, initially Entrenched

<sup>2</sup>(For MONO,  $t_{(3184)} = 32.65$ ,  $p < 0.0001$ , for FACT,  $t_{(1019)} = 14.81$ ,  $p < 0.0001$ , For EMOT,  $t_{(979)} = 14.35$ ,  $p < 0.0001$ ).

people showed less change ( $M = 0.43$ ) than those who began with Neutral views ( $M = 0.51$ ), ANOVA ( $F_{(1,5179)}=5.97$ ,  $p = 0.015$ ).

## 4.2 Argument Type and Belief Change

We wanted to test whether the engaging, socially interesting, dialogic materials of EMOT and FACT might promote more belief change than balanced curated monologic summaries. We tested the differences between argument types, finding a main effect for argument type ( $F_{(2,5179)}=31.59$ ,  $p < 0.0001$ ), with Tukey post-hoc tests showing MONO led to more belief change than both EMOT and FACT (both  $p < 0.0001$ ), but no differences between EMOT and FACT overall across all subjects (See Table 6). Finally there was no interaction between Initial Belief and Argument Type ( $F_{(2,5179)}=1.25$ ,  $p > 0.05$ ): so although neutrals show more belief change overall, this susceptibility does not vary by argument type.

## 5 Predicting Belief Change

Our results so far show that our arguments changed people’s beliefs as a function of their prior beliefs and argument type. However we aim to automatically **predict** belief change, and hypothesize that knowing a person’s **personality** in combination with their **prior beliefs** will allow us to select social-media arguments that are more persuasive **for a particular individual**.

Thus, we vary whether providing a learner with features about a person’s personality improves performance for predicting belief change, when compared with providing information about degree of entrenchment alone. We use different representations for personality and prior beliefs as features, the raw score from the Likert slider for belief change and the TIPI score, as well as normalizations of the raw scores according to the distributions per topic, and finally categorical binning of the transformed scores.

### 5.1 Feature Development and Selection

New features were created by computing the z-transformation score from the raw prior beliefs and personality traits scores. Applying Equation 1 to the raw data creates a normal distribution where the new mean is 0 and the standard deviation is 1. For prior beliefs,  $x_i$  is an individual prior belief for a particular topic,  $\bar{x}_i$  is the mean, and  $\sigma_i$  is the standard deviation for the particular topic.

$$\frac{x_i - \bar{x}_i}{\sigma_{x_i}} \quad (1)$$

Categorical bins are derived from the transformed scores to describe the direction of the belief change by comparing prior and final recorded beliefs. The belief change is positive or negative depending upon where the Turkers rate themselves on the belief scale, moving more towards one side (1) or the other (5). Next, to control for variance, we apply a z-transformation on change scores to create a normal distribution. We classify the resulting distribution into three bins: Low, Medium, and High. The interpretation of what stance the Low and High bins represent is strictly topic dependent. The Medium bin consists of z-transformation values between -1 and 1. These are the people whose belief change is less than one standard deviation from the transformed mean. The Low bin contains z-transform scores of less than -1 and translates to belief changes of a large magnitude (more than a standard deviation from the mean) in a negative direction, where again, the meaning of “negative” is dependent upon how the question was framed. The High bin contains z-transformation scores of greater than 1 and translates to belief changes of a large magnitude in a positive direction. For example, the stance question *Should the death penalty be allowed?* has “no” at the -5 end and “yes” at the +5 end of the likert scale. A Low bin is indicative as moving in the direction of the “no” stance and High towards the “yes” stance.

Bins were also derived for the personality traits, e.g. for Openness, the High bin indicates someone who is very open, the Medium bin is average, and the Low bin is not open at all.

Finally, a binary feature was created to represent how entrenched an individual is in a particular topic. This feature is based on the raw prior belief score and is True if the prior belief score is within 0.5 points of either end point on the stance scale. This feature is different from the prior belief bins because this entrenchment feature groups together people who are in the extremes on both sides of the stance scale, while the prior belief bins distinguishes between the two ends.

We created a development set using data from a prior Mechanical Turk experiment which had 20 HITs, 5 questions per HIT, and 20 people who completed each HIT. In the same manner as the FACT and EMOT HITs, these Turkers (whose per-

sonality was already profiled) were asked about their prior beliefs about a topic, then presented with a factual or emotional argument. But in this case they were asked to rate the strength of the argument rather than to report their belief about the topic. We then identified the combination of features that best predicted argument strength in this development data, and then used this feature set for the belief change experiments below. Turkers who participated in this initial study did not participate in the belief change study and vice versa.

Results on the development set showed that the z-transformation scores for prior belief and personality performed better than the raw scores and bins. On the other hand, the belief change feature was most effective when represented as a categorical variable via binning and directionality. We also found that it is better to have **both** the z-transformed prior belief feature and the entrenchment feature. Thus our experiments below use these feature representations.

We test on three different datasets: MONO, FACT and EMOT, to elicit responses from reading the monologic summaries, and the factual and emotional dialogic arguments. The FACT and EMOT datasets have specific information in terms of scalar values about their degree of factuality or emotionality, on a scale of -5,+5 and a feature with this value is created for these datasets derived from the crowdsourced Turker judgments about the degree of Fact/Emotion in a Q/R pair, as described earlier. The monologic summaries (MONO) are assumed to be neutral and are not assigned a value for degree of factuality or emotionality.

## 5.2 Belief Change Experimental Results

Our dataset consists of 5185 items, with 3185 responses to the balanced MONO summaries, 1020 responses to FACT, and 980 responses to EMOT. We first applied 10-fold cross-validation with Naive Bayes, Nearest Neighbor, AdaBoost, and JRIP, from the Weka toolkit (Hall et al., 2005). Overall, Naive Bayes had the most consistent scores with our feature sets, thus we only report Naive Bayes experimental results below.

Seven feature sets were created for each of the three {MONO, FACT, EMOT} datasets. *None* feature sets are the no-personality baseline within each dataset. The baseline features contain **no information** about the personality of the unseen human subjects. We use the {MONO, FACT,

EMOT}+None feature sets for testing our hypothesis that personality affects belief change, and **our ability to predict belief change** using personality features. *All* feature sets have information about **all** of the human subjects' personality traits as 5 distinct features. The remaining five {O,C,E,A,N} feature sets examine the effect of providing information to the learner about personality using only **one personality trait at a time**, in order to determine if any personality trait is having a larger impact for belief change prediction.

Table 7 summarizes our key results, reporting accuracy, precision, recall, and F1 for predicting belief change as a discrete bin, Low, Medium, and High. We balanced each dataset to contain the same number of instances in bins, thus the accuracy for majority classification is 33% (Row 1).

After running Naive Bayes over all feature sets in the three datasets, we compared the experimental classifier performance of *All* and {O,C,E,A,N} against the None baselines using a Bonferroni corrected t-test for F1 measure. Using statistical ANOVA tests that control for pre and post test sample variance, we found small but highly reliable effects. We show all of our results, but focus our discussion below on statistically significance differences in F1. We boldface personality feature sets in Table 7 that are statistically significant when comparing {MONO, FACT, EMOT}+None with the other feature sets in the group.

The effect of argument alone (without personality information) can be seen by the no-personality baseline for each argument type, where we exclude personality information ({MONO, FACT, EMOT}+None). All these feature sets perform above the baseline of 33% (Row 1). This supports the results of our prior ANOVA testing over all subjects for belief change, and shows that the argument itself partially predicts belief change.

However, more interestingly, Table 7 also shows that providing the learner with information about personality consistently improves the ability of the learner to predict belief change. For all types of arguments, ie. the neutral, monologic summaries and the factual and emotional dialogs, the feature sets without any information about the personality traits of the unseen human subjects perform significantly worse than the feature sets that contain all five personality traits. MONO+None compared to MONO+All (rows 2 and 8 respectively) show a slight but significant increase in F1 from 0.51 to

row #	Dataset	TIPI	Accuracy	Precision	Recall	F1
1	<b>Baseline</b>		33%			
2	MONO	None	57%	0.50	0.58	0.51
3		<b>Open</b>	58%	0.52	0.59	<b>0.52</b>
4		Conscientious	58%	0.51	0.58	0.51
5		Extrovert	58%	0.49	0.57	0.49
6		Agreeable	58%	0.52	0.57	0.50
7		Neurotic	57%	0.49	0.55	0.47
8		<b>All</b>	58%	0.52	0.58	<b>0.52</b>
9		FACT	None	49%	0.47	0.47
10	Open		46%	0.45	0.47	0.46
11	Conscientious		48%	0.48	0.45	0.46
12	Extrovert		48%	0.46	0.45	0.44
13	<b>Agreeable</b>		51%	0.52	0.49	<b>0.49</b>
14	Neurotic		47%	0.45	0.44	0.43
15	<b>All</b>		50%	0.49	0.50	<b>0.49</b>
16	EMOT	None	53%	0.42	0.52	0.44
17		<b>Open</b>	56%	0.54	0.53	<b>0.51</b>
18		<b>Conscientious</b>	53%	0.49	0.51	<b>0.48</b>
19		Extrovert	49%	0.43	0.47	0.44
20		<b>Agreeable</b>	52%	0.48	0.50	<b>0.48</b>
21		Neurotic	53%	0.43	0.51	0.44
22		<b>All</b>	56%	0.55	0.57	<b>0.56</b>

Table 7: Predicting Belief Change with Naive Bayes for Three Data Sets: Statistics are based on 10-fold cross validation. Row numbers provided to reference particular results in the text.

0.52 (using a paired t-test on 10 fold cross validation scores, ( $p = .001$ )). Similarly, FACT+None versus FACT+All (rows 9 and 15) shows a significantly greater increase in F1: from 0.46 to 0.49 ( $p = .0002$ ), as does EMOT+None versus EMOT+All (rows 16 and 22) with F1 increasing from 0.44 to 0.56 ( $p = .00001$ ). This confirms that the personality traits improves a model’s ability to predict belief change in unseen human subjects.

Next we compared the effects of providing the learner with information about each individual personality feature **in isolation** by comparing {MONO, FACT, EMOT}+None with individual personality factors. For MONO, we found that adding personality information about Openness to Experience (MONO+O, row 3) improved F1 from 0.51 to 0.52 compared with a no-personality baseline ( $p = .0006$ ). This suggests that open people are more persuaded by balanced monologic arguments.

A more interesting result is that Openness to Experience (EMOT+O, row 17) was also important for Emotional arguments, increasing F1 from 0.44 to 0.51 ( $p = .00001$ ). In contrast, Openness had no effect for Factual arguments (Row 10) ( $p > 0.05$ ). Models for predicting belief change for Emotional arguments also benefit from information about Conscientiousness and Agreeableness. Row 17 (EMOT+O), Row 18 (EMOT+C) and Row 20 (EMOT+A) all show significant differences in

F1, with EMOT+O better than EMOT+None ( $p = .00001$ ), EMOT+C better than EMOT+None ( $p = .00001$ ) and EMOT+A better than EMOT+None ( $p = .0001$ ).

Information about Agreeableness also improves the quality of the belief change models for the factual dialogs (FACT+A, row 5) with an increase in F1 from 0.46 baseline to 0.49 ( $p = .004$ ), suggesting that people who are more Agreeable are more influenced by factual arguments. This confirms one of our initial hypotheses that Agreeable people would be more sensitive to the fact/emotional dimension of arguments because of their desire to either avoid conflict (highly Agreeable people) or to seek conflict (Disagreeable people).

## 6 Conclusions

To the best of our knowledge we are the first to examine the interaction of social media argument types with audience factors. Our contributions are:

- A new corpus of personality information and belief change in socio-political arguments;
- A new method for identifying and deploying social media content to inform and engage the public about important social and political topics;
- Results showing at scale (hundreds of users) that we can mine arguments from online discussions to change people’s beliefs;

- Results showing that different types of arguments have different effects: while balanced monologic summaries led to the greatest belief change, socio-emotional online exchanges also caused changes in belief.

Although our short question/response pairs did not induce as much belief change as the curated balanced monologs, we believe that these are striking results given that the materials we extracted from online discussions are not balanced or professionally produced, but instead are simple fragments extracted from online discussions.

Further, confirming prior work on persuasion (Eagly and Chaiken, 1975; Kelman, 1961; Petty et al., 1981), we found that these effects depend on audience characteristics. As expected, belief depended on the strength of prior beliefs so that initially neutral people were more likely to be persuaded than entrenched individuals, regardless of the type of argument. Again supporting our predictions, argument effectiveness depended on personality type. People who are Open to Experience were influenced by balanced and emotional materials. In contrast, Agreeable people are most affected by factual materials. Emotional arguments had very different effects from factual and balanced monologs: Openness is important but so too are Conscientiousness and Agreeableness.

How can we explain this? People who are more Open are typically receptive to new ideas. But our results for emotional arguments also show that Conscientious people change their views when presented with emotional arguments, possibly because they are careful to process the arguments however expressed. And Agreeable people may also be motivated to change belief by emotional arguments because they are less likely to be influenced by personal feelings.

Our results have numerous implications that suggest further technical experimentation. The fact that we can induce belief change by extracting simple discussion fragments suggests that belief change can be induced without the application of sophisticated text processing tools. While our results for balanced monologs suggest that summaries increase belief change, summary tools for such arguments are still under development (Misra et al., 2015). However, perhaps high quality summaries may not be needed if compelling argument fragments can be automatically extracted (Misra et al., 2016b; Subba and Di Eugenio, 2007; Nguyen

and Litman, 2015; Swanson et al., 2015).

Our work also suggests the importance of personalization for persuasion: with different personality types being open to different styles of argument. Future work might be based on methods for profiling participant personality from simple online behaviors (Di Eugenio et al., 2013; Liu et al., 2016; Pan and Zhou, 2014; Yee et al., 2011), or from user-generated content such as first-person narratives or conversations (Mairesse and Walker, 2006a; Mairesse and Walker, 2006b; Rahimtoroghi et al., 2016; Rahimtoroghi et al., 2014). We could then select personalized arguments to meet a participant's processing style.

While here we used crowdsourced judgments to select arguments of particular types. Elsewhere, we present algorithms for automatically identifying and bootstrapping arguments with different properties. We have methods to extract arguments that represent different stances on an issue (Misra et al., 2016a; Anand et al., 2011; Sridhar et al., 2015; Walker et al., 2012a; Walker et al., 2012b), as well as argument exchanges that are agreements vs. disagreements (Misra and Walker, 2015), factual vs. emotional arguments (Oraby et al., 2015), sarcastic and not-sarcastic arguments, and nasty vs. nice arguments (Oraby et al., 2016; Lukin and Walker, 2013; Justo et al., 2014).

An open question is to whether these effects are long term. Our approach limits us to examining belief change during a single session for practical reasons; long-term cross-session comparisons lead to significant participant retention issues.

Our results also suggest new empirical and theoretical methods for studying persuasion at scale. Only recently have studies of persuasion moved beyond small scale lab studies involving simple single arguments (Habernal and Gurevych, 2016b; Habernal and Gurevych, 2016a; Tan et al., 2016). Our research also suggests new methods and tools for larger scale studies of persuasion. While care must be taken in deploying these results, studies of juries and other decision making bodies suggest that exposure to a diversity of opinions and minority views are very important to countering extremism and understanding the issues at stake (Devine et al., 2000; Ludford et al., 2004). The ability to repurpose the huge number of varied opinions available in social media sites for educational purposes could provide a novel way to expose people to a diversity of views.

## Abstract

There have been many attempts at automatically recognising author personality traits from text, typically incorporating linguistic features with conventional machine learning models, e.g. linear regression or Support Vector Machines. In this work, we propose to use deep-learning-based models with atomic features of text – the characters – to build hierarchical, vectorial word and sentence representations for the task of trait inference. On a corpus of tweets, this method shows state-of-the-art performance across five traits and three languages (English, Spanish and Italian) compared with prior work in author profiling. The results, supported by preliminary visualisation work, are encouraging for the ability to detect complex human traits.

## 1 Introduction

Deep-learning methods are becoming increasingly applied to problems in the area of Natural Language Processing (NLP) (Manning, 2016). Such techniques can be applied to tasks such as part-of-speech-tagging (Ling et al., 2015; Huang et al., 2015) and sentiment analysis (Socher et al., 2013; Kalchbrenner et al., 2014; Kim, 2014). At their core, these tasks can be seen as learning representations of language at different levels. Our work reported here is no different, though we choose a less commonplace level of representation – rather than the text itself, we focus on the author behind the text. Automatically modelling individuals from their language use is a task founded on the long-standing understanding that language use is influenced by sociodemographic characteristics

such as gender and personality (Tannen, 1990; Pennebaker et al., 2003). The study of personality traits in particular is considered reliable as such traits are generally temporally stable (Matthews et al., 2003). As such, our ability to model our target – the author – is enriched by the acquisition of more data over time.

The volume of literature on computational personality recognition, and its broader applications, has grown steadily over the last decade. There have also been a number of dedicated workshops (Celli et al., 2014; Tkalčič et al., 2014) and shared tasks (Rangel et al., 2015) on the topic occurring in recent years. A significant portion of this prior literature has used some variation of enriched bag-of-words; e.g. the Open vocabulary approach (Schwartz et al., 2013). This is, theoretically speaking, entirely understandable as study of the relationship between word use and traits has delivered significant insight into human behaviour (Pennebaker et al., 2003). Language has been represented at a number of different levels in this work such as syntactic, semantic, and categorical - for example the psychologically-derived lexica of the Linguistic Inquiry and Word Count (LIWC) tool (Pennebaker et al., 2015).

These bag-of-linguistic-features approaches, however, require considerable feature engineering effort. In addition, many linguistic techniques and features are language-dependent, e.g. LIWC (Pennebaker et al., 2015), making the adaptation of models to multi-lingual scenarios more challenging. Another concern is a common assumption that these features, like the traits with which their use correlates, are similarly stable: the same language features always indicate the same traits. However, this is not the case: the relationship between language and personality is not consistent across all forms of communication, it is more complex (Nowson and Gill, 2014).

\*Work carried out at Xerox Research Centre Europe

In order to address these challenges we propose a novel feature-engineering-free, deep-learning-based approach to the problem of personality trait recognition, enabling the model to work in various languages without the need to create language-specific linguistic features. We frame the problem as a supervised sequence regression task, taking only the joint atomic representation of the text: hierarchically on the character and word level. In this work, we focus on short texts. As pointed out by Han and Baldwin (2011), classification of such texts can often be challenging for even state-of-the-art BoW based approaches, which is, in part, caused by the noisy nature of such data. In this work, we address this by proposing a novel hierarchical neural network architecture, free of feature engineering and, once trained, capable of inferring personality across five traits and three languages.

The paper is structured as follows: we consider previous approaches to computational personality recognition, including those few which have a deep-learning component, and subsequently describe our model. We report two sets of experiments, the first to demonstrate the effectiveness of the model in inferring personality compared to the current state-of-the-art models, while the second reports analysis against other feature-engineering-free models. In both settings, the proposed model achieves state-of-the-art performance across five personality traits and three languages.

## 2 Related Work

Early work in computational personality recognition (Argamon et al., 2005; Nowson and Oberlander, 2006) were mainly SVM-based approaches, relying on syntactic and lexical features. A decade later, still “most” participants of the PAN 2015 Author Profiling task use SVM with feature engineering, according to the organisers (Rangel et al., 2015). Ensemble methods have been proposed (Verhoeven et al., 2013), but the base model was still SVM – the ensemble came from the combination of data from different sources as opposed to models. Data – not just text – labelled with personality traits is sparse (Nowson and Gill, 2014) and most work has focused on reporting novel feature sets rather than techniques. In the PAN task alone<sup>1</sup>, there were features, in the form of surface forms of text, present on multiple levels of

---

<sup>1</sup>Due to space consideration we are unable to cite the individual works.

language representation, ranging from lexical features (e.g., word, lemma and character n-grams) to syntactic ones (e.g., POS tags and dependency relations). Some, on the other hand, focused on feature curation, analysing the correlation between personality and the use of punctuation and emotion, along with the use of the topic modelling method: latent semantic analysis. In addition, external resources, such as LIWC (Pennebaker et al., 2015), constructed over 20 years of psychology-based feature engineering, are another often-used set of features. When applied to tweets, however, LIWC requires further cleaning of the data (Kreindler, 2016).

Approaches to personality trait recognition based on deep-learning are few, which is not surprising given the relatively small scale of the data sets used. Kalghatgi et al. (2015) employed a neural network based approach. In this model, a Multilayer Perceptron (MLP) takes as input a number of carefully hand-crafted syntactic and social behavioural features from each user and attempts to predict a label for each of the 5 personality traits. However, the authors reported neither evaluation of this work, nor details of the dataset. The work of Su et al. (2016), on the other hand, employs a Recurrent Neural Network (RNN), exploiting the turn-taking nature of conversation for personality trait prediction. In their work, the RNN processes the evolution of a dialogue over time, taking as input LIWC-based and grammatical features, the output of which is then fed into the classifier for the prediction of personality trait scores of each participant of the conversations. It should be noted that both works take manually-designed features, heavily relying on domain expertise. Also, the focus is on the prediction of trait scores on the author level based on modelling all available text from a user. In contrast, not only does our approach infer the personality of a user given a collection of short texts, it is also flexible enough to predict trait scores from a single short text, arguably a more challenging task considering the limited amount of information.

In Section 3.2, we propose a model inspired by the work of Ling et al. (2015) where representations are hierarchically constructed from characters to words. This is based on the assumption that character sequences are syntactically and semantically informative of the words they compose. Their model – a widely used RNN vari-

ant Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) – learns how to construct word embeddings via its constituent characters. When applied to the tasks of language modelling and part-of-speech tagging, the model successfully improves the accuracy upon traditional baselines, performing particularly well in morphologically rich languages. Not only does the model achieve better performance on both tasks, it also has significantly fewer parameters to learn compared to a word look-up table based approach as the number of different characters is much fewer than the number of different words in a vocabulary. Moreover, the model is able to generate a sensible representation for previously unseen words. Following this, Yang et al. (2016) took it further to the document level, introducing Hierarchical Attention Networks where two bi-directional Gated Recurrent Units (GRUs) are used to process the sequence of words and then sentences respectively with the sentence-level GRU taking as input the output of the word-level GRU and returning the representation of the document. While Yang et al. (2016) describe a means to hierarchically build representations of documents from words to sentences and eventually to documents (Word to Sentence to Document, W2S2D), the work of (Ling et al., 2015) is positioned at a more fine-grained level, incorporating information from the sequence of characters (Character to Word, C2W). In this paper, the model we propose is situated between C2W and W2S2D – connecting characters, words and sentences, and ultimately personality traits (Character to Word to Sentence for Personality Trait, C2W2S4PT).

### 3 Model

In this section, we first identify some current issues and limitations associated with a commonly-used approach to representing text to motivate our methodology. Then, we detail the elements of the proposed language-independent, compositional model to address the problems.

#### 3.1 Issues with the Current Approach

When applying deep learning models to NLP problems, a commonly used approach is to map words to dense real-valued vectors in a low-dimensional space with word lookup tables. Typically, for this approach to work well, one needs to train on a large corpus in an unsupervised fash-

ion, e.g. `word2vec` (Mikolov et al., 2013a; Mikolov et al., 2013b) and `GloVe` (Pennington et al., 2014), in order to obtain a sensible set of embeddings. While this approach has demonstrated its strong capabilities of capturing syntactic and semantic information and been successfully applied to a number of NLP tasks (Socher et al., 2013; Kalchbrenner et al., 2014; Kim, 2014), as identified by Ling et al. (2015), there are two practical problems with it. First, given that language is flexible, previously unseen words are bound to occur regardless of the size of the unsupervised training corpus. This problem is even more pronounced when dealing with user-generated text, such as from social media (e.g. Twitter and Facebook) due to the noisy nature of such platforms – e.g. typos, ad hoc acronyms and abbreviations, phonetic substitutions, and even meaningless strings (Han and Baldwin, 2011). One simple solution is to represent all unknown words with a special UNK vector. However, this sacrifices the meaning of the unknown word which may be critical. Moreover, it is unable to generalise to made up words, for instance, *beautification*, despite the constituent words *beautiful* and *-ification* having been observed. Second, the large number of parameters for a model to learn tends to cause overfitting. Suppose a vector of  $d$  dimensions is used to represent each word and the word lookup table is therefore of size  $d \times |V|$  where  $|V|$  is the vocabulary size, which normally scales to the order of hundreds and thousands. Again, this problem is particularly serious in noisier domain.

In author profiling, a large array of character-based features have been explored and shown to be effective for trait inference, such as character flooding (Nowson et al., 2015; Giménez et al., 2015), character n-grams (González-Gallardo et al., 2015; Sulea and Dichiu, 2015), and emoticons (Nowson et al., 2015; Palomino-Garibay et al., 2015). This motivates our proposed model, described in the next section, where character, word and sentence representations are hierarchically constructed, independent of a specific language and capable of harnessing personality-sensitive signals buried as deep as the character level.

#### 3.2 Character to Word to Sentence for Personality Traits

We address the identified problems in Section 3.1 by extending the compositional character to word

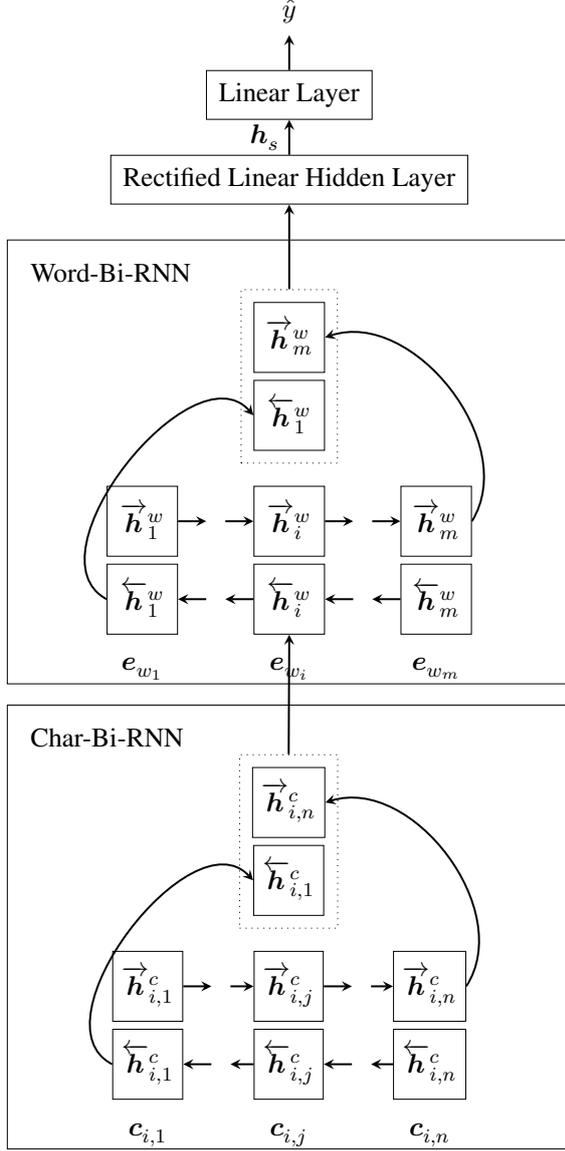

Figure 1: Illustration of the C2W2S4PT model. Dotted boxes indicate concatenation.

model (C2W) (Ling et al., 2015) wherein the constituent characters of each word is taken as input to a character-level bi-directional RNN (Char-Bi-RNN) to construct the representation of the word. A sentence is in turn represented, via another bi-directional RNN operating at the word level (Word-Bi-RNN), by the concatenation of the last and first hidden states of the forward and backward Word-RNNs respectively. Ultimately, a feedforward neural network predicts a scalar for a specific personality trait based on the input of the representation of a sentence. Given the hierarchical nature of the model, we name it C2W2S4PT (Character to Word to Sentence for Personality Traits)

depicted in Figure 1. The formal definition is provided as follows where we illustrate C2W2S4PT with an example in which a sentence  $s$  is seen as a sequence of words  $\{w_1, w_2, \dots, w_i, \dots, w_m\}$  and a word  $w_i$  is in turn a sequence of characters  $c_{i,j}$  whose embedding is denoted:  $c_{i,j}$ . Next, the Char-Bi-RNN takes as input the sequence of character embeddings  $\{c_{i,1}, \dots, c_{i,n}\}$  (assuming  $w_i$  is comprised of  $n$  characters) to construct the representation of word  $w_i$ , resulting in the word embedding  $e_{w_i}$ . Here, the recurrent unit we employ in the Bi-RNNs is GRU as suggested by recent studies that GRUs achieve comparable, if not better, results to LSTM but are less demanding computationally (Chung et al., 2014; Kumar et al., 2015; Jozefowicz et al., 2015).<sup>2</sup> Concretely, the character embeddings are processed by the Char-Bi-RNN using the following:

$$\vec{z}_{i,j}^c = \sigma(\vec{W}_z^c c_{i,j} + \vec{U}_{hz}^c \vec{h}_{i,j-1}^c + \vec{b}_z^c) \quad (1)$$

$$\vec{r}_{i,j}^c = \sigma(\vec{W}_r^c c_{i,j} + \vec{U}_{hr}^c \vec{h}_{i,j-1}^c + \vec{b}_r^c) \quad (2)$$

$$\vec{h}_{i,j}^c = f(\vec{W}_h^c c_{i,j} + \vec{r}_{i,j}^c \odot \vec{U}_{hh}^c \vec{h}_{i,j-1}^c + \vec{b}_h^c) \quad (3)$$

$$\vec{h}_{i,j}^c = \vec{z}_{i,j}^c \odot \vec{h}_{i,j-1}^c + (1 - \vec{z}_{i,j}^c) \odot \vec{h}_{i,j}^c \quad (4)$$

where  $\odot$  is the element-wise product,  $\sigma$  the sigmoid function,  $f$  the hyperbolic tangent function  $\tanh$ ,  $\vec{W}_z^c, \vec{W}_r^c, \vec{W}_h^c, \vec{U}_{hz}^c, \vec{U}_{hr}^c, \vec{U}_{hh}^c$  are the parameter matrices to learn, and  $\vec{b}_z^c, \vec{b}_r^c, \vec{b}_h^c$  the bias terms. In addition to the forward pass, the Char-Bi-RNN also processes the character sequence backwards (symbolised by  $\overleftarrow{h}_{i,j}^c$ ) with another set of GRU weight matrices and bias terms. Note that the same character embeddings are shared across the forward and backward pass. Eventually, we represent  $w_i$  as the concatenation of the last and first hidden states of the forward and backward Char-RNNs:

$$e_{w_i} = \begin{bmatrix} \vec{h}_{i,n}^c \\ \overleftarrow{h}_{i,1}^c \end{bmatrix} \quad (5)$$

Sentence representations are built in a similar fashion to word representations with another Bi-RNN operating at the word level (Word-Bi-RNN) where  $e_{w_i}$  (for  $i \in [1, n]$ ) once all the word repre-

<sup>2</sup>We performed additional experiments which confirmed this finding. Therefore due to space considerations, we do not report results using LSTMs here.

sentations have been constructed from their constituent characters) are processed:

$$\vec{z}_i^w = \sigma(\vec{W}_z^w e_{w_i} + \vec{U}_{hz}^w \vec{h}_{i-1}^w + \vec{b}_z^w) \quad (6)$$

$$\vec{r}_i^w = \sigma(\vec{W}_r^w e_{w_i} + \vec{U}_{hr}^w \vec{h}_{i-1}^w + \vec{b}_r^w) \quad (7)$$

$$\vec{h}_i^w = f(\vec{W}_h^w e_{w_i} + \vec{r}_i^w \odot \vec{U}_{hh}^w \vec{h}_{i-1}^w + \vec{b}_h^w) \quad (8)$$

$$\vec{h}_i^w = \vec{z}_i^w \odot \vec{h}_{i-1}^w + (1 - \vec{z}_i^w) \odot \vec{h}_i^w \quad (9)$$

where  $\vec{W}_z^w, \vec{W}_r^w, \vec{W}_h^w, \vec{U}_{hz}^w, \vec{U}_{hr}^w, \vec{U}_{hh}^w$  are the parameter matrices to learn, and  $\vec{b}_z^w, \vec{b}_r^w, \vec{b}_h^w$  the bias terms. The representation of the sentence is constructed, in a similar manner to how words are represented, by taking the concatenation of the last and first hidden states of the forward and backward Word-RNN:

$$e_s = \begin{bmatrix} \vec{h}_m^w \\ \vec{h}_1^w \end{bmatrix} \quad (10)$$

Lastly, the score for a particular personality trait is estimated with an MLP, taking as input the sentence embedding  $e_s$  and returning the estimated score  $\hat{y}_s$ :

$$\mathbf{h}_s = \text{ReLu}(\mathbf{W}_{eh} e_s + \mathbf{b}_h) \quad (11)$$

$$\hat{y}_s = \mathbf{W}_{hy} \mathbf{h}_s + b_y \quad (12)$$

where ReLU (REctified Linear Unit) is defined as  $\text{ReLU}(x) = \max(0, x)$ ,  $\mathbf{W}_{eh}, \mathbf{W}_{hy}$  the parameter matrices to learn,  $\mathbf{b}_h, b_y$  the bias terms, and  $\mathbf{h}_s$  the hidden representation of the MLP. All the trainable parameter/embedding matrices and bias terms are jointly optimised using *mean square error* as the objective function:

$$L(\theta) = \frac{1}{n} \sum_{i=1}^n (y_{s_i} - \hat{y}_{s_i})^2 \quad (13)$$

where  $y_{s_i}$  is the gold standard personality score of sentence  $s_i$  and  $\theta$  the collection of all parameter/embedding matrices and bias terms for the model to learn. Note that no language-dependent component is present in the proposed model.

## 4 Experiments and Results

We evaluate our model in two settings, against models with or without feature engineering, to fully study the effectiveness of the proposed method. In the former, we compare – at the user

level – our feature-engineering-free and language-independent model with current state-of-the-art models which make much use of linguistic features. In the latter, on the other hand, we investigate the performance against other feature-engineering-free models on individual short texts. In both settings, we show that our model achieves better results across two language (English and Spanish) and is equally competitive in Italian.

### 4.1 Dataset and Preprocessing

The dataset we adopt in this paper is the English, Spanish and Italian data from the PAN 2015 Author Profiling task dataset (Rangel et al., 2015), collected from Twitter and consisting of 14,166 English (EN), 9,879 Spanish (ES) and 3,687 Italian (IT) tweets (from 152, 110 and 38 users respectively). Due to space constraints and the limited size of the data, the Dutch dataset is not included. Each user encompasses a set of tweets (average  $n = 100$ ) with gold standard personality labels, the five trait labels (essentially scores between -0.5 and 0.5), calculated following the author’s self-assessment responses to the short Big 5 test, BFI-10 (Rammstedt and John, 2007) which has the most solid grounding in language and is considered to be the most widely accepted and exploited scheme for personality recognition (Poria et al., 2013).

In our experiments, we tokenise each tweet with Twokenizer (Owoputi et al., 2013) to preserve user mentions and hashtag-preceded topics. User mentions and URLs, unlike the majority of the language used in tweets, are intended for their targets, whose surface forms are deemed hardly informative. We therefore further normalise these features to single characters (e.g., `@username`  $\rightarrow$  `@`, `http://t.co/`  $\rightarrow$  `^`), limiting the risk of modelling unnecessary character usage not directly influenced by nor reflecting the personality of the author.

### 4.2 Evaluation Metric

As the test corpus is unavailable, withheld by the PAN 2015 organisers,  $k$ -fold cross-validation is used instead to compare the performance ( $k = 5$  or  $10$ ) on the available dataset. To evaluate the performance, we measure the Root Mean Square Error (RMSE) at either the tweet or user level depending on the granularity of the task:  $RMSE_{tweet} = \sqrt{\frac{\sum_{i=1}^T (y_{s_i} - \hat{y}_{s_i})^2}{T}}$  and  $RMSE_{user} = \sqrt{\frac{\sum_{i=1}^U (y_{user_i} - \hat{y}_{user_i})^2}{U}}$  where  $y_{s_i}$

and  $\hat{y}_{s_i}$  are the gold standard and predicted personality trait score of the  $i^{\text{th}}$  tweet whereas  $y_{user_i}$  and  $\hat{y}_{user_i}$  are their user-level counterparts,  $T$  and  $U$  the total numbers of tweets and users in the corpus. Note that in the dataset utilised in this work, each user is assigned a single score for a particular personality trait and every tweet collected from the same account inherits the same five personality trait assignments as its author. The predicted user level trait score is calculated:  $\hat{y}_{user_i} = \frac{1}{T_i} \sum_{j=1}^{T_i} \hat{y}_{s_j}$  where  $T_i$  is the total number of tweets of  $user_i$ . In Section 4.3 and 4.4, the results, measured with  $RMSE_{user}$  and  $RMSE_{tweet}$ , in the two settings, i.e. against models with and without feature-engineering, are presented respectively. Consistent with prior work in author profiling (Sulea and Dichiu, 2015; Mirkin et al., 2015; Nowson et al., 2015), we employ exactly the same evaluation metric on the same dataset to enable direct comparison.

### 4.3 Evaluation against State-of-the-art Models

We present the results obtained by the proposed model tested on the dataset described in Section 4.1. Note that our model is trained to predict personality trait scores, relying only on the text without any additional features. To enable direct comparison, we evaluate C2W2S4PT on the user level against current state-of-the-art models which incorporate linguistic features based on psychological studies.

For 5-fold cross-validation, we select the tied-highest ranked (in EN under evaluation conditions) amongst the PAN 2015 participants (Sulea and Dichiu, 2015) (also ranked 7<sup>th</sup> and 4<sup>th</sup> in ES and IT).<sup>3</sup> Similarly, we choose baselines by ranking and metric reporting for 10-fold cross validation (Nowson et al., 2015) (ranked 9<sup>th</sup>, 6<sup>th</sup> and 8<sup>th</sup> in EN, ES and IT). In addition to the above works which predicted scores on text level and then averaged for each user, we also include subsequent work by (Mirkin et al., 2015) who reported results on concatenated tweets (a single document per author). Also, there is the most straightforward baseline Average Baseline assigning the average of all the scores to each user. We train C2W2S4PT with Adam (Kingma and Ba, 2014) over 100 epochs with a batch size of 32 and the fol-

<sup>3</sup>Cross-validation  $RMSE_{user}$  performance is not reported for the other top system (Álvarez-Carmona et al., 2015).

lowing hyper-parameters:  $\vec{h}_{i,j}^c$  and  $\overleftarrow{h}_{i,j}^c \in \mathbb{R}^{256}$ ,  $E_c \in \mathbb{R}^{50 \times |C|}$ , dropout rate to the embedding output: 0.5,  $\vec{h}_i^w$  and  $\overleftarrow{h}_i^w \in \mathbb{R}^{256}$ ,  $W_{hy} \in \mathbb{R}^{256 \times 1}$ ,  $b_y \in \mathbb{R}$ ,  $W_{eh} \in \mathbb{R}^{512 \times 256}$ ,  $b_h \in \mathbb{R}^{256}$ . The  $RMSE_{user}$  results are presented in Table 1 where EXT, STA, AGR, CON and OPN are abbreviations for Extroversion, Emotional Stability (the inverse of Neuroticism), Agreeableness, Conscientiousness and Openness respectively.

**C2W2S4PT outperforms the current state of the art in EN and ES.** In the 5-fold cross-validation group, C2W2S4PT demonstrates its advantages, attaining superior performance to the baselines except for CON in ES. In terms of 10-fold cross validation, the superiority of our model is even more evident, supported by the dominating performance over the two selected baselines across all personality traits and two languages. In both groups, 5 or 10-fold cross validation, not only does C2W2S4PT outperform the baseline systems, particularly significantly in the 10-fold group, it also does so without the aid of any hand-crafted features, stressing the technical soundness of C2W2S4PT.

**On CON in ES, 5-fold cross-validation.** We suspect that the surprisingly good performance of Sulea and Dichiu (2015) may likely be attributed to overfitting. Indeed, the performance on the test set on CON in ES is even inferior to Nowson et al. (2015), further confirming our speculation.

**The superiority of C2W2S4PT is less clear in IT.** This can possibly be caused by the inadequate amount of Italian data, less than 4k tweets as compared to 14k and 10k in the English and Spanish datasets, limiting the capability of C2W2S4PT to learn a reasonable model.

### 4.4 Evaluation against Other Feature-engineering-free Methods

While it is common practice in personality trait inference to evaluate at the user level, we also look into tweet-level performance to further study the models' capabilities at a more fine-grained level. A number of baselines, incorporating only the surface form of the text for the purpose of fair comparison, have been created to support our evaluation. First, we inherit the same Average Baseline as in Section 4.3. Next, we select two BoW-based system, Random Forest and SVM Regression, and

		Nowson et al. (2015)	0.137	0.168	0.142	0.098	0.141
	C2W2S4PT	0.118	<b>0.147</b>	<b>0.128</b>	<b>0.095</b>	<b>0.127</b>	

Table 1:  $RMSE_{user}$  across five traits. **Bold** highlights best performance.

perform grid search for the best hyper-parameter setup ranging: kernel  $\in$  {linear, rbf} and  $C \in$  {0.01, 0.1, 1.0, 10.0} whereas for Random Forest, the number of trees is chosen from the set {10, 50, 100, 500, 1000}.

In addition to the above conventional machine-learning-based models, we further implement two simpler RNN-based models, Bi-GRU-Char and Bi-GRU-Word, which work only on the character and word level respectively. On top of the GRUs, both Bi-GRU-Char and Bi-GRU-Word share the same MLP classifier,  $h_s$  and  $\hat{y}_s$ , as in C2W2S4PT. For training, we use the same set of hyper-parameters as described in Section 4.3 for C2W2S4PT. Similarly, we set the character and word embedding size to 50 and 256 for Bi-GRU-Char and Bi-GRU-Word respectively. Hyper-parameter fine-tuning was not performed mainly due to time constraints. We present the  $RMSE_{tweet}$  of each effort, measured by 10-fold stratified cross-validation, in Table 2.

**C2W2S4PT is comparable with, if not superior to, the strong baselines SVM Regression and Random Forest in EN and ES.** C2W2S4PT achieves state-of-the-art results in almost every trait except for two, AGR in EN and STA in ES. It is worth noting that C2W2S4PT

generates this competitive performance, in the feature-engineering-free setting, against SVM Regression and Random Forest without exhaustive hyper-parameter fine-tuning.

**C2W2S4PT achieves better performance than the RNN-based baselines in EN and ES.** Compared with Bi-GRU-Word, C2W2S4PT is less prone to overfitting because of the relatively fewer parameters for the model to learn whereas Bi-GRU-Word needs to maintain a large vocabulary embedding matrix (Ling et al., 2015). In regards to Bi-GRU-Char, the success can be attributed to C2W2S4PT’s capability of coping with arbitrary words while not forgetting information due to excessive lengths as can arise from representing a text as a sequence of characters.

**The performance of C2W2S4PT is inferior to Bi-GRU-Word in IT.** Bi-GRU-Word achieves the best performance across all personality traits with C2W2S4PT coming in as a close second and tying in 3 traits. Apart from the inadequate amount of Italian data causing the fluctuation in performance as explained in Section 4.3, further investigation is needed to analyse the strong performance of Bi-GRU-Word.

Table 2:  $RMSE_{tweet}$  across five traits level. **Bold** highlights best performance.

#### 4.5 Visualisation

In order to investigate the features automatically learned by the models, we select C2W2S4PT trained on a single personality trait (EXT) and visualise the 2D PCA (Tipping and Bishop, 1999) scatter plot of the representations of the sentences.<sup>4</sup> As examples, we randomly select 100 tweets, 50 each from either extreme of the EXT spectrum - Extraversion being selected for this exercise as it is the most commonly studied and well understood trait. The text representations are automatically constructed by C2W2S4PT, with the resultant plot presented in Figure 2. Here, two clusters are easily identifiable, representing positive and negative Extraversion, with the former intersecting the latter. We consider three examples, highlighted in Figure 2, for discussion.

- POS7: “@username: Feeling like you’re not good enough is probably the worst thing to feel.”
- NEG3: “Being good ain’t enough lately.”
- POS20: “o.O Lovely.”

The first two examples, POS7 and NEG3, although essentially similar in terms of semantics,

<sup>4</sup>We also experimented with t-SNE (Van der Maaten and Hinton, 2008) but it did not produce an interpretable plot.

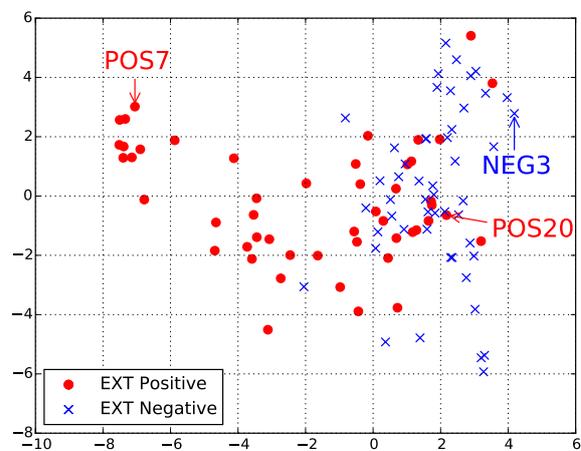

Figure 2: Scatter plot of sentence representations processed by PCA.

are placed distantly from each other at the far ends of the distribution. Despite the semantic similarities, the linguistic attributes they possess are commonly understood to be associated with Extraversion differently (Gill and Oberlander, 2002): the longer tweet, POS7, together with its use of the second person pronoun, suggests that the author is more inclusive of others while NEG3, on the other hand, is self-focused and shorter, ele-

ments signifying Introversion. The third example, POS20, while appearing to be mapped to an Introvert space, is a tweet from an Extravert. Apart from being short, POS20 incorporates the use of non-rotated, “Eastern” style emoticons (*o.O*), aspects shown to be linked to Introversion on social media (Schwartz et al., 2013). This is perhaps not the venue to consider the implications of this further, although one explanation might be that the model has uncovered a flexibility often associated with Ambiverts (Grant, 2013). However, it is worth noting that the model is capable of capturing, without feature engineering, well-understood dimensions of language.

## 5 Conclusion and Future Work

Overall, the results in this paper demonstrate the validity of our methodology: not only does C2W2S4PT provide state-of-the-art results compared to previous feature-engineering-heavy works, but it also performs well when compared with other widely used strong baselines in the feature-engineering-free setting. More importantly, the lack of feature engineering enables us to adapt the same model, with zero alteration to the model itself, to other languages. To further examine this property of the proposed model, we plan to explore the TwiSty dataset (Verhoeven et al., 2016), a recently introduced corpus consisting of 6 languages and labelled with MBTI type indicators (Myers and Myers, 2010).

## Abstract

While cross-lingual word embeddings have been studied extensively in recent years, the qualitative differences between the different algorithms remain vague. We observe that whether or not an algorithm uses a particular feature set (sentence IDs) accounts for a significant performance gap among these algorithms. This feature set is also used by traditional alignment algorithms, such as IBM Model-1, which demonstrate similar performance to state-of-the-art embedding algorithms on a variety of benchmarks. Overall, we observe that different algorithmic approaches for utilizing the sentence ID feature space result in similar performance. This paper draws both empirical and theoretical parallels between the embedding and alignment literature, and suggests that adding additional sources of information, which go beyond the traditional signal of bilingual sentence-aligned corpora, may substantially improve cross-lingual word embeddings, and that future baselines should at least take such features into account.

## 1 Introduction

Cross-lingual word embedding algorithms try to represent the vocabularies of two or more languages in one common continuous vector space. These vectors can be used to improve monolingual word similarity (Faruqui and Dyer, 2014) or support cross-lingual transfer (Gouws and Søgaard, 2015). In this work, we focus on the second (cross-lingual) aspect of these embeddings, and try to determine what makes some embedding approaches better than others *on a set of*

*translation-oriented benchmarks*. While cross-lingual word embeddings have been used for a variety of cross-lingual transfer tasks, we prefer evaluating on translation-oriented benchmarks, rather than across specific NLP tasks, since the translation setting allows for a cleaner examination of cross-lingual similarity. Another important delineation of this work is that we focus on algorithms that rely on *sentence-aligned data*; in part, because these algorithms are particularly interesting for low-resource languages, but also to make our analysis and comparison with alignment algorithms more focused.

We observe that the top performing embedding algorithms share the same underlying feature space – sentence IDs – while their different algorithmic approaches seem to have a negligible impact on performance. We also notice that several statistical alignment algorithms, such as IBM Model-1 (Brown et al., 1993), operate under the same data assumptions. Specifically, we find that using the translation probabilities learnt by Model-1 as the cross-lingual similarity function (in place of the commonly-used cosine similarity between word embeddings) performs on-par with state-of-the-art cross-lingual embeddings on word alignment and bilingual dictionary induction tasks. In other words, as long as the similarity function is based on the sentence ID feature space and the embedding/alignment algorithm itself is not too naïve, the actual difference in performance between different approaches is marginal.

This leads us to revisit another statistical alignment algorithm from the literature that uses the same sentence-based signal – the Dice aligner (Och and Ney, 2003). We first observe that the vanilla Dice aligner is significantly outperformed by the Model-1 aligner. We then recast Dice as the dot-product between two word vectors (based on the sentence ID feature space), which allows us to

---

\*These authors contributed equally to this work.

generalize it, resulting in an embedding model that is as effective as Model-1 and other sophisticated state-of-the-art embedding methods, but takes a fraction of the time to train.

Existing approaches for creating cross-lingual word embeddings are typically restricted to training bilingual embeddings, mapping exactly two languages onto a common space. We show that our generalization of the Dice coefficient can be augmented to jointly train *multi*-lingual embeddings for any number of languages. We do this by leveraging the fact that the space of sentence IDs is shared among all languages in the parallel corpus; the verses of the Bible, for example, are identical across all translations. Introducing this multi-lingual signal shows a significant performance boost, which eclipses the variance in performance among pre-existing embedding algorithms.

**Contributions** We first establish the importance of the sentence ID feature space for cross-lingual word embedding algorithms through experiments across several translation-oriented benchmarks. We then compare cross-lingual word embedding algorithms to traditional word alignment algorithms that also rely on sentence ID signals. We show that a generalization of one of these, the Dice aligner, is a very strong baseline for cross-lingual word embedding algorithms, performing better than several state-of-the-art algorithms, especially when exploiting a multi-lingual signal. Our code and data are publicly available.<sup>1</sup>

## 2 Background: Cross-lingual Embeddings

Previous approaches to cross-lingual word embeddings can be divided into three categories, according to assumptions on the training data. The first category assumes *word-level alignments*, in the form of bilingual dictionaries (Mikolov et al., 2013a; Xiao and Guo, 2014) or automatically produced word alignments (Klementiev et al., 2012; Zou et al., 2013; Faruqui and Dyer, 2014). Sizable bilingual dictionaries are not available for many language pairs, and the quality of automatic word alignment greatly affects the quality of the embeddings. It is also unclear whether the embedding process provides significant added value beyond the initial word alignments (Zou et al., 2013). We

<sup>1</sup>[bitbucket.org/omerlevy/xling\\_embeddings](http://bitbucket.org/omerlevy/xling_embeddings)

therefore exclude these algorithms for this study, also in order to focus our analysis and make the comparison with traditional word alignment algorithms more straightforward.

The second category makes a much weaker assumption, *document-level alignments*, and uses comparable texts in different languages (not necessarily translations) such as Wikipedia articles or news reports of the same event. Algorithms in this category try to leverage massive amounts of data to make up for the lack of lower-level alignments (Søgaard et al., 2015; Vulić and Moens, 2016).

Algorithms in the third category take the middle ground; they use *sentence-level alignments*, common in legal translations and religious texts. Also known as “parallel corpora”, sentence-aligned data maps each sentence (as a whole) to its translation. We focus on this third category, because it does not require the strict assumption of word-aligned data (which is difficult to obtain), while still providing a cleaner and more accurate signal than document-level alignments (which have been shown, in monolingual data, to capture mainly syntagmatic relations (Sahlgren, 2006)). In §6, we provide evidence to the hypothesis that sentence-aligned data is indeed far more informative than document-aligned data.

Algorithms that rely on sentence-aligned data typically create intermediate sentence representations from each sentence’s constituent words. Hermann and Blunsom (2014) proposed a deep neural model, BiCVM, which compared the two sentence representations at the final layer, while Chandar et al. (2014) proposed a shallower autoencoder-based model, representing both source and target language sentences as the same intermediate sentence vector. Recently, a simpler model, BilBOWA (Gouws et al., 2015), showed similar performance *without* using a hidden sentence-representation layer, giving it a dramatic speed advantage over its predecessors. BilBOWA is essentially an extension of skip-grams with negative sampling (SGNS) (Mikolov et al., 2013b), which simultaneously optimizes each word’s similarity to its inter-lingual context (words that appeared in the aligned target language sentence) and its intra-lingual context (as in the original monolingual model). Luong et al. (2015) proposed a similar SGNS-based model over the same features.

We study which factors determine the success of cross-lingual word embedding algorithms

that use sentence-aligned data, and evaluate them against baselines from the statistical machine translation literature that incorporate the same data assumptions. We go on to generalize one of these, the Dice aligner, showing that one variant is a much stronger baseline for cross-lingual word embedding algorithms than standard baselines.

Finally, we would like to point out the work of Upadhyay et al. (2016), who studied how different data assumptions affect embedding quality in both monolingual and cross-lingual tasks. Our work focuses on one specific data assumption (sentence-level alignments) and only on cross-lingual usage. This more restricted setting allows us to: (a) compare embeddings to alignment algorithms, (b) decouple the feature space from the algorithm, and make a more specific observation about the contribution of each component to the end result. In that sense, our findings complement those of Upadhyay et al. (2016).

### 3 Which Features Make Better Cross-lingual Embeddings?

We group state-of-the-art cross-lingual embedding algorithms according to their feature sets, and compare their performance on two cross-lingual benchmarks: word alignment and bilingual dictionary induction. In doing so, we hope to learn which features are more informative.

#### 3.1 Features of Sentence-aligned Data

We observe that cross-lingual embeddings typically use parallel corpora in one of two ways:

**Source + Target Language Words** Each word  $w$  is represented using all the other words that appeared with it in the same sentence (source language words) *and* all the words that appeared in target language sentences that were aligned to sentences in which the word  $w$  appeared (target language words). This representation also stores the number of times each pair of word  $w$  and feature (context) word  $f$  co-occurred.

These features are analogous to the ones used by Vulić and Moens (2016) for document-aligned data, and can be built in a similar manner: create a pseudo-bilingual sentence from each aligned sentence, and for each word in question, consider all the other words in this sentence as its features. BilBOWA (Gouws et al., 2015) also uses a similar set of features, but restricts the source language words to those that appeared within a certain distance

from the word in question, and defines a slightly different interaction with target language words.

**Sentence IDs** Here, each word is represented by the set of sentences in which it appeared, indifferent to the number of times it appeared in each one. This feature set is also indifferent to the word ordering within each sentence. This approach is implicitly used by Chandar et al. (2014), who encode the bag-of-words representations of parallel sentences into the same vector. Thus, each word is not matched directly to another word, but rather used to create the sentence’s language-independent representation. Sjøgaard et al. (2015) use similar features, document IDs, for leveraging comparable Wikipedia articles in different languages. In §6 we show that when using sentence IDs, even a small amount of sentence-aligned data is more powerful than a huge amount of comparable documents.

#### 3.2 Experiment Setup

**Algorithms** We use the four algorithms mentioned in §3.1: BilBOWA (Gouws et al., 2015), BWE-SkipGram (Vulić and Moens, 2016), Bilingual Autoencoders (Chandar et al., 2014), and Inverted Index (Sjøgaard et al., 2015). While both BWE-SkipGram and Inverted Index were originally trained on document-aligned data, in this work, we apply them to sentence-aligned data.

**Data** Christodouloupoulos and Steedman (2015) collected translations of the Bible (or parts of it) in over 100 languages, naturally aligned by book, chapter, and verse (31,102 verses in total).<sup>2</sup> This corpus allows us to evaluate methods across many different languages, while controlling for the training set’s size. The corpus was decapitalized and tokenized using white spaces after splitting at punctuation.

**Benchmarks** We measure the quality of each embedding using both manually annotated word alignment datasets and bilingual dictionaries. We use 16 manually annotated word alignment datasets – Hansards<sup>3</sup> and data from four other sources (Graca et al., 2008; Lambert et al., 2005; Mihalcea and Pedersen, 2003; Holmqvist and Ahrenberg, 2011; Cakmak et al., 2012) – as well as 16 bilingual dictionaries from Wiktionary.

<sup>2</sup>[homepages.inf.ed.ac.uk/s0787820/bible/](http://homepages.inf.ed.ac.uk/s0787820/bible/)

<sup>3</sup>[www.isi.edu/natural-language/download/hansard/](http://www.isi.edu/natural-language/download/hansard/)

In the word alignment benchmark, each word in a given source language sentence is aligned with the most similar target language word from the target language sentence – this is exactly the same greedy decoding algorithm that is implemented in IBM Model-1 (Brown et al., 1993). If a source language word is out of vocabulary, it is not aligned with anything, whereas target language out-of-vocabulary words are given a default minimal similarity score, and never aligned to any candidate source language word in practice. We use the inverse of alignment error rate (1-AER) as described in Koehn (2010) to measure performance, where higher scores mean better alignments.

High quality, freely available, manually annotated word alignment datasets are rare, especially for non-European languages. We therefore include experiments on bilingual dictionary induction. We obtain bilingual dictionaries from Wiktionary for five non-Indo-European languages, namely: Arabic, Finnish, Hebrew, Hungarian, and Turkish (all represented in the Edinburgh Bible Corpus). We emphasize that unlike most previous work, we experiment with finding translation equivalents of all words and do not filter the source and target language words by part of speech. We use precision-at-one (P@1), essentially selecting the closest target-language word to the given source-language word as the translation of choice. This often means that 100% precision is unattainable, since many words have multiple translations.

**Hyperparameters** Levy et al. (2015) exposed a collection of hyperparameters that affect the performance of monolingual embeddings. We assume that the same is true for cross-lingual embeddings, and use their recommended settings across all algorithms (where applicable). Specifically, we used 500 dimensions for every algorithm, context distribution smoothing with  $\alpha = 0.75$  (applicable to BilBOWA and BWE-SkipGram), the symmetric version of SVD (applicable to Inverted Index), and run iterative algorithms for 100 epochs to ensure convergence (applicable to all algorithms except Inverted Index). For BilBOWA’s monolingual context window, we used the default of 5. Similarity is always measured by the vectors’ cosine. Most importantly, we use a shared vocabulary, consisting of every word that appeared at least twice in the corpus (tagged with language ID). While hyperparameter tuning could admittedly affect results, we rarely have data for reliably

tuning hyperparameters for truly low-resource languages.

### 3.3 Results

Table 1 shows that the two algorithms based on the sentence-ID feature space perform consistently better than those using source+target words. We suspect that the source+target feature set might be capturing more information than is actually needed for translation, such as syntagmatic or topical similarity between words (e.g. “dog”  $\sim$  “kennel”). This might be distracting for cross-lingual tasks such as word alignment and bilingual dictionary induction. Sentence ID features, on the other hand, are simpler, and might therefore contain a cleaner translation-oriented signal.

It is important to state that, in absolute terms, these results are quite poor. The fact that the best inverse AER is around 50% calls into question the ability to actually utilize these embeddings in a real-life scenario. While one may suggest that this is a result of the small training dataset (Edinburgh Bible Corpus), previous work (e.g. (Chandar et al., 2014)) used an even smaller dataset (the first 10K sentences in Europarl (Koehn, 2005)). To ensure that our results are not an artifact of the Edinburgh Bible Corpus, we repeated our experiments on the full Europarl corpus (180K sentences) for a subset of languages (English, French, and Spanish), and observed similar trends. As this is a comparative study focused on analyzing the qualitative differences between algorithms, we place the issue of low absolute performance aside for the moment, and reopen it in §5.4.

## 4 Comparing Cross-lingual Embeddings with Traditional Alignment Methods

Sentence IDs are not unique to modern embedding methods, and have been used by statistical machine translation from the very beginning. In particular, the Dice coefficient (Och and Ney, 2003), which is often used as a baseline for more sophisticated alignment methods, measures the cross-lingual similarity of words according to the number of aligned sentences in which they appeared. IBM Model-1 (Brown et al., 1993) also makes exactly the same data assumptions as other sentence-ID methods. It therefore makes sense to use Dice similarity and the translation probabilities derived from IBM Model-1 as baselines for cross-lingual embeddings that use sentence IDs.

Table 1: The performance of four state-of-the-art cross-lingual embedding methods. \* Averages across two different metrics.

From Table 2 we learn that the existing embedding methods are not really better than IBM Model-1. In fact, their average performance is even slightly lower than Model-1’s. Although Bilingual Autoencoders, Inverted Index, and Model-1 reflect entirely different algorithmic approaches (respectively: neural networks, matrix factorization, and EM), the overall difference in performance seems to be rather marginal. This suggests that the main performance factor is not the algorithm, but the feature space: sentence IDs.

However, Dice also relies on sentence IDs, yet its performance is significantly worse. We suggest that Dice uses the sentence-ID feature set naïvely, resulting in degenerate performance with respect to the other methods. In the following section, we analyze this shortcoming and show that generalizations of Dice actually do yield similar perfor-

mance Model-1 and other sentence-ID methods.

## 5 Generalized Dice

In this section, we show that the Dice coefficient (Och and Ney, 2003) can be seen as the dot-product between two word vectors represented over the sentence-ID feature set. After providing some background, we demonstrate the mathematical connection between Dice and word-feature matrices. We then introduce a new variant of Dice, SID-SGNS, which performs on-par with Model-1 and the other embedding algorithms. This variant is able to seamlessly leverage the multi-lingual nature of sentence IDs, giving it a small but significant edge over Model-1.

## 5.1 Word-Feature Matrices

In the word similarity literature, it is common to represent words as real-valued vectors and compute their “semantic” similarity with vector similarity metrics, such as the cosine of two vectors. These word vectors are traditionally derived from sparse word-feature matrices, either by using the matrix’s rows as-is (also known as “explicit” representation) or by inducing a lower-dimensional representation via matrix factorization (Turney and Pantel, 2010). Many modern methods, such as those in word2vec (Mikolov et al., 2013b), also create vectors by factorizing word-feature matrices, only without representing these matrices explicitly.

Formally, we are given a vocabulary of words  $V_W$  and a feature space (“vocabulary of features”)

$V_F$ . These features can be, for instance, the set of sentences comprising the corpus. We then define a matrix  $M$  of  $|V_W|$  rows and  $|V_F|$  columns. Each entry in  $M$  represents some statistic pertaining to that combination of word and feature. For example,  $M_{w,f}$  could be the number of times the word  $w$  appeared in the document  $f$ .

The matrix  $M$  is typically processed into a “smarter” matrix that reflects the strength of association between each given word  $w$  and feature  $f$ . We present three common association metrics:  $L_1$  row normalization (Equation (1)), Inverse Document Frequency (IDF, Equation (2)), and Pointwise Mutual Information (PMI, Equation (3)). The following equations show how to compute their respective matrices:

$$M_{w,f}^{L_1} = \frac{I(w,f)}{I(w,*)} \quad (1)$$

$$M_{w,f}^{IDF} = \log \frac{|V_F|}{I(w,*)} \quad (2)$$

$$M_{w,f}^{PMI} = \log \frac{\#(w,f) \cdot \#(*,*)}{\#(w,*) \cdot \#(*,f)} \quad (3)$$

where  $\#(\cdot, \cdot)$  is the co-occurrence count function,  $I(\cdot, \cdot)$  is the co-occurrence indicator function, and  $*$  is a wildcard.<sup>4</sup>

To obtain word vectors of lower dimensionality ( $V_F$  may be huge), the processed matrix is then decomposed, typically with SVD. An alternative way to create low-dimensional word vectors without explicitly constructing  $M$  is to use the negative sampling algorithm (SGNS) (Mikolov et al., 2013b).<sup>5</sup> This algorithm factorizes  $M^{PMI}$  using a weighted non-linear objective (Levy and Goldberg, 2014).

## 5.2 Reinterpreting the Dice Coefficient

In statistical machine translation, the Dice coefficient is commonly used as a baseline for word alignment (Och and Ney, 2003). Given sentence-aligned data, it provides a numerical measure of how likely two words – a source-language word  $w_s$  and a target-language word  $w_t$  – are each other’s translation:

$$Dice(w_s, w_t) = \frac{2 \cdot S(w_s, w_t)}{S(w_s, *) \cdot S(*, w_t)} \quad (4)$$

where  $S(\cdot, \cdot)$  is the number of aligned sentences in the data where both arguments occurred.

We claim that this metric is mathematically equivalent to the dot-product of two  $L_1$ -normalized sentence-ID word-vectors, multiplied by 2. In other words, if we use the combination of sentence-ID features and  $L_1$ -normalization to create our word vectors, then for any  $w_s$  and  $w_t$ :

$$w_s \cdot w_t = \frac{Dice(w_s, w_t)}{2} \quad (5)$$

To demonstrate this claim, let us look at the dot-product of  $w_s$  and  $w_t$ :

$$w_s \cdot w_t = \sum_i \left( \frac{I(w_s, i)}{I(w_s, *)} \cdot \frac{I(w_t, i)}{I(w_t, *)} \right) \quad (6)$$

where  $i$  is the index of an aligned sentence. Since  $I(w_s, *) = S(w_s, *)$  and  $I(w_t, *) = S(*, w_t)$ , and both are independent of  $i$ , we can rewrite the equation as follows:

$$w_s \cdot w_t = \frac{\sum_i I(w_s, i) \cdot I(w_t, i)}{S(w_s, *) \cdot S(*, w_t)} \quad (7)$$

<sup>4</sup>A function with a wildcard should be interpreted as the sum of all possible instantiations, e.g.  $I(w, *) = \sum_x I(w, x)$ .

<sup>5</sup>For consistency with prior art, we refer to this algorithm as SGNS (skip-grams with negative sampling), even when it is applied without the skip-gram feature model.

Since  $I(w, i)$  is an indicator function of whether the word  $w$  appeared in sentence  $i$ , it stands to reason that the product  $I(w_s, i) \cdot I(w_t, i)$  is an indicator of whether both  $w_s$  and  $w_t$  appeared in  $i$ . Ergo, the numerator of Equation (7) is exactly the number of aligned sentences in which both  $w_s$  and  $w_t$  occurred:  $S(w_s, w_t)$ . Therefore:

$$w_s \cdot w_t = \frac{S(w_s, w_t)}{S(w_s, *) \cdot S(*, w_t)} = \frac{Dice(w_s, w_t)}{2} \quad (8)$$

This theoretical result implies that the cross-lingual similarity function derived from embeddings based on sentence IDs is essentially a generalization of the Dice coefficient.

## 5.3 SGNS with Sentence IDs

The Dice coefficient appears to be a particularly naïve variant of matrix-based methods that use sentence IDs. For example, Inverted Index (Søgaard et al., 2015)), which uses SVD over IDF followed by  $L_2$  normalization (instead of  $L_1$  normalization), shows significantly better performance. We propose using a third variant, sentence-ID SGNS (SID-SGNS), which simply applies SGNS (Mikolov et al., 2013b) to the word/sentence-ID matrix (see §5.1).

Table 3 compares its performance (Bilingual SID-SGNS) to the other methods, and shows that indeed, this algorithm behaves similarly to other sentence-ID-based methods. We observe similar results for other variants as well, such as SVD over positive PMI (not shown).

## 5.4 Embedding Multiple Languages

Up until now, we used bilingual data to train cross-lingual embeddings, even though our parallel corpus (the Bible) is in fact multi-lingual. Can we make better use of this fact?

An elegant property of the sentence-ID feature set is that it is a truly inter-lingual representation. This means that multiple languages can be represented together in the same matrix before factorizing it. This raises a question: does dimensionality reduction over a *multi*-lingual matrix produce better cross-lingual vectors than doing so over a bilingual matrix?

We test our hypothesis by comparing the performance of embeddings trained with SID-SGNS over all 57 languages of the Bible corpus to that of the bilingual embeddings we used earlier. This consistently improves performance across all the development benchmarks, providing a 4.69% average increase in performance (Table 3). With this

advantage, SID-SGNS performs significantly better than the other methods combined.<sup>6</sup> This result is similar in vein to recent findings in the parsing literature (Ammar et al., 2016; Guo et al., 2016), where multi-lingual transfer was shown to improve upon bilingual transfer.

In absolute terms, Multilingual SID-SGNS’s performance is still very low. However, this experiment demonstrates that one way of making significant improvement in cross-lingual embeddings is by considering additional sources of information, such as the multi-lingual signal demonstrated here. We hypothesize that, regardless of the algorithmic approach, relying solely on sentence IDs

<sup>6</sup>We observed a similar increase in performance when applying the multi-lingual signal to Søgaard et al.’s (2015) IDF-based method and to SVD over positive PMI.

from bilingual parallel corpora will probably not be able to improve much beyond IBM Model-1.

## 6 Data Paradigms

In §2, we assumed that using sentence-aligned data is a better approach than utilizing document-aligned data. Is this the case?

To compare the data paradigms, we run the same algorithm, SID-SGNS, also on document IDs from Wikipedia.<sup>7</sup> We use the bilingual (not multilingual) version for both data types to control for external effects. During evaluation, we use a common vocabulary for both sentence-aligned and document-aligned embeddings.

<sup>7</sup>We use the word-document matrix mined by Søgaard et al. (2015), which contains only a subset of our target languages: English, French, and Spanish.

Table 4: The performance of SID-SGNS with sentence-aligned data from the Bible (31,102 verses) vs document-aligned data from Wikipedia (195,000 documents).

Table 4 shows that using sentence IDs from the Bible usually outperforms Wikipedia. This remarkable result, where a small amount of parallel sentences is enough to outperform one of the largest collections of multi-lingual texts in existence, indicates that document-aligned data is an inferior paradigm for translation-related tasks such as word alignment and dictionary induction.

## 7 Conclusions

In this paper, we draw both empirical and theoretical parallels between modern cross-lingual word embeddings based on sentence alignments and traditional word alignment algorithms. We show the importance of sentence ID features and present a new, strong baseline for cross-lingual word embeddings, inspired by the Dice aligner. Our results suggest that apart from faster algorithms and more compact representations, recent cross-lingual word embedding algorithms are still unable to outperform the traditional methods by a significant margin. However, introducing our new multi-lingual signal considerably improves performance. Therefore, we hypothesize that the information in bilingual sentence-aligned data has been thoroughly mined by existing methods, and suggest that future work explore additional sources of information in order to make substantial progress.

## Abstract

This paper presents a new, efficient method for learning task-specific word vectors using a variant of the Passive-Aggressive algorithm. Specifically, this algorithm learns a word embedding matrix in tandem with the classifier parameters in an online fashion, solving a biconvex constrained optimization at each iteration. We provide a theoretical analysis of this new algorithm in terms of regret bounds, and evaluate it on both synthetic data and NLP classification problems, including text classification and sentiment analysis. In the latter case, we compare various pre-trained word vectors to initialize our word embedding matrix, and show that the matrix learned by our algorithm vastly outperforms the initial matrix, with performance results comparable or above the state-of-the-art on these tasks.

## 1 Introduction

Recently, distributed word representations have become a crucial component of many natural language processing systems (Koo et al., 2008; Turian et al., 2010; Collobert et al., 2011). The main appeal of these word embeddings is twofold: they can be derived directly from raw text data in an unsupervised or weakly-supervised manner, and their latent dimensions condense interesting distributional information about the words, thus allowing for better generalization while also mitigating the presence of rare and unseen terms. While there are now many different spectral, probabilistic, and deep neural approaches for building vectorial word representations, there is still no clear understanding as to which syntactic and semantic information they really cap-

ture and whether or how these representations really differ (Chen et al., 2013; Levy and Goldberg, 2014b; Schnabel et al., 2015). Also poorly understood is the relation between the word representations and the particular learning algorithm (e.g., whether linear or non-linear) that uses them as input (Wang and Manning, 2013).

What seems clear, however, is that there is no single best embedding and that their impact is very much task-dependent. This in turn raises the question of how to learn word representations that are adapted to a particular task and learning objective. Three different research routes have been explored towards learning task-specific word embeddings. A first approach (Collobert et al., 2011; Maas et al., 2011) is to learn the embeddings for the target problem jointly with additional unlabeled or (weakly-)labeled data in a semi-supervised or multi-task approach. While very effective, this joint training typically requires large amounts of data and often prohibitive processing times in the case of multi-layer neural networks (not to mention their lack of theoretical learning guarantees in part due to their strong non-convexity). Another approach consists in training word vectors using some existing algorithm as in like word2vec (Mikolov et al., 2013) in a way that exploits prior domain knowledge (e.g., by defining more informative, task-specific contexts) (Bansal et al., 2014; Levy and Goldberg, 2014a). In this case, there is still a need for additional weakly- or hand-labeled data, and there is no guarantee that the newly learned embeddings will indeed benefit the performance, as they are trained independently of the task objective. A third approach is to start with some existing pre-trained embeddings and fine-tune them to the task by integrating them in a joint learning objective either using backpropagation (Lebret et al., 2013) or regularized logistic regression (Labutov and Lipson, 2013). These

approaches in effect hit a sweet spot by leveraging pre-trained embeddings and requiring no additional data or domain knowledge, while directly tying them to task learning objective.

Inspired by these latter approaches, we propose a new, online soft-margin classification algorithm, called Re-embedding Passive-Aggressive (or RPA), that jointly learns an embedding matrix in tandem with the model parameters. As its name suggests, this algorithm generalizes the Passive-Aggressive (PA) algorithm of Crammer and Singer (2006) by allowing the data samples to be projected into the lower dimension space defined by the original embedding matrix. Our approach may be seen as extending the work of (Grandvalet and Canu, 2003) which addresses the problem of simultaneously learning the features and the weight vector of an SVM classifier. An important departure, beyond the online nature of RPA, is that it learns a projection matrix and not just a diagonal one (which is essentially what this earlier work does). Our approach and analysis are also related to (Blondel et al., 2014), which tackles non-negative matrix factorization with the PA philosophy.

The main contributions of this paper are as follows. First, we derive a new variant of the Passive-Aggressive algorithm able to jointly learn an embedding matrix along with the weight vector of the model (section 2). Second, we provide theoretical insights as to bound the cumulative squared loss of our learning procedure over any given sequence of examples—the results we give are actually related to a learning procedure that slightly differs from the algorithm we introduce but that is more easily and compactly amenable to a theoretical study. Third, we further study the behavior of this algorithm on synthetic data (section 4) and we finally show that it performs well on five real-world NLP classification problems (section 5).

## 2 Algorithm

We consider the problem of learning a binary linear classification function  $f_{\Phi, w}$ , parametrized by both a weight vector  $w \in \mathbb{R}^k$  and an embedding matrix  $\Phi \in \mathbb{R}^{k \times p}$  (typically, with  $k \ll p$ ), which is defined as:

$$f_{\Phi, w} : \mathcal{X} \subset \mathbb{R}^p \rightarrow \{-1, +1\} \\ \mathbf{x} \mapsto \text{sign}(\langle w, \Phi \mathbf{x} \rangle)$$

We aim at an online learning scenario, wherein both  $w$  and  $\Phi$  will be updated in a sequential fashion. Given a labeled data steam  $S =$

$\{(\mathbf{x}_t, y_t)\}_{t=1}^T$ , it seems relevant at each step to solve the following soft-margin constrained optimization problem:

$$\underset{\substack{w \in \mathbb{R}^k \\ \Phi \in \mathbb{R}^{k \times p}}}{\text{argmin}} \frac{1}{2} \|w - w_t\|_2^2 + \frac{\lambda}{2} \|\Phi - \Phi_t\|_F^2 + C\xi^2 \quad (1a)$$

$$\text{s.t. } \ell_t(w; \Phi; \mathbf{x}_t) \leq \xi \quad (1b)$$

where  $\|\cdot\|_2$ ,  $\|\cdot\|_F$  stand for the  $l_2$  and Frobenius norms, respectively, and  $C$  controls the “aggressiveness” of the update (as larger  $C$  values imply updates that are directly proportional to the incurred loss). We define  $\ell_t(w; \Phi; \mathbf{x}_t)$  as the hinge loss, that is:

$$\ell_t(w; \Phi; \mathbf{x}_t) \doteq \max(0, 1 - y_t \langle w, \Phi \mathbf{x}_t \rangle). \quad (2)$$

The optimization problem in (1) is reminiscent of the soft-margin Passive-Aggressive algorithm proposed in (Crammer et al., 2006) (specifically, PA-II), but both the objective and the constraint now include a term based on the embedding matrix  $\Phi$ . The  $\lambda$  regularization parameter in the objective controls the allowed divergence in the embedding parameters between iterations.

Interestingly, the new objective remains convex, but the margin constraint doesn’t as it involves a multiplicative term between the weight vector and the embedding matrix, making the overall problem bi-convex (Gorski et al., 2007). That is, the problem is convex in  $w$  for fixed values of  $\Phi$  and convex in  $\Phi$  for fixed values of  $w$ . Incidentally, the formulation presented by (Labutov and Lipson, 2013) is also bi-convex (as it also involves a similar multiplicative term), although the authors proceed as if it were jointly convex (i.e., convex in both  $w$  and  $\Phi$ ). In order to solve this problem, we resort to an alternating update procedure which updates each set of parameters (i.e., either the weight vector or the embedding matrix) while holding the other fixed until some stopping criterion is met (in our case, the value of the objective doesn’t change). As shown in Algorithm 1, this procedure allows us to compute closed-form updates similar to those of PA, and to make use of the same theoretical apparatus for analyzing RPA.

### 2.1 Unified Formalization

Suppose from now on that  $C$  and  $\lambda$  are fixed and so are  $w_t$  and  $\Phi_t$ : this will allow us to drop the explicit dependence on these values and to keep

---

**Algorithm 1** Re-embedding Passive-Aggressive

---

**Require:**

- $S = \{(\mathbf{x}_t, y_t)\}_{t=1}^T$ , a stream of data
- a base embedding  $\Phi_0$

**Ensure:**

- a classification vector  $\mathbf{w}$
- a re-embedding matrix  $\Phi$

Initialize  $\mathbf{w}_0$  $t \leftarrow 0$ **repeat**

$$\mathbf{w}_{t+1}^0 \leftarrow \mathbf{w}_t, \Phi_{t+1}^0 \leftarrow \Phi_t,$$

$$n \leftarrow 1$$

**repeat**

$$\mathbf{w}_{t+1}^{n+1} \leftarrow \mathbf{w}_{t+1}^n + \frac{\ell_t(\mathbf{w}_{t+1}^n; \Phi_{t+1}^n)}{\|\Phi_{t+1}^n \mathbf{x}_t\|_2^2 + \frac{\lambda}{2C}} y_t \mathbf{x}_t$$

$$\Phi_{t+1}^{n+1} \leftarrow \Phi_{t+1}^n + \frac{\ell_t(\mathbf{w}_{t+1}^{n+1}; \Phi_{t+1}^n)}{\|\mathbf{w}_{t+1}^{n+1}\|_2^2 \|\mathbf{x}_t\|_2^2 + \frac{\lambda}{2C}} y_t \mathbf{w}_{t+1}^{n+1} \mathbf{x}_t^\top.$$

with

$$\ell_t(\mathbf{w}; \Phi) = \max(0, 1 - y_t \langle \mathbf{w}, \Phi \mathbf{x}_t \rangle).$$

**until**  $\mathbf{w}_{t+1}^n \rightarrow \mathbf{w}_{t+1}^\infty$  and  $\Phi_{t+1}^n \rightarrow \Phi_{t+1}^\infty$   
Update  $\mathbf{w}_{t+1}$  and  $\Phi_{t+1}$ :

$$\mathbf{w}_{t+1} \leftarrow \mathbf{w}_{t+1}^\infty \quad \Phi_{t+1} \leftarrow \Phi_{t+1}^\infty$$

**until** some stopping criterion is met**return**  $\mathbf{w}_t, \Phi_t$ 

---

the notation light. Let  $Q_t$  be defined as:

$$Q_t(\mathbf{w}, \Phi, \xi) \doteq \frac{1}{2} \|\mathbf{w} - \mathbf{w}_t\|_2^2 + \frac{\lambda}{2} \|\Phi - \Phi_t\|_F^2 + C\xi^2. \quad (3)$$

and margin  $q_t$  be defined as:

$$q_t(\mathbf{w}, \Phi) \doteq 1 - \langle \mathbf{w}, y_t \Phi \mathbf{x}_t \rangle \quad (4a)$$

$$= 1 - \left\langle \Phi, y_t \mathbf{w} \mathbf{x}_t^\top \right\rangle_F. \quad (4b)$$

Here  $\langle \cdot, \cdot \rangle_F$  denote the Frobenius inner product. We have purposely provided the two equivalent forms (4a) and (4b) to emphasize the (syntactic) exchangeability of  $\mathbf{w}$  and  $\Phi$ . As we shall see, this is going to be essential to derive an alternating update procedure—which alternates the updates with respect to  $\mathbf{w}$  and  $\Phi$ —in a compact way.

Given  $Q_t$  and  $q_t$ , we are now interested in solving the following optimization problem:

$$\mathbf{w}_{t+1}, \Phi_{t+1}, \xi_{t+1} = \operatorname{argmin}_{\mathbf{w}, \Phi, \xi} Q_t(\mathbf{w}, \Phi, \xi) \quad (5a)$$

$$\text{s.t. } q_t(\mathbf{w}, \Phi) \leq \xi. \quad (5b)$$

## 2.2 Bi-convexity

It turns out that problem (5) is a bi-convex optimization problem: it is indeed straightforward to observe that if  $\Phi$  is fixed then the problem is convex in  $(\mathbf{w}, \xi)$ —it is the classical passive-aggressive II optimization problem—and if  $\mathbf{w}$  is fixed then the problem is convex in  $(\Phi, \xi)$ . If there exist theoretical results on the solving of bi-convex optimization problems, the machinery to use pertains to combinatorial optimization, which might be too expensive. In addition, computing the solution of (5) would drive us away from the spirit of passive-aggressive learning which rely on cheap and statistically meaningful (from the mistake-bound perspective) updates. This is the reason why we propose to resort to an alternate online procedure to solve a proxy of (5).

## 2.3 An Alternating Online Procedure

Instead of tackling problem (5) directly we propose to solve, at each time  $t$ , either of:

$$\mathbf{w}_{t+1}, \xi_{t+1} = \operatorname{argmin}_{\mathbf{w}, \xi} Q_t(\mathbf{w}, \Phi_t, \xi) \text{ s.t. } q_t(\mathbf{w}, \Phi_t) \leq \xi, \quad (6)$$

$$\Phi_{t+1}, \xi_{t+1} = \operatorname{argmin}_{\Phi, \xi} Q_t(\mathbf{w}_t, \Phi, \xi) \text{ s.t. } q_t(\mathbf{w}_t, \Phi) \leq \xi. \quad (7)$$

This means that the optimization is performed with either  $\Phi$  fixed to  $\Phi_t$  or  $\mathbf{w}$  fixed to  $\mathbf{w}_t$ .

Informally, the iterative Algorithm 1, resulting from this alternate scheme, will solve at each round a simple constrained optimization problem, in which the objective is to minimize the squared Euclidean distances between the new weight vector (resp. the new embedding matrix) and the current one, while making sure that both sets of parameters achieve a correct prediction with a sufficiently high margin. Note that one may recover the standard passive-aggressive algorithm by simply fixing the embedding matrix to the identity matrix. Also note that if the right stopping criteria are retained, Algorithm 1 is guaranteed to converge to a local optimum of (5) (see (Gorski et al., 2007)).

When fully developed, problems (6)-(7) respectively write as:

$$\mathbf{w}_{t+1}, \xi_{t+1} = \operatorname{argmin}_{\mathbf{w}, \xi} \frac{1}{2} \|\mathbf{w} - \mathbf{w}_t\|_2^2 + C\xi^2$$

$$\text{s.t. } 1 - \langle \mathbf{w}, y_t \Phi_t \mathbf{x}_t \rangle \leq \xi,$$

or

$$\begin{aligned} \Phi_{t+1}, \xi_{t+1} = \operatorname{argmin}_{\Phi, \xi} & \frac{\lambda}{2} \|\Phi - \Phi_t\|_F^2 + C\xi^2 \\ \text{s.t. } & 1 - \langle \Phi, y_t \mathbf{w}_t \mathbf{x}_t^\top \rangle_F \leq \xi. \end{aligned}$$

Using the equivalence in (4), both problems can be seen as special instances of the generic problem:

$$\mathbf{u}^*, \xi^* = \operatorname{argmin}_{\mathbf{u}, \xi} \frac{\lambda}{2} \|\mathbf{u} - \mathbf{u}_t\|_*^2 + C\xi^2 \quad (8a)$$

$$\text{s.t. } 1 - \langle \mathbf{u}, \mathbf{v}_t \rangle_* \leq \xi. \quad (8b)$$

where  $\|\cdot\|_*$  and  $\langle \cdot, \cdot \rangle_*$  are generalized versions of the  $l_2$  norm and the inner product, respectively.

This is a convex optimization problem that can be readily solved using classical tools from convex optimization to give:

$$\mathbf{u}^* = \mathbf{u}_t + \tau_u \mathbf{v}_t, \text{ with } \tau_u = \frac{\max(0, 1 - \langle \mathbf{u}_t, \mathbf{v}_t \rangle_*)}{\|\mathbf{v}_t\|_* + \frac{\lambda}{2C}}, \quad (9)$$

which comes from the following proposition.

**Proposition 1.** *The solution of (8) is (9).*

*Proof.* The Lagrangian associated with the problem is given by:

$$\mathcal{L}(\mathbf{u}, \xi, \tau) = \frac{\lambda}{2} \|\mathbf{u} - \mathbf{u}_t\|_*^2 + C\xi^2 + \tau (1 - \xi - \langle \mathbf{u}, \mathbf{v}_t \rangle_*) \quad (10)$$

with  $\tau > 0$ .

Necessary conditions for optimality are  $\nabla_{\mathbf{u}} \mathcal{L} = \mathbf{0}$ , and  $\nabla_{\xi} \mathcal{L} = 0$ , which imply  $\mathbf{u} = \mathbf{u}_t + \frac{\tau}{\lambda} \mathbf{v}_t$ , and  $\xi = \frac{\tau}{2C}$ . Using this in (10) gives the function:

$$g(\tau) = \frac{\tau^2 \|\mathbf{v}_t\|_*^2}{2\lambda} + \frac{\tau^2}{4C} + \tau - \frac{\tau^2}{2C} - \tau \langle \mathbf{u}_t, \mathbf{v}_t \rangle_* - \frac{\tau^2 \|\mathbf{v}_t\|_*^2}{\lambda},$$

which is maximized with respect to  $\tau$  when  $g'(\tau) = 0$ , i.e.:

$$\left( \frac{\|\mathbf{v}_t\|_*^2}{\lambda} - \frac{1}{2C} - \frac{2\|\mathbf{v}_t\|_*^2}{\lambda} \right) \tau + 1 - \langle \mathbf{u}_t, \mathbf{v}_t \rangle_* = 0.$$

Taking into account the constraint  $\tau \geq 0$ , the maximum of  $g$  is attained at  $\tilde{\tau}$  with:

$$\tilde{\tau} = \frac{\lambda \max(0, 1 - \langle \mathbf{u}_t, \mathbf{v}_t \rangle_*)}{\|\mathbf{v}_t\|_*^2 + \frac{\lambda}{2C}},$$

which, setting  $\tau_u = \tilde{\tau}/\lambda$  gives (9).  $\square$

The previous proposition allows us to readily have the solutions of (6) and (7) as follows.

**Proposition 2.** *The updates induced by the solutions of (6) and (7) are respectively given by:*

$$\mathbf{w}^* = \mathbf{w}_t + \tau_w y_t \mathbf{x}_t, \text{ with } \tau_w = \frac{\ell_t(\mathbf{w}_t; \Phi_t)}{\|\Phi_t \mathbf{x}_t\|_2^2 + \frac{1}{2C}} \quad (11)$$

$$\Phi^* = \Phi_t + \tau_\Phi y_t \mathbf{w}_t \mathbf{x}_t^\top, \text{ with } \tau_\Phi = \frac{\ell_t(\mathbf{w}_t; \Phi_t)}{\|\mathbf{w}_t\|_2^2 \|\mathbf{x}_t\|_2^2 + \frac{\lambda}{2C}}, \quad (12)$$

where  $\ell_t(\mathbf{w}; \Phi) = \max(0, q_t(\mathbf{w}, \Phi))$ .

*Proof.* Just instantiate the results of Proposition 1 with  $(\mathbf{u}, \mathbf{v}_t) = (\mathbf{w}, y_t \Phi_t \mathbf{x}_t)$  for (11) and  $(\mathbf{u}, \mathbf{v}_t) = (\Phi, y_t \mathbf{x}_t \mathbf{w}_t^\top)$  for (12).  $\square$

**Remark 1** (Hard-margin case). *Note that the hard-margin version of the previous problem:*

$$\operatorname{argmin}_{\substack{\mathbf{w} \in \mathbb{R}^k \\ \Phi \in \mathbb{R}^{k \times p}}} \frac{1}{2} \|\mathbf{w} - \mathbf{w}_t\|_2^2 + \frac{\lambda}{2} \|\Phi - \Phi_t\|_F^2 \quad (13)$$

$$\text{s.t. } 1 - y_t \langle \mathbf{w}, \Phi \mathbf{x}_t \rangle \leq 0 \quad (14)$$

is degenerate from the alternated optimization point of view. It suffices to observe that the updates entailed by the hard-margin problem correspond to (9) with  $C$  set to  $\infty$ ; if it happens that either  $\Phi_0 = \mathbf{0}$  or  $\mathbf{w}_0 = \mathbf{0}$ , then one of the optimization problems (wrt to  $\mathbf{w}$  or  $\Phi$ ) has no solution.

### 3 Analysis

Using the same technical tools as in (Crammer et al., 2006), and the unified formalization of section 2, we have the following result.

**Proposition 3.** *Suppose that problem (8) is iteratively solved for a sequence of vectors  $\mathbf{v}_1, \dots, \mathbf{v}_T$  to give  $\mathbf{u}_2, \dots, \mathbf{u}_{T+1}$ ,  $\mathbf{u}_1$  being given. Suppose that, at each time step,  $\|\mathbf{v}_t\|_* \leq R$ , for some  $R > 0$ . Let  $\mathbf{u}^*$  be an arbitrary vector living in the same space as  $\mathbf{u}_1$ . The following result holds*

$$\sum_{t=1}^T \ell_t^2 \leq \left( R^2 + \frac{\lambda}{2C} \right) \left( \|\mathbf{u}^* - \mathbf{u}_1\|_*^2 + \frac{2C}{\lambda} \sum_{t=1}^T (\ell_t^*)^2 \right) \quad (15)$$

where

$$\ell_t = \max(0, 1 - \langle \mathbf{u}_t, \mathbf{v}_t \rangle_*), \text{ and } \ell_t^* = \max(0, 1 - \langle \mathbf{u}^*, \mathbf{v}_t \rangle_*). \quad (16)$$

This proposition and the accompanying lemmas are simply a variation of the results of (Crammer et al., 2006), with the addition that they are based on the generic problem (8). The loss bound applies for a version of Algorithm 1 where one of the parameters, either the weight vector or the re-embedding matrix, is kept fixed for some time.

Proposition 3 makes use of the following lemma (see Lemma 1 in (Crammer et al., 2006)):

**Lemma 1.** Suppose that problem (8) is iteratively solved for a sequence of vectors  $\mathbf{v}_1, \dots, \mathbf{v}_T$  to give  $\mathbf{u}_2, \dots, \mathbf{u}_{T+1}$ ,  $\mathbf{u}_1$  being given. The following holds:

$$\sum_{t=1}^T \tau_u (2\ell_t - \tau_u \|\mathbf{v}_t\|_*^2 - 2\ell_t^*) \leq \|\mathbf{u}^* - \mathbf{u}_1\|_*^2. \quad (17)$$

*Proof.* As in (Crammer et al., 2006), simply set  $\Delta_t = \|\mathbf{u}_t - \mathbf{u}^*\|_*^2 - \|\mathbf{u}_{t+1} - \mathbf{u}^*\|_*^2$  and bound  $\sum_{\tau=1}^T \Delta_t$  from above and below. For the upper bound:  $\sum_{\tau=1}^T \Delta_t = \|\mathbf{u}_1 - \mathbf{u}^*\|_*^2 - \|\mathbf{u}_{T+1} - \mathbf{u}^*\|_*^2 \leq \|\mathbf{u}_1 - \mathbf{u}^*\|_*^2$ .

For the lower bound, we focus on the nontrivial situation where  $\ell_t > 0$ , otherwise  $\Delta_t = 0$  (i.e. no update is made) and the bounding is straightforward. Making use of the value of  $\tau_u$ :

$$\begin{aligned} \Delta_t &= \|\mathbf{u}_t - \mathbf{u}^*\|_*^2 - \|\mathbf{u}_{t+1} - \mathbf{u}^*\|_*^2 \\ &= \|\mathbf{u}_t - \mathbf{u}^*\|_*^2 - \|\mathbf{u}_t + \tau_u \mathbf{v}_t - \mathbf{u}^*\|_*^2 \quad (\text{see (8)}) \\ &= -2\tau_u \langle \mathbf{u}_t - \mathbf{u}^*, \mathbf{v}_t \rangle_* - \tau_u^2 \|\mathbf{v}_t\|_*^2 \\ &= -2\tau_u \langle \mathbf{u}_t, \mathbf{v}_t \rangle_* + 2\tau_u \langle \mathbf{u}^*, \mathbf{v}_t \rangle_* - \tau_u^2 \|\mathbf{v}_t\|_*^2. \end{aligned}$$

Since  $\ell_t > 0$ , then  $\langle \mathbf{u}_t, \mathbf{v}_t \rangle_* = 1 - \ell_t$ ; also, by the definition of  $\ell_t^*$  (see (16)),  $\ell_t^* \geq 1 - \langle \mathbf{u}^*, \mathbf{v}_t \rangle_*$ , or  $\langle \mathbf{u}^*, \mathbf{v}_t \rangle_* \geq 1 - \ell_t^*$ . This readily gives

$$\begin{aligned} \Delta_t &\geq -2\tau_u(1 - \ell_t) + 2\tau_u(1 - \ell_t^*) - \tau_u^2 \|\mathbf{v}_t\|_*^2 \\ &= 2\tau_u \ell_t - 2\tau_u \ell_t^* - \tau_u^2 \|\mathbf{v}_t\|_*^2, \end{aligned}$$

hence the targeted lower bound and, in turn, (17).  $\square$

*Proof of Proposition 3.* As for the proof of Proposition 3, it suffices, again, to follow the steps given in (Crammer et al., 2006), but this time, for the proof of Theorem 5.

Note that for any  $\beta \neq 0$ ,  $(\beta\tau_u - \ell_t^*/\beta)^2$  is well-defined and nonnegative and thus:

$$\begin{aligned} &\|\mathbf{u}^* - \mathbf{u}_1\|_*^2 \\ &\geq \sum_{t=1}^T [\tau_u (2\ell_t - \tau_u \|\mathbf{v}_t\|_*^2 - 2\ell_t^*) - (\beta\tau_u - \ell_t^*/\beta)^2] \\ &= \sum_{t=1}^T (2\tau_u \ell_t - \tau_u^2 (\|\mathbf{v}_t\|_*^2 + \beta^2) - 2\tau_u \ell_t^* \\ &\quad + 2\tau_u \ell_t^* - (\ell_t^*)^2 / \beta^2) \\ &= \sum_{t=1}^T (2\tau_u \ell_t - \tau_u^2 (\|\mathbf{v}_t\|_*^2 + \beta^2) - (\ell_t^*)^2 / \beta^2). \end{aligned}$$

Setting  $\beta = \sqrt{\lambda/2C}$  and using  $\tau_u = \ell_t / (\|\mathbf{v}_t\|_*^2 +$

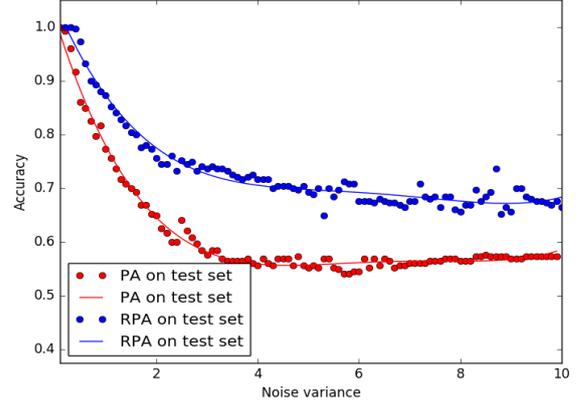

Figure 1: Accuracy rates for PA and RPA as a function of the variance of the Gaussian noise added to the “true” embedding  $\Phi$ . The observed  $X$  matrix is  $n = 500 \times p = 1000$ .

$\frac{\lambda}{2C}$ ) (see (9)) gives

$$\begin{aligned} &\|\mathbf{u}^* - \mathbf{u}_1\|_*^2 \\ &\geq \sum_{t=1}^T \left( 2\tau_u \ell_t - \tau_u^2 \left( \|\mathbf{v}_t\|_*^2 + \frac{\lambda}{2C} \right) - \frac{2C}{\lambda} (\ell_t^*)^2 \right), \\ &= \sum_{t=1}^T \left( \frac{\ell_t^2}{\|\mathbf{v}_t\|_*^2 + \frac{\lambda}{2C}} - \frac{2C}{\lambda} (\ell_t^*)^2 \right). \end{aligned}$$

Using the assumption that  $\|\mathbf{v}_t\|_* \leq R$  for all  $t$  and rearranging terms concludes the proof.  $\square$

The result given in Proposition 3 bounds the cumulative loss of the learning procedure when one of the parameters, either  $\Phi$  or  $\mathbf{w}$ , is fixed and the other is the optimization variable. Therefore, it does not directly capture the behavior of Algorithm 1, which alternates between the updates of  $\Phi$  and  $\mathbf{w}$ . A proper analysis of Algorithm 1 would require a refinement of Lemma 1 which, to our understanding, would be the core of a new result. This is a problem we intend to put our energy on in the near future, as an extension to this work.

## 4 Experiments on Synthetic Data

In order to better understand and validate the RPA algorithm, we first conducted some synthetic experiments. Specifically, we simulated a high-dimensional matrix  $X \in \mathbb{R}^{n \times p}$ , with  $n$  data samples realizing  $p$  “words” and  $p \gg n$ , using the following generative model:

$$X = Z\tilde{\Phi}, \text{ where } \tilde{\Phi} = \Phi + \mathcal{E}$$

That is, each  $p$ -dimensional data point  $x_i$  was generated from a hidden lower  $k$ -dimensional  $z_i$  and

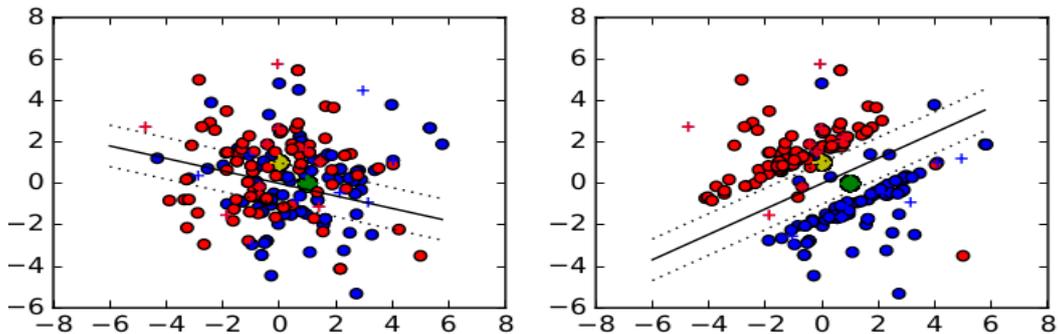

Figure 2: Hyper-plane learned by PA on  $X\tilde{\Phi}^\top$  (left pane) compared to hyper-plane and data representations learned by RPA (right pane).  $X$  is  $n = 200 \times p = 500$ , and noise  $\sigma = 2$ . Training and test points appear as circles or plus marks, respectively. RPA’s hyper-parameters are set to  $C = 100$  and  $\lambda = .5$ .

an embedding matrix  $\Phi \in \mathbb{R}^{k \times p}$ , mapping  $k$  latent concepts to the  $p$  observed words. For simplicity, we assume that: (i) there are only two concepts (i.e.,  $k = 2$ ), (ii) each data point realizes a single concept (i.e., each  $x_i$  is a  $p$ -dimensional indicator vector), (iii) each concept is equally represented in the data (with  $n/2$  data points), and (iv) each concept deterministically signals a class label, either  $-1$  or  $+1$ . Recovering  $Z$  and predicting the  $z_i$ ’s labels is trivial if one is given  $X$  and the true embedding  $\Phi$ , so we added Gaussian noise  $\varepsilon_i \sim \mathcal{N}(\mathbf{0}, \sigma^2 \mathbb{I}_p)$  to each  $\phi_i$ . The resulting, observed noisy matrix is denoted  $\tilde{\Phi}$ .

Given this setting, the goal of the RPA is to learn a set of classification parameters  $w \in \mathbb{R}^k$  in the latent space and to “de-noise” the observed embedding matrix  $\tilde{\Phi}$  by exploiting the labeled data. We are interested in comparing the RPA with a regular PA that directly learns from the noisy data  $X\tilde{\Phi}^\top$ . The outcome of this comparison is plotted in Figure 1. For this experiment, we randomly splitted the  $X$  data according to 80/10/10 for train/dev/test and considered increasing noise variance from 0 to 10 by increment of 0.1. Each dot in Figure 1 corresponds to the average accuracy over 10 separate, random initializations of the embedding matrix at a particular noise level. Hyper-parameters were optimized using a grid search on the dev set for both the PA and RPA.<sup>1</sup>

As shown in Figure 1, the PA’s accuracy quickly drops to levels that are only slightly above chance, while the RPA manages to maintain an accuracy close to .7 even with large noise. This indicates

that the RPA is able to recover some of the structure in the embedding matrix. This behavior is also illustrated in Figure 2, wherein the two hidden concepts appear in yellow and green. While the standard PA learns a very bad hyper-plane, which fails to separate the two concepts, the RPA learns a much better hyper-plane. Interestingly, most of the data points appear to have been projected on the margins of the hyper-plane.

## 5 Experiments on NLP tasks

This section assesses the effectiveness of RPA on several text classification tasks.

### 5.1 Evaluation Datasets

We consider five different classification tasks which are concisely summarized in Table 1.

**20 Newsgroups** Our first three text classification tasks from this dataset<sup>2</sup> consists in categorizing documents into two related sub-topics: (i) **Comp.**: IBM vs. Mac, (ii) **Religion**: atheism vs. christian, and (iii) **Sports**: baseball vs. hockey.

**IMDB Movie Review** This movie dataset<sup>3</sup> was introduced by (Maas et al., 2011) for sentiment analysis, and contains 50,000 reviews, divided into a balanced set of highly positive (7 stars out of 10 or more) and negative scores (4 stars or less).

**TREC Question Classification** This dataset<sup>4</sup> (Li and Roth, 2002) involves six question types: abbreviation, description, entity, human, location, and number.

<sup>1</sup>We use  $\{1, 5, 10, 50\}$  for the number iterations,  $C$ ’s values were  $\{.1, .5, 1.0, 2.0, 10.0\}$ , and  $\lambda$  was set to  $10^k$ , with  $k \in \{-2, -1, 0, 1, 2\}$ .

<sup>2</sup>[qwone.com/~jason/20Newsgroups](http://qwone.com/~jason/20Newsgroups)

TREC	6	5 452	500	9 775	3 771

Table 1: Number of labels, samples, vocabulary sizes (incl. non-hapax words) per dataset.

## 5.2 Preprocessing and Document Vectors

All datasets were pre-preprocessed with the Stanford tokenizer<sup>5</sup>, except for the TREC corpus which comes pre-tokenized. Case was left intact unless used in conjunction with word embeddings that assume down-casing (see below).

For constructing document or sentence vectors, we used a simple 0-1 bag-of-word model, simply summing over the word vectors of occurring tokens, followed by L2-normalization of the resulting vector in order to avoid document/sentence length effects. For each dataset, we restricted the vocabulary to non-hapax words (i.e., words occurring more than once). Words unknown to the embedding were mapped to zero vectors.

## 5.3 Initial Word Vector Representations

Five publicly available word vectors were used to define initial embedding matrices in the RPA. The coverage of the different embeddings wrt each dataset vocabulary is reported in Table 2.

**CnW** These word vectors were induced using the neural language model of (Collobert and Weston, 2008) re-implemented by (Turian et al., 2010).<sup>6</sup> They were trained on 63M word news corpus, covering 268, 810 word forms (intact case), with 50, 100 or 200 dimensions for each word.

**HLBL** These were obtained using the probabilistic Hierarchical log-bilinear language model of (Mnih and Hinton, 2009), again re-implemented by (Turian et al., 2010) with 50 or 100 dimensions. They cover 246, 122 word forms.

**HPCA** (Lebret and Collobert, 2014) present a variant of Principal Component Analysis, Hellinger PCA, for learning spectral word vectors. These were trained over 1.62B words from

<sup>5</sup>[nlp.stanford.edu/software/tokenizer.shtml](http://nlp.stanford.edu/software/tokenizer.shtml)

Table 2: Out-of-vocabulary rates for non-hapax words in each dataset-embedding pair.

Wikipedia, RCV1, and WSJ with all words lower-cased, and digits mapped to a special symbol. Vocabulary is restricted to words occurring 100 times or more (hence, a total of 178, 080 words). These come in 50, 100 and 200 dimensions.<sup>7</sup>

**GloVe** These global word vectors are trained using a log-bilinear regression model on aggregated global word co-occurrence statistics (Pennington et al., 2014). We use two different releases:<sup>8</sup> (i) **GV6B** trained on Wikipedia 2014 and Gigaword 5 (amounting to 6B down-cased words and a vocabulary of 400k) with vectors in 50, 100, 200, or 300 dimensions, and (ii) **GV840B** trained over 840B uncased words (a 2.2M vocabulary) with vectors of length 300.

**SkGr** Finally, we use word vectors pre-trained with the skip-gram neural network model of (Mikolov et al., 2013): each word’s Huffman code is fed to a log-linear classifier with a continuous projection layer that predicts context words within a specified window. The embeddings were trained on a 100B word corpus of Google news data (a 3M vocabulary) and are of length 300.<sup>9</sup>

**rand** In addition to these pre-trained word representations, we also use random vectors of lengths 50, 100, and 200 as a baseline embedding. Specifically, each component of these word vector is uniformly distributed on the unit interval  $(-1, 1)$ .

## 5.4 Settings

The hyperparameters of the model,  $C$ ,  $\lambda$ , and the number  $it$  of iterations over the training set, were estimated using a grid search over  $C = 10^{k \in \{-6, -4, -2, 0, 2, 4, 6\}}$ ,  $\lambda = 10^{l \in \{-3, -2, -1, 0, 1, 2, 3\}}$ , and  $it \in \{1, 5, 10\}$  in a 10-fold cross-validation

Table 3: Accuracy results on our five datasets for the Re-embedding Passive-Aggressive (RPA) against standard PA-II (PA). For each task, the best results for each embedding method (across different dimensions) has been greyed out, while the overall highest accuracy score has been underlined.

over the training data. For the alternating on-line procedure, we used the difference between the objective values from one iteration to the next for defining the stopping criterion, with maximum number of iterations of 50. In practice, we found that the search often converged much few iterations. The multi-class classifier used for the TREC dataset was obtained by training the RPA in simple One-versus-All fashion, thus learning one embedding matrix per class.<sup>10</sup> For datasets with label imbalance, we set a different  $C$  parameter for each class, re-weighting it in proportion to the inverse frequency of the class.

## 5.5 Results

Table 3 summarizes accuracy results for the RPA against those obtained by a PA trained with fixed pre-trained embeddings. The first thing to notice is that the RPA delivers massive accuracy improvements over the vanilla PA across datasets and embedding types and sizes, thus showing that the RPA is able to learn word representations that are better tailored to each problem. On average, accuracy gains are between 22% and 31% for CnW, HLBL, and HPCA. Sizable improvements, ranging from 8% and 18%, are also found for the better

<sup>10</sup>More interesting configurations (e.g., a single embedding matrix shared across classes), are left for future work.

performing GV6B, GV840B, and SkGr. Second, RPA is able to outperform on all five datasets the strong baseline provided by the one-hot version of PA trained on the original high-dimensional space, with some substantial gains on *sports* and *trec*.

Overall, the best scores are obtained with the re-embedded SkGr vectors, which yield the best average accuracy, and outperform all the other configurations on two of the five datasets (*trec* and *imdb*). GV6B (dimension 300) has the second best average scores, outperforming all the other configurations on *sports*. Interestingly, embeddings learned from random vectors achieve performance that are often on a par or higher than those given by HLBL, HPCA or CnW initializations. They actually yield the best performance for the two remaining datasets: *comp* and *religion*. On these tasks, RPA does not seem to benefit from the information contained in the pre-trained embeddings, or their coverage is not just good enough.

For both PA and RPA, performance appear to be positively correlated with embedding coverage: embeddings with lower OOV rates generally perform better those with more missing words. The correlation is only partial, since GV840B do not yield gains compared to GV6B and SkGr despite its better word coverage. Also, SkGr largely outperforms HPCA although they have similar OOV

Table 4: Accuracy results for RPA against standard PA both run for a single iteration.

rates. As for dimensions, embeddings of length 100 and more perform the best, although they involve estimating larger number of parameters, which is a priori difficult given the small sizes of the datasets.

By comparison with previous work on *imdb*, the RPA performance are substantially better than those reported by (Labutov and Lipson, 2013), whose best re-embedding score is 81.15 with CnW. By comparison, our best score with CnW is 86.64, and 88.52 with SkGr, thus closing the gap on (Maas et al., 2011) who report an accuracy of 88.89 using a much more computationally intensive approach specifically tailored to sentiment analysis. Interestingly, (Labutov and Lipson, 2013) show that accuracy can be further improved by concatenating re-embedded and 1-hot representations. This option is also available to us, but we leave it to future work.

Finally, Table 4 report accuracy results for RPA against PA when both algorithms are trained in a genuine online mode, that is with a single pass over the data. As expected, performance drop for the RPA and the PA, but the decreases are comparatively much smaller for the RPA (from 2% to 3%) compared to the PA (from 0.4% to 14%).

## 6 Conclusion and Future Work

In this paper, we have proposed a new scalable algorithm for learning word representations that

are specifically tailored to a classification objective. This algorithm generalizes the well-known Passive-Aggressive algorithm, and we showed how to extend the regret bounds results of the PA to the RPA when either the weight vector or the embedding matrix is fixed. In addition, we have also provided synthetic and NLP experiments, demonstrating that the good classification performance of RPA.

In future work, we first would like to achieve a more complete analysis of the RPA algorithm when both  $w$  and  $\Phi$  both get updated. Also, we intend to investigate potential exact methods for solving biconvex minimization (Floudas and Viswewaran, 1990), as well as to develop a stochastic version of RPA, thus foregoing running the inner alternate search to convergence. More empirical perspectives include extending the RPA to linguistic structured prediction tasks, better handling of unknown words, and a deeper intrinsic and statistical evaluation of the embeddings learned by the RPA.

# Nonsymbolic Text Representation

Hinrich Schütze

CIS, LMU Munich, Germany

inquiries@cislmu.org

## Abstract

We introduce the first generic text representation model that is completely nonsymbolic, i.e., it does not require the availability of a segmentation or tokenization method that attempts to identify words or other symbolic units in text. This applies to training the representations as well as to using them in an application. We demonstrate better performance than prior work on entity typing and text denoising.

## 1 Introduction

Character-level models can be grouped into three classes. (i) **End-to-end models** learn a separate model on the raw character (or byte) input for each task; these models estimate task-specific parameters, but no representation of text that would be usable across tasks is computed. Throughout this paper, we refer to  $r(x)$  as the “representation” of  $x$  only if  $r(x)$  is a generic rendering of  $x$  that can be used in a general way, e.g., across tasks and domains. The activation pattern of a hidden layer for a given input sentence in a multilayer perceptron (MLP) is not a representation according to this definition if it is not used outside of the MLP. (ii) **Character-level models of words** derive a representation of a word  $w$  from the character string of  $w$ , but they are symbolic in that they need text segmented into tokens as input. (iii) **Bag-of-character-ngram models, bag-of-ngram models** for short, use character ngrams to encode sequence-of-character information, but sequence-of-ngram information is lost in the representations they produce.

Our premise is that text representations are needed in NLP. A large body of work on word embeddings demonstrates that a generic text representation, trained in an unsupervised fashion on

large corpora, is useful. Thus, we take the view that **group (i) models**, end-to-end learning without any representation learning, is not a good general approach for NLP.

We distinguish **training** and **utilization** of the text representation model. We use “training” to refer to the method by which the model is learned and “utilization” to refer to the application of the model to a piece of text to compute a representation of the text. In many text representation models, utilization is trivial. For example, for word embedding models, utilization amounts to a simple lookup of a word to get its precomputed embedding. However, for the models we consider, utilization is not trivial and we will discuss different approaches.

Both training and utilization can be either **symbolic** or **nonsymbolic**. We define a symbolic approach as one that is based on tokenization, i.e., a segmentation of the text into tokens. Symbol identifiers (i.e., tokens) can have internal structure – a tokenizer may recognize tokens like “to and fro” and “London-based” that contain delimiters – and may be morphologically analyzed downstream.<sup>1</sup>

We define a nonsymbolic approach as one that is tokenization-free, i.e., no assumption is made that there are segmentation boundaries and that each segment (e.g., a word) should be represented (e.g., by a word embedding) in a way that is independent of the representations (e.g., word embeddings) of neighboring segments. Methods for training text representation models that require tokenized text include word embedding models like word2vec (Mikolov et al., 2013) and most **group**

<sup>1</sup>The position-embedding representation of a text introduced below is a sequence of position embeddings. An embedding that represents a single character must be viewed as symbolic since a character is a symbol – just like a representation of text as a sequence of word embeddings is symbolic since each word corresponds to a symbol. But position embeddings do not represent single characters. See §4.

(ii) **methods**, i.e., character-level models like fast-Text skipgram (Bojanowski et al., 2016).

**Bag-of-gram models**, group (iii) models, are text representation utilization models that typically compute the representation of a text as the sum of the embeddings of all character ngrams occurring in it, e.g., WordSpace (Schütze, 1992) and CHARAGRAM (Wieting et al., 2016). WordSpace and CHARAGRAM are examples of mixed training-utilization models: training is performed on tokenized text (words and phrases), utilization is nonsymbolic.

We make two contributions in this paper. (i) We propose the first generic method for training text representation models without the need for tokenization and address the challenging sparseness issues that make this difficult. (ii) We propose the first nonsymbolic utilization method that fully represents sequence information – in contrast to utilization methods like bag-of-ngrams that discard sequence information that is not directly encoded in the character ngrams themselves.

## 2 Motivation

Chung et al. (2016) give two motivations for their work on character-level models. First, **tokenization** (or, equivalently, segmentation) **algorithms make many mistakes** and are brittle: “we do not have a perfect word segmentation algorithm for any one language”. Tokenization errors then propagate throughout the NLP pipeline.

Second, there is currently **no general solution for morphology** in statistical NLP. For many languages, high-coverage and high-quality morphological resources are not available. Even for well resourced languages, problems like ambiguity make morphological processing difficult; e.g., “rung” is either the singular of a noun meaning “part of a ladder” or the past participle of “to ring”. In many languages, e.g., in German, syncretism, a particular type of systematic morphological ambiguity, is pervasive. Thus, there is no simple morphological processing method that would produce a representation in which all inflected forms of “to ring” are marked as having a common lemma; and no such method in which an unseen form like “aromatizing” is reliably analyzed as a form of “aromatize” whereas an unseen form like “anti-trafficking” is reliably analyzed as the compound “anti+trafficking”.

Of course, it is an open question whether non-

symbolic methods can perform better than morphological analysis, but the foregoing discussion motivates us to investigate them.

Chung et al. (2016) focus on problems with the tokens produced by segmentation algorithms. Equally important is the problem that **tokenization fails to capture structure across multiple tokens**. The job of dealing with cross-token structure is often given to downstream components of the pipeline, e.g., components that recognize multiwords and named entities in English or in fact any word in a language like Chinese that uses no overt delimiters. However, there is no linguistic or computational reason in principle why we should treat the recognition of a unit like “electromechanical” (containing no space) as fundamentally different from the recognition of a unit like “electrical engineering” (containing a space). Character-level models offer the potential of uniform treatment of such linguistic units.

## 3 Text representation model: Training

### 3.1 Methodology

Many text representation learning algorithms can be understood as estimating the parameters of the model from a unit-context matrix  $C$  where each row corresponds to a unit  $u_i$ , each column to a context  $c_j$  and each cell  $C_{ij}$  measures the degree of association between  $u_i$  and  $c_j$ . For example, the skipgram model is closely related to an SVD factorization of a pointwise mutual information matrix (Levy and Goldberg, 2014). Many text representation learning algorithms are formalized as matrix factorization (e.g., (Deerwester et al., 1990; Hofmann, 1999; Stratos et al., 2015)), but there may be no big difference between implicit (e.g., (Pennington et al., 2014)) and explicit factorization methods; see also (Mohamed, 2011; Rastogi et al., 2015).

Our goal in this paper is not to develop new matrix factorization methods. Instead, we will focus on defining the unit-context matrix in such a way that no symbolic assumption has to be made. This unit-context matrix can then be processed by any existing or still to be invented algorithm.

**Definition of units and contexts.** How to define units and contexts without relying on segmentation boundaries? In initial experiments, we simply generated all character ngrams of length up to  $k_{\max}$  (where  $k_{\max}$  is a parameter), including character ngrams that cross token boundaries; i.e., no

segmentation is needed. We then used a skipgram-type objective for learning embeddings that attempts to predict, from ngram  $g_1$ , an ngram  $g_2$  in  $g_1$ 's context. Results were poor because many training instances consist of pairs  $(g_1, g_2)$  in which  $g_1$  and  $g_2$  overlap, e.g., one is a subsequence of the other. So the objective encourages trivial predictions of ngrams that have high string similarity with the input and nothing interesting is learned.

In this paper, we propose an alternative way of defining units and contexts that supports well-performing nonsymbolic text representation learning: **multiple random segmentation**. A pointer moves through the training corpus. The current position  $i$  of the pointer defines the left boundary of the next segment. The length  $l$  of the next move is uniformly sampled from  $[k_{\min}, k_{\max}]$  where  $k_{\min}$  and  $k_{\max}$  are the minimum and maximum segment lengths. The right boundary of the segment is then  $i + l$ . Thus, the segment just generated is  $c_{i, i+l}$ , the subsequence of the corpus between (and including) positions  $i$  and  $i + l$ . The pointer is positioned at  $i + l + 1$ , the next segment is sampled and so on. An example of a random segmentation from our experiments is “@he@had@b egu n@to@show @his@cap acity@f” where space was replaced with “@” and the next segment starts with “or@”.

The corpus is segmented this way  $m$  times (where  $m$  is a parameter) and the  $m$  random segmentations are concatenated. The unit-context matrix is derived from this concatenated corpus.

Multiple random segmentation has two advantages. First, there is no redundancy since, in any given random segmentation, two ngrams do not overlap and are not subsequences of each other. Second, a single random segmentation would only cover a small part of the space of possible ngrams. For example, a random segmentation of “a rose is a rose is a rose” might be “[a ros][e is a ros][e is][a rose]”. This segmentation does not contain the segment “rose” and this part of the corpus can then not be exploited to learn a good embedding for the fourgram “rose”. However, with multiple random segmentation, it is likely that this part of the corpus does give rise to the segment “rose” in one of the segmentations and can contribute information to learning a good embedding for “rose”.

We took the idea of random segmentation from work on biological sequences (Asgari and Mofrad, 2015; Asgari and Mofrad, 2016). Such sequences have no delimiters, so they are a good model if

one believes that delimiter-based segmentation is problematic for text.

### 3.2 Ngram equivalence classes/Permutation

**Form-meaning homomorphism premise.** Nonsymbolic representation learning does not preprocess the training corpus by means of tokenization and considers many ngrams that would be ignored in tokenized approaches because they span token boundaries. As a result, the number of ngrams that occur in a corpus is an order of magnitude larger for tokenization-free approaches than for tokenization-based approaches. See supplementary for details.

We will see below that this sparseness impacts performance of nonsymbolic text representation negatively. We address sparseness by defining ngram equivalence classes. All ngrams in an equivalence class receive the same embedding.

The relationship between form and meaning is mostly arbitrary, but there are substructures of the ngram space and the embedding space that are systematically related by homomorphism. In this paper, **we will assume the following homomorphism:**

$$g_1 \sim_{\tau} g_2 \Leftrightarrow \vec{v}(g_1) \sim_{=} \vec{v}(g_2)$$

where  $g_1 \sim_{\tau} g_2$  iff  $\tau(g_1) = \tau(g_2)$  for string transduction  $\tau$  and  $\vec{v}(g_1) \sim_{=} \vec{v}(g_2)$  iff  $|\vec{v}(g_1) - \vec{v}(g_2)|_2 < \epsilon$ .

As a simple example consider a transduction  $\tau$  that deletes spaces at the beginning of ngrams, e.g.,  $\tau(@Mercedes) = \tau(Mercedes)$ . This is an example of a meaning-preserving  $\tau$  since for, say, English,  $\tau$  will not change meaning. We will propose a procedure for learning  $\tau$  below.

We define  $\sim_{=}$  as “closeness” – not as identity – because of estimation noise when embeddings are learned. We assume that there are no true synonyms and therefore the direction  $g_1 \sim_{\tau} g_2 \Leftarrow \vec{v}(g_1) \sim_{=} \vec{v}(g_2)$  also holds. For example, “car” and “automobile” are considered synonyms, but we assume that their embeddings are different because only “car” has the literary sense “chariot”. If they were identical, then the homomorphism would not hold since “car” and “automobile” cannot be converted into each other by any plausible meaning-preserving  $\tau$ .

**Learning procedure.** To learn  $\tau$ , we define three templates that transform one ngram into another: (i) replace character  $a_1$  with character  $a_2$ ,

(ii) delete character  $a_1$  if its immediate predecessor is character  $a_2$ , (iii) delete character  $a_1$  if its immediate successor is character  $a_2$ . The learning procedure takes a set of ngrams and their embeddings as input. It then exhaustively searches for all pairs of ngrams, for all pairs of characters  $a_1/a_2$ , for each of the three templates. When two matching embeddings exist, we compute their cosine. For example, for the operation “delete space before M”, an ngram pair from our embeddings that matches is “@Mercedes” / “Mercedes” and we compute its cosine. As the characteristic statistic of an operation we take the average of all cosines; e.g., for “delete space before M” the average cosine is .7435. We then rank operations according to average cosine and take the first  $N_o$  as the definition of  $\tau$  where  $N_o$  is a parameter. For characters that are replaced by each other (e.g., 1, 2, 3 in Table 1), we compute the equivalence class and then replace the learned operations with ones that replace a character by the canonical member of its equivalence class (e.g.,  $2 \rightarrow 1, 3 \rightarrow 1$ ).

**Permutation premise.** Tokenization algorithms can be thought of as assigning a particular function or semantics to each character and making tokenization decisions accordingly; e.g., they may disallow that a semicolon, the character “;”, occurs inside a token. If we want to learn representations from the data without imposing such hard constraints, then characters should not have any particular function or semantics. A consequence of this desideratum is that if any two characters are exchanged for each other, this should not affect the representations that are learned. For example, if we interchange space and “A” throughout a corpus, then this should have no effect on learning: what was the representation of “NATO” before, should now be the representation of “N TO”. We can also think of this type of permutation as a sanity check: it ensures we do not inadvertently make use of text preprocessing heuristics that are pervasive in NLP.<sup>2</sup>

Let  $A$  be the alphabet of a language, i.e., its set of characters,  $\pi$  a permutation on  $A$ ,  $C$  a corpus and  $\pi(C)$  the corpus permuted by  $\pi$ . For example, if  $\pi(a) = e$ , then all “a” in  $C$  are replaced with “e” in  $\pi(C)$ . **The learning procedure should learn**

<sup>2</sup>An example of such an inadvertent use of text preprocessing heuristics is that fastText seems to default to lowercase ngrams if embeddings of uppercase ngrams are not available: when fastText is trained on lowercased text and then applied to uppercased text, it still produces embeddings.

**identical equivalence classes on  $C$  and  $\pi(C)$ .** So, if  $g_1 \sim_\tau g_2$  after running the learning procedure on  $C$ , then  $\pi(g_1) \sim_\tau \pi(g_2)$  after running the learning procedure on  $\pi(C)$ .

This premise is motivated by our desire to come up with a general method that does not rely on specific properties of a language or genre; e.g., the premise rules out exploiting the fact through feature engineering that in many languages and genres, “c” and “C” are related. Such a relationship has to be learned from the data.

### 3.3 Experiments

We run experiments on  $C$ , a 3 gigabyte English Wikipedia corpus, and train word2vec skipgram (W2V, (Mikolov et al., 2013)) and fastText skipgram (FTX, (Bojanowski et al., 2016)) models on  $C$  and its derivatives. We randomly generate a permutation  $\pi$  on the alphabet and learn a transduction  $\tau$  (details below). In Table 2 (left), the columns “method”,  $\pi$  and  $\tau$  indicate the method used (W2V or FTX) and whether experiments in a row were run on  $C$ ,  $\pi(C)$  or  $\tau(\pi(C))$ . The values of “whitespace” are: (i) ORIGINAL (whitespace as in the original), (ii) SUBSTITUTE (what  $\pi$  outputs as whitespace is used as whitespace, i.e.,  $\pi^{-1}(\text{“ ”})$  becomes the new whitespace) and (iii) RANDOM (random segmentation with parameters  $m = 50, k_{\min} = 3, k_{\max} = 9$ ). Before random segmentation, whitespace is replaced with “@” – this character occurs rarely in  $C$ , so that the effect of conflating two characters (original “@” and whitespace) can be neglected. The random segmenter then indicates boundaries by whitespace – unambiguously since it is applied to text that contains no whitespace.

We learn  $\tau$  on the embeddings learned by W2V on the random segmentation version of  $\pi(C)$  (C-RANDOM in the table) as described in §3.2 for  $N_o = 200$ . Since the number of equivalence classes is much smaller than the number of ngrams,  $\tau$  reduces the number of distinct character ngrams from 758M in the random segmentation version of  $\pi(C)$  (C/D-RANDOM) to 96M in the random segmentation version of  $\tau(\pi(C))$  (E/F-RANDOM).

Table 1 shows a selection of the  $N_o$  operations. Throughout the paper, if we give examples from  $\pi(C)$  or  $\tau(\pi(C))$  as we do here, we convert characters back to the original for better readability. The two uppercase/lowercase conversions shown

substitution	$2 \rightarrow 1$	predeletion	$/r \rightarrow r$	postdeletion	$\ddagger@ \rightarrow \ddagger$
	$3 \rightarrow 1$		$@\ddagger \rightarrow \ddagger$		$e@ \rightarrow e$
	$:$		$@\ddagger \rightarrow \ddagger$		$l@ \rightarrow l$
	$;$		$@H \rightarrow H$		$m@ \rightarrow m$
	$E \rightarrow e$		$@I \rightarrow I$		$ml \rightarrow m$
	$C \rightarrow c$				

Table 1: String operations that on average do not change meaning. “@” stands for space.  $\ddagger$  is the left or right boundary of the ngram.

in the table ( $E \rightarrow e$ ,  $C \rightarrow c$ ) were the only ones that were learned (we had hoped for more). The post-deletion rule  $ml \rightarrow m$  usefully rewrites “html” as “htm”, but is likely to do more harm than good. We inspected all 200 rules and, with a few exceptions like  $ml \rightarrow m$ , they looked good to us.

**Evaluation.** We evaluate the three models on an entity typing task, similar to (Yaghoobzadeh and Schütze, 2015), but based on an entity dataset released by Xie et al. (2016) in which each entity has been assigned one or more types from a set of 50 types. For example, the entity “Harrison Ford” has the types “actor”, “celebrity” and “award winner” among others. We extract mentions from FACC (<http://lemurproject.org/clueweb12/FACC1>) if an entity has a mention there or we use the Freebase name as the mention otherwise. This gives us a data set of 54,334, 6085 and 6747 mentions in train, dev and test, respectively. Each mention is annotated with the types that its entity has been assigned by Xie et al. (2016). The evaluation has a strong cross-domain aspect because of differences between FACC and Wikipedia, the training corpus for our representations. For example, of the 525 mentions in dev that have a length of at least 5 and do not contain lowercase characters, more than half have 0 or 1 occurrences in the Wikipedia corpus, including many like “JOHNNY CARSON” that are frequent in other case variants.

Since our goal in this experiment is to evaluate tokenization-free learning, not tokenization-free utilization, we use a simple utilization baseline, the bag-of-ngram model (see §1). A mention is represented as the sum of all character ngrams that embeddings were learned for. Linear SVMs (Chang and Lin, 2011) are then trained, one for each of the 50 types, on train and applied to dev and test. Our evaluation measure is micro  $F_1$  on all typing decisions; e.g., one typing decision is:

“Harrison Ford” is a mention of type “actor”. We tune thresholds on dev to optimize  $F_1$  and then use these thresholds on test.

### 3.4 Results

Results are presented in Table 2 (left). Overall performance of FTX is higher than W2V in all cases. For ORIGINAL, FTX’s recall is a lot higher than W2V’s whereas precision decreases slightly. This indicates that FTX is stronger in both learning and application: in learning it can generalize better from sparse training data and in application it can produce representations for OOVs and better representations for rare words. For English, prefixes, suffixes and stems are of particular importance, but there often is not a neat correspondence between these traditional linguistic concepts and internal FTX representations; e.g., Bojanowski et al. (2016) show that “asphal”, “sphalt” and “phalt” are informative character ngrams of “asphaltic”.

Running W2V on random segmentations can be viewed as an alternative to the learning mechanism of FTX, which is based on character ngram cooccurrence; so it is not surprising that for RANDOM, FTX has only a small advantage over W2V.

For C/D-SUBSTITUTE, we see a dramatic loss in performance if tokenization heuristics are not used. This is not surprising, but shows how powerful tokenization can be.

C/D-ORIGINAL is like C/D-SUBSTITUTE except that we artificially restored the space – so the permutation  $\pi$  is applied to all characters except for space. By comparing C/D-ORIGINAL and C/D-SUBSTITUTE, we see that the space is the most important text preprocessing feature employed by W2V and FTX. If space is restored, there is only a small loss of performance compared to A/B-ORIGINAL. So text preprocessing heuristics other than whitespace tokenization in a narrow definition of the term (e.g., downcasing) do not seem to play a big role, at least not for our entity typing task.

For tokenization-free embedding learning on random segmentation, there is almost no difference between original data (A/B-RANDOM) and permuted data (C/D-RANDOM). This confirms that our proposed learning method is insensitive to permutations and makes no use of text preprocessing heuristics.

We achieve an additional improvement by applying the transduction  $\tau$ . In fact, FTX perfor-

		whitespace	ORIGINAL			SUBSTITUTE			RANDOM			query	neighbor	$r$	
		measure	$P$	$R$	$F_1$	$P$	$R$	$F_1$	$P$	$R$	$F_1$				
method	$\pi$	$\tau$

												10	ilitating	e-to-face	1

Table 2: Left: Evaluation results for named entity typing. Right: Neighbors of character ngrams. Rank  $r = 1/r = 2$ : nearest / second-nearest neighbor.

mance for F-RANDOM ( $F_1$  of .582) is better than tokenization-based W2V and FTX performance. Thus, our proposed method seems to be an effective tokenization-free alternative to tokenization-based embedding learning.

### 3.5 Analysis of ngram embeddings

Table 2 (right) shows nearest neighbors of ten character ngrams, for the A-RANDOM space. Queries were chosen to contain only alphanumeric characters. To highlight the difference to symbol-based representation models, we restricted the search to 9-grams that contained a delimiter at positions 3, 4, 5, 6 or 7.

Lines 1–4 show that “delimiter variation”, i.e., cases where a word has two forms, one with a delimiter, one without a delimiter, is handled well: “Abdulaziz” / “Abdul Azi”, “codenamed” / “code name”, “Quarterfinal” / “Quarter-Final”, “world-record” / “world-record”.

Lines 5–9 are cases of ambiguous or polysemous words that are disambiguated through “character context”. “stem”, “cell”, “rear”, “wheel”, “crash”, “land”, “scripts”, “through”, “downtown” all have several meanings. In contrast, the meanings of “stem cell”, “rear wheel”, “crash land”, “(write) scripts for” and “through downtown” are less ambiguous. A multiword recognizer may find the phrases “stem cell” and “crash land” automatically. But the examples of “scripts for” and “through downtown” show that what is accomplished here is not multiword detection, but a more general use of character context for disambiguation.

Line 10 shows that a 9-gram of “face-to-face” is the closest neighbor to a 9-gram of “facilitating”. This demonstrates that form and meaning sometimes interact in surprising ways. Facilitating a meeting is most commonly done face-to-face. It is not inconceivable that form – the shared trigram “fac” or the shared fourgram “faci” in “facilitate”

/ “facing” – is influencing meaning here in a way that also occurs historically in cases like “ear” ‘organ of hearing’ / “ear” ‘head of cereal plant’, originally unrelated words that many English speakers today intuit as one word.

## 4 Utilization: Tokenization-free representation of text

### 4.1 Methodology

The main text representation model that is based on ngram embeddings similar to ours is the **bag-of-ngram model**. A sequence of characters is represented by a single vector that is computed as the sum of the embeddings of all ngrams that occur in the sequence. In fact, this is what we did in the entity typing experiment. In most work on bag-of-ngram models, the sequences considered are words or phrases (see (Schuetze, 2016) for citations). In a few cases, the model is applied to longer sequences, including sentences and documents; e.g., (Schütze, 1992), (Wieting et al., 2016).

The basic assumption of the bag-of-ngram model is that sequence information is encoded in the character ngrams and therefore a “bag-of” approach (which usually throws away all sequence information) is sufficient. The assumption is not implausible: for most bags of character sequences, there is only a single way of stitching them together to one coherent sequence, so in that case information is not necessarily lost (although this is likely when embeddings are added). But the assumption has not been tested experimentally.

Here, we propose **position embeddings**, character-ngram-based embeddings that more fully preserve sequence information.<sup>3</sup> The simple idea is to represent each position as the sum of all ngrams that contain that position. When we set

<sup>3</sup>Position embeddings were independently proposed by Kalchbrenner et al. (2016), see Section 3.6 of their paper.

POS		$r = 1$	$r = 2$	$r = 3$	$r = 4$	$r = 5$
2	e	wealthies	accolades	bestselle	bestselli	Billboard
3	s	estseller	wealthies	bestselli	accolades	bestselle
15	o	fortnight	afternoon	overnight	allowance	Saturdays
16	n	fortnight	afternoon	Saturdays	Wednesday	magazines
23	o	superhero	ntagraphi	adventure	Astonishi	bestselli
24	m	superhero	ntagraphi	anthology	Daredevil	Astonishi

30	o	anthology	paperback	tagraphic	Lovecraft	agraphics
34	u	antagraph	agraphics	paperback	hardcover	ersweekly
35	b	ublishing	ublishers	ublicatio	antagraph	aperbacks

Table 3: Nearest ngram embeddings (rank  $r \in [1, 5]$ ) of the position embeddings for “POS”, the positions 2/3 (best), 15/16 (monthly), 23/24 (comic), 29/30 (book) and 34/35 (publications) in the Wikipedia excerpt “best-selling monthly comic book publications sold in North America”

$k_{\min} = 3$ ,  $k_{\max} = 9$ , this means that the position is the sum of  $(\sum_{3 \leq k \leq 9} k)$  ngram embeddings (if all of these ngrams have embeddings, which generally will be true for some, but not for most positions). A sequence of  $n$  characters is then represented as a sequence of  $n$  such position embeddings.

## 4.2 Experiments

We again use the embeddings corresponding to A-RANDOM in Table 2. We randomly selected 2,000,000 contexts of size 40 characters from Wikipedia. We then created a noise context for each of the 2,000,000 contexts by replacing one character at position  $i$  ( $15 \leq i \leq 25$ , uniformly sampled) with space (probability  $p = .5$ ) or a random character otherwise. Finally, we selected 1000 noise contexts randomly and computed their nearest neighbors among the 4,000,000 contexts (excluding the noise query). We did this in two different conditions: for a bag-of-ngram representation of the context (sum of all character ngrams) and for the concatenation of 11 position embeddings, those between 15 and 25. Our evaluation measure is mean reciprocal rank of the clean context corresponding to the noise context. This simulates a text denoising experiment: if the clean context has rank 1, then the noisy context can be corrected.

Table 4 shows that sequence-preserving position embeddings perform better than bag-of-

	bag-of-ngram	position embeddings
MRR	.64	.76

Table 4: Mean reciprocal rank of text denoising experiment for bag-of-ngram text representation and position embedding text representation

	exchange@f (in exchange for)	ic@exchang (many contexts)	ing@exchan (many contexts)
exchange@f	1.000	0.008	-0.056
ic@exchang	0.008	1.000	0.108
ing@exchan	-0.056	0.108	1.000

	xchange@ra (exchange rates)	ival@rates (survival rates)	rime@rates (crime rates)
xchange@ra	1.000	0.036	0.050
ival@rates	0.036	1.000	0.331
rime@rates	0.050	0.331	1.000

Table 6: Cosine similarity of ngrams that cross word boundaries and disambiguate polysemous words. The tables show three disambiguating ngrams for “exchange” and “rates” that have different meanings as indicated by low cosine similarity. In phrases like “floating exchange rates” and “historic exchange rates”, disambiguating ngrams overlap. Parts of the word “exchange” are disambiguated by preceding context (ic@exchang, ing@exchan) and parts of “exchange” provide context for disambiguating “rates” (xchange@ra).

ngram representations.

Table 5 shows an example of a context in which position embeddings did better than bag-of-ngrams, demonstrating that sequence information is lost by bag-of-ngram representations, in this case the exact position of “Seahawks”.

Table 3 gives further intuition about the type of information position embeddings contain, showing the ngram embeddings closest to selected position embeddings; e.g., “estseller” (the first 9-gram on the line numbered 3 in the table) is closest to the embedding of position 3 (corresponding to the first “s” of “best-selling”). The kNN search space is restricted to alphanumeric ngrams.

## 5 Discussion

**Single vs. multiple segmentation.** The motivation for multiple segmentation is *exhaustive cov-*

	rep. space	similarity	$r$	left context	center	right context
1	correct			s and Seattle S	eahawks th	at led to publi
2	noise (query)			s and Seattle S	eahawks t	at led to publi
3	position-emb	.761	1	s and Seattle S	eahawks th	at led to publi
4	bag-of-ngram	.904	1	arted 15 games	fsr the Se	ahawks, leading
5	bag-of-ngram	.864	6	s and Seattle S	eahawks th	at led to publi

Table 5: Illustration of the result in Table 4. “rep. space” = “representation space”. We want to correct the error in the corrupted “noise” context (line 2) and produce “correct” (line 1). The nearest neighbor to line 2 in position-embedding space is the correct context (line 3,  $r = 1$ ). The nearest neighbor to line 2 in bag-of-ngram space is incorrect (line 4,  $r = 1$ ) because the precise position of “Seahawks” in the query is not encoded. The correct context in bag-of-ngram space is instead at rank  $r = 6$  (line 5). “similarity” is average cosine (over eleven position embeddings) for position embeddings.

erage of the space of possible segmentations. An alternative approach would be to attempt to find a single optimal segmentation.

Our intuition is that in many cases *overlapping segments contain complementary information*. Table 6 gives an example. Historic exchange rates are different from floating exchange rates and this is captured by the low similarity of the ngrams `ic@exchang` and `ing@exchan`. Also, the meaning of “historic” and “floating” is non-compositional: these two words take on a specialized meaning in the context of exchange rates. The same is true for “rates”: its meaning is not its general meaning in the compound “exchange rates”. Thus, we need a representation that contains overlapping segments, so that “historic” / “floating” and “exchange” can disambiguate each other in the first part of the compound and “exchange” and “rates” can disambiguate each other in the second part of the compound. A single segmentation cannot capture these overlapping ngrams.

**What text-type are tokenization-free approaches most promising for?** The reviewers thought that language and text-type were badly chosen for this paper. Indeed, a morphologically complex language like Turkish and a noisy text-type like Twitter would seem to be better choices for a paper on robust text representation.

However, robust word representation methods like FTX are effective for *within-token* generalization, in particular, effective for both complex morphology and OOVs. If linguistic variability and noise only occur on the token level, then a tokenization-free approach has fewer advantages.

On the other hand, the foregoing discussion of *cross-token* regularities and disambiguation applies to well-edited English text as much as it does to other languages and other text-types as the example of “exchange” shows (which is dis-

ambiguated by prior context and provides disambiguating context to following words) and as is also exemplified by lines 5–9 in Table 2 (right).

Still, this paper does not directly evaluate the different contributions that within-token character ngram embeddings vs. cross-token character ngram embeddings make, so this is an open question. One difficulty is that few corpora are available that allow the separate evaluation of white-space tokenization errors; e.g., OCR corpora generally do not distinguish a separate class of white-space tokenization errors.

**Position embeddings vs. phrase/sentence embeddings.** Position embeddings may seem to stand in opposition to phrase/sentence embeddings. For many tasks, we need a fixed length representation of a longer sequence; e.g., sentiment analysis models compute a fixed-length representation to classify a sentence as positive / negative.

To see that position embeddings are compatible with fixed-length embeddings, observe first that, in principle, there is *no difference between word embeddings and position embeddings* in this respect. Take a sequence that consists of, say, 6 words and 29 characters. The initial representation of the sentence has length 6 for word embeddings and length 29 for position embeddings. In both cases, we need a model that reduces the variable length sequence into a fixed length vector at some intermediate stage and then classifies this vector as positive or negative. For example, both word and position embeddings can be used as the input to an LSTM whose final hidden unit activations are a fixed length vector of this type.

So assessing position embeddings is not a question of variable-length vs. fixed-length representations. Word embeddings give rise to variable-length representations too. The question is solely whether the position-embedding representation is

a more effective representation.

A more specific form of this argument concerns architectures that compute fixed-length representations of subsequences on intermediate levels, e.g., CNNs. The difference between position-embedding-based CNNs and word-embedding-based CNNs is that the former have access to a *vastly increased range of subsequences*, including substrings of words (making it easier to learn that “exchange” and “exchanges” are related) and cross-token character strings (making it easier to learn that “exchange rate” is noncompositional). Here, the questions are: (i) how useful are subsequences made available by position embeddings and (ii) is the increased level of noise and decreased efficiency caused by many useless subsequences worth the information gained by adding useful subsequences.

#### **Independence of training and utilization.**

We note that our proposed training and utilization methods are completely independent. Position embeddings can be computed from any set of character-ngram-embeddings (including FTX) and our character ngram learning algorithm could be used for applications other than position embeddings, e.g., for computing word embeddings.

**Context-free vs. context-sensitive embeddings.** Word embeddings are context-free: a given word  $w$  like “king” is represented by the same embedding independent of the context in which  $w$  occurs. Position embeddings are context-free as well: if the maximum size of a character ngram is  $k_{\max}$ , then the position embedding of the center of a string  $s$  of length  $2k_{\max} - 1$  is the same independent of the context in which  $s$  occurs.

It is conceivable that text representations could be context-sensitive. For example, the hidden states of a character language model have been used as a kind of nonsymbolic text representation (Chrupala, 2013; Evang et al., 2013; Chrupala, 2014) and these states are context-sensitive. However, such models will in general be a second level of representation; e.g., the hidden states of a character language model generally use character embeddings as the first level of representation. Conversely, position embeddings can also be the basis for a context-sensitive second-level text representation. We have to start somewhere when we represent text. Position embeddings are motivated by the desire to provide a representation that can be computed easily and quickly (i.e., without taking

context into account), but that on the other hand is much richer than the symbolic alphabet.

**Processing text vs. speech vs. images.** Gillick et al. (2016) write: “It is worth noting that noise is often added . . . to images . . . and speech where the added noise does not fundamentally alter the input, but rather blurs it. [bytes allow us to achieve] something like blurring with text.” It is not clear to what extent blurring on the byte level is useful; e.g., if we blur the bytes of the word “university” individually, then it is unlikely that the noise generated is helpful in, say, providing good training examples in parts of the space that would otherwise be unexplored. In contrast, the text representation we have introduced in this paper can be blurred in a way that is analogous to images and speech. Each embedding of a position is a vector that can be smoothly changed in every direction. We have showed that the similarity in this space gives rise to natural variation.

#### **Prospects for completely tokenization-free processing.**

We have focused on whitespace tokenization and proposed a whitespace-tokenization-free method that computes embeddings of higher quality than tokenization-based methods. However, there are many properties of edited text beyond whitespace tokenization that a complex rule-based tokenizer exploits. In a small explorative experiment, we replaced all non-alphanumeric characters with whitespace and repeated experiment A-ORIGINAL for this setting. This results in an  $F_1$  of .593, better by .01 than the best tokenization-free method. This illustrates that there is still a lot of work to be done before we can obviate the need for tokenization.

## **6 Conclusion**

We introduced the first generic text representation model that is completely nonsymbolic, i.e., it does not require the availability of a segmentation or tokenization method that identifies words or other symbolic units in text. This is true for the training of the model as well as for applying it when computing the representation of a new text. In contrast to prior work that has assumed that the sequence-of-character information captured by character ngrams is sufficient, position embeddings also capture sequence-of-ngram information. We showed that our model performs better than prior work on entity typing and text denoising.

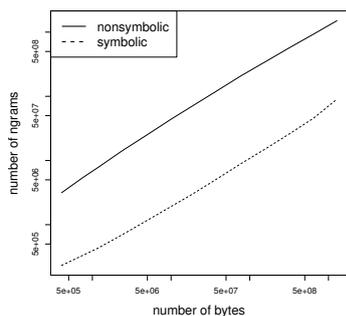

Figure 1: The graph shows how many different character ngrams ( $k_{\min} = 3$ ,  $k_{\max} = 10$ ) occur in the first  $n$  bytes of the English Wikipedia for symbolic (tokenization-based) vs. nonsymbolic (tokenization-free) processing. The number of ngrams is an order of magnitude larger in the nonsymbolic approach. We counted all segments, corresponding to  $m = \infty$ . For the experiments in the paper ( $m = 50$ ), the number of nonsymbolic character ngrams is smaller.

## A Supplementary material

### A.1 Related work

The related work section appears in the long version of this paper (Schuetze, 2016).

### A.2 Acknowledgments

This work was supported by DFG (SCHUE 2246/10-1) and Volkswagenstiftung. We are grateful for their comments to: the anonymous reviewers, Ehsan Asgari, Annemarie Friedrich, Helmut Schmid, Martin Schmitt and Yadollah Yaghoobzadeh.

### A.3 Sparseness in tokenization-free approaches

Nonsymbolic representation learning does not preprocess the training corpus by means of tokenization and considers many ngrams that would be ignored in tokenized approaches because they span token boundaries. As a result, the number of ngrams that occur in a corpus is an order of magnitude larger for tokenization-free approaches than for tokenization-based approaches. See Figure 1.

### A.4 Experimental settings

**W2V hyperparameter settings.** size of word vectors: 200, max skip length between words: 5, threshold for occurrence of words: 0, hierarchical softmax: 0, number of negative examples: 5,

threads: 50, training iterations: 1, min-count: 5, starting learning rate: .025, classes: 0

**FTX hyperparameter settings.** learning rate: .05, lrUpdateRate: 100, size of word vectors: 200, size of context window: 5, number of epochs: 1, minimal number of word occurrences: 5, number of negatives sampled: 5, max length of word ngram: 1, loss function: ns, number of buckets: 2,000,000, min length of char ngram: 3, max length of char ngram: 6, number of threads: 50, sampling threshold: .0001

We ran some experiments with more epochs, but this did not improve the results.

### A.5 Other hyperparameters

We did not tune  $N_o = 200$ , but results are highly sensitive to the value of this parameter. If  $N_o$  is too small, then beneficial conflation (collapse punctuation marks, replace all digits with one symbol) are not found. If  $N_o$  is too large, then precision suffers – in the extreme case all characters are collapsed into one.

We also did not tune  $m = 50$ , but we do not consider results to be very sensitive to the value of  $m$  if it is reasonably large. Of course, if a larger range of character ngram lengths is chosen, i.e., a larger interval  $[k_{\min}, k_{\max}]$ , then at some point  $m = 50$  will not be sufficient and possible segmentations would not be covered well enough in sampling.

The type of segmentation used in multiple segmentation can also be viewed as a hyperparameter. An alternative to random segmentation would be exhaustive segmentation, but a naive implementation of that strategy would increase the size of the training corpus by several orders of magnitude. Another alternative is to choose one fixed size, e.g., 4 or 5 (similar to (Schütze, 1992)). Many of the nice disambiguation effects we see in Table 2 (right) and in Table 6 would not be possible with short ngrams. On the other hand, a fixed ngram size that is larger, e.g., 10, would make it difficult to get 100% coverage: there would be positions for which no position embedding can be computed.

# Fine-Grained Entity Type Classification by Jointly Learning Representations and Label Embeddings

## Abstract

Fine-grained entity type classification (FETC) is the task of classifying an entity mention to a broad set of types. Distant supervision paradigm is extensively used to generate training data for this task. However, generated training data assigns same set of labels to every mention of an entity without considering its local context. Existing FETC systems have two major drawbacks: assuming training data to be noise free and use of hand crafted features. Our work overcomes both drawbacks. We propose a neural network model that jointly learns entity mentions and their context representation to eliminate use of hand crafted features. Our model treats training data as noisy and uses non-parametric variant of hinge loss function. Experiments show that the proposed model outperforms previous state-of-the-art methods on two publicly available datasets, namely FIGER(GOLD) and BBN with an average relative improvement of 2.69% in micro-F1 score. Knowledge learnt by our model on one dataset can be transferred to other datasets while using same model or other FETC systems. These approaches of transferring knowledge further improve the performance of respective models.

## 1 Introduction

Entity type classification is the task for assigning types or labels such as *organization*, *location* to entity mentions in a document. This classification is useful for many natural language processing (NLP) tasks such as relation extraction (Mintz et al., 2009), machine translation (Koehn et al.,

2007), question answering (Lin et al., 2012) and knowledge base construction (Dong et al., 2014).

There has been considerable amount of work on Named Entity Recognition (NER) (Collins and Singer, 1999; Tjong Kim Sang and De Meulder, 2003; Ratnov and Roth, 2009; Manning et al., 2014), which classifies entity mentions into a small set of mutually exclusive types, such as *Person*, *Location*, *Organization* and *Misc*. However, these types are not enough for some NLP applications such as relation extraction, knowledge base construction (KBC) and question answering. In relation extraction and KBC, knowing fine-grained types for entities can significantly increase the performance of the relation extractor (Ling and Weld, 2012; Koch et al., 2014; Mitchell et al., 2015) since this helps in filtering out candidate relation types that do not follow the type constrain. Fine-grained entity types provide additional information while matching questions to its potential answers and significantly improves performance (Dong et al., 2015). For example, Li and Roth (2002) rank questions based on their expected answer types (will the answer be *food*, *vehicle* or *disease*).

Typically, FETC systems use over hundred labels, arranged in a hierarchical structure. An important aspect of FETC is that based on local context, two different mentions of same entity can have different labels. We illustrate this through an example in Figure 1. All three sentences *S1*, *S2*, and *S3* mention same entity *Barack Obama*. However, looking at the context, we can infer that *S1* mentions Obama as a *person/author*, *S2* mentions Obama only as a *person*, and *S3* mentions Obama as a *person/politician*.

Available training data for FETC has noisy labels. Creating manually annotated training data for FETC is time consuming, expensive, and error prone. Note that, a human annotator will

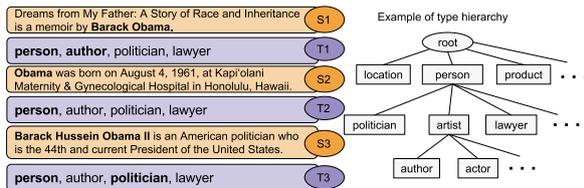

Figure 1: Noise introduced via distant supervision process. S1-S3 indicates sentences where only a subset of labels for entity mention (bold typeface) are relevant given context, highlighted in T1-T3.

have to assign a subset of correct labels from a set of around hundred labels for each entity mention in the corpus. Existing FETC systems use distant supervision paradigm (Craven and Kumlien, 1999) to automatically generate training data. Distant supervision maps each entity in the corpus to knowledge bases such as Freebase (Bollacker et al., 2008), DBpedia (Auer et al., 2007), YAGO (Suchanek et al., 2007). This method assigns same set of labels to all mentions of an entity across the corpus. For example, *Barack Obama* is a person, politician, lawyer, and author. If a knowledge base has these four matching labels for Barack Obama, then distant supervision assigns all of them to every mention of Barack Obama. Training data generated with distant supervision will fail to distinguish between mentions of Barack Obama in sentences *S1*, *S2*, and *S3*.

Existing FETC systems have one or both of following drawbacks:

1. Assuming training data to be noise free (Ling and Weld, 2012; Yosef et al., 2012; Yogatama et al., 2015; Shimaoka et al., 2016)
2. Use of hand crafted features (Ling and Weld, 2012; Yosef et al., 2012; Yogatama et al., 2015; Ren et al., 2016)

We have observed that for real world datasets, more than twenty five percent of training data has noisy labels. First drawback propagates this noise in training data to the FETC model. To extract hand crafted features various NLP tools are used. Since errors inevitably exist in such tools, the second drawback propagates errors of these tools to FETC model.

We propose a neural network based model to overcome the two drawbacks of existing FETC systems. First, we separate training data into *clean* and *noisy* partitions using the same method as in AFET system (Ren et al., 2016). For these parti-

tions, we use simple yet effective non-parametric variant of hinge loss function while training. To avoid use of hand crafted features, we learn representations for given entity mention and its context.

Additionally, we investigate effectiveness of using transfer learning (Pratt, 1993) for FETC task both at feature and model level. We show that feature level transfer learning can be used to improve performance of other FETC system such as AFET, by up to 4.5% in micro-F1 score. Similarly, model level transfer learning can be used to improve performance of the same model using different dataset by up to 3.8% in micro-F1 score.

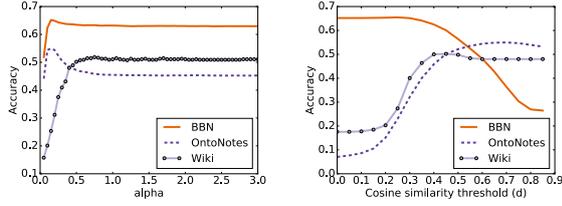

Our contributions can be summarized as follows:

1. We propose a simple neural network model that learns representations for entity mention and its context, and incorporate noisy label information using a variant of non-parametric hinge loss function. Experimental results on two publicly available datasets demonstrate the effectiveness of proposed model, with an average relative improvement of 2.69% in micro-F1 score.
2. We investigate the use of feature level and model level transfer-learning strategies in the domain of the FETC task. The proposed transfer learning strategies further improve the state-of-the-art on BBN dataset by 3.8% in micro-F1 score.

## 2 Related Work

Ling et al. (2012) proposed the first system for FETC task, which used 112 overlapping labels. They used linear classifier perceptron for multi-label classification. Yosef et al. (2012) used multiple binary SVM classifiers in a hierarchy, to classify an entity mention to a set of 505 types. While the initial work assumed that all labels present in a training dataset for an entity mention are correct, Gillick et al. (2014) introduced context dependent FETC and proposed a set of heuristics for pruning labels that might not be relevant given the entity mention's local context. Yogatama et al. (2015) proposed an embedding based model where user-defined features and labels were embedded into a low dimensional feature space to facilitate information sharing among labels.

Shimaoka et al. (2016) proposed an attentive neural network model that used LSTMs to encode entity mention's context and used an atten-

(a)  $\alpha$  models label-label correlation. Higher the  $\alpha$ , lower above this threshold are predicted as positive correlation labels.

Figure 2: Effect of change of parameters on AFET’s performance.

tion mechanism to allow the model to focus on relevant expressions in the entity mention’s context. However, the model assumed that all labels obtained via distant supervision are correct. In contrast, our model does not assume that all labels are correct. To learn entity representation, we propose a scheme which is simpler yet more effective.

Most recently, Ren et al. (2016) have proposed AFET, an FETC system. AFET separates the loss function for *clean* and *noisy* entity mentions. AFET uses label-label correlation information obtained by given data in its parametric loss function (model parameter  $\alpha$ ). During inference, AFET uses a threshold to separate positive types from negative types (similarity threshold parameter  $d$ ). However, AFET’s loss function is sensitive to change in parameters, which are data dependent. Figure 2 shows the effect of parameter  $\alpha$  and  $d$ , on AFET performance evaluated on different datasets. In contrast, our model uses a simple yet effective variant of hinge loss function. This function does not need to tune the similarity threshold.

Transfer learning is well applied to many NLP applications, such as cross-domain document classification (Shi et al., 2010), multi-lingual word clustering (Täckström et al., 2012) and sentiment classification (Mou et al., 2016). Initialization of word vectors with pre-trained word vectors in neural network models can be considered as one of the best example of transfer learning in NLP. Wang et al. (2015) provide a broad overview of transfer learning techniques used for language processing.

### 3 The Proposed Model

#### 3.1 Problem description

Our task is to automatically classify type information of entity mentions present in natural language

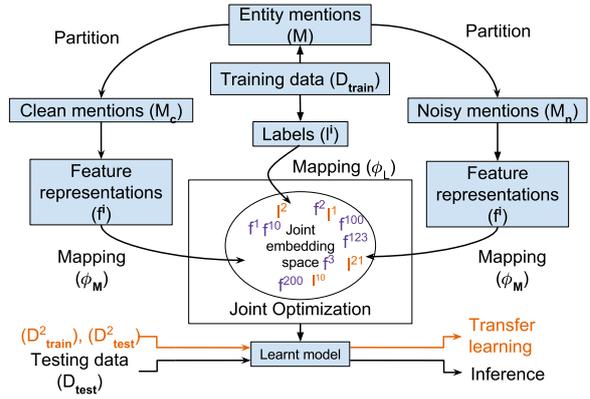

Figure 3: The system overview.

sentences. Figure 3 shows a general overview of our proposed approach.

**Input:** The input to the model is a training and testing corpus consisting of a set of sentences on which entity mentions have been identified. In training corpus, every entity mention will have corresponding labels according to a given hierarchy. Formally, a training corpus  $\mathcal{D}_{train}$  consists of a set of sentences,  $\mathcal{S} = \{s^i\}_{i=1}^N$ . Each sentence  $s^i$  will have one or more entity mentions denoted by  $m_{j,k}^i$ , where  $j$  and  $k$  denotes indices of start and end tokens, respectively. Set  $\mathcal{M}$  consists of all the entity mentions  $m_{j,k}^i$ . For every entity mention  $m_{j,k}^i$ , there will be a corresponding label vector  $l_{j,k}^i \in \{0, 1\}^K$ , which is a binary vector, where  $l_{j,k}^i = 1$  if  $t^{th}$  type is true otherwise it will be zero.  $K$  denotes the total number of labels in a given hierarchy  $\Psi$ . Testing corpus  $\mathcal{D}_{test}$  will only contain sentences and entity mentions.

**Output:** For entity mentions in testing corpus  $\mathcal{D}_{test}$ , predict their corresponding labels.

#### 3.2 Training set partition

Similar to AFET, we partition the mention set  $\mathcal{M}$  of training corpus  $\mathcal{D}_{train}$  into two parts, a set  $\mathcal{M}_c$ , consisting only of *clean* entity mentions and a set  $\mathcal{M}_n$ , consisting only of *noisy* entity mentions. An entity mention  $m_{j,k}^i$  is said to be *clean* if its labels  $l_{j,k}^i$  belong to only a single path (not necessary to be leaf) in the hierarchy  $\Psi$ , that is its labels are not ambiguous; otherwise, it is *noisy*. For example, as per hierarchy given in figure 1, an entity mention with labels *person*, *artist* and *politician* will be considered as *noisy*, whereas entity mention with labels *person*, *artist* and *actor* will be considered as *clean*.

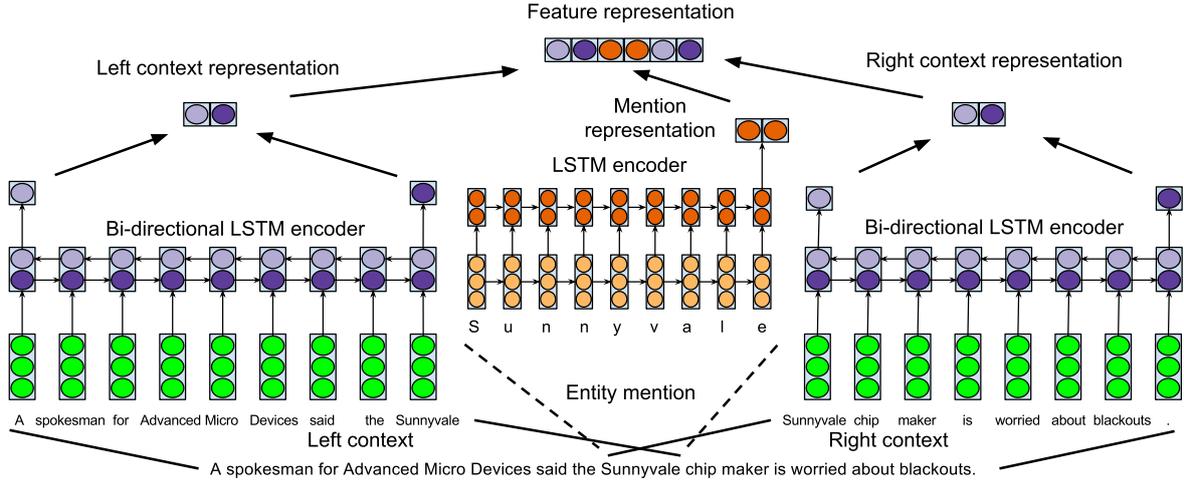

Figure 4: The architecture of the proposed model.

### 3.3 Feature representations

**Mention representation:** This representation captures information about entity mention’s morphology and orthography. We decompose an entity mention into character sequence, and use a vanilla LSTM encoder (Hochreiter and Schmidhuber, 1997) to encode character sequences to a fixed dimensional vector. Formally, for entity mention  $m_{j,k}^i$ , we decompose it into a sequence of character tokens  $c_{j,k_1}^i, c_{j,k_2}^i, \dots, c_{j,k_{|m_{j,k}^i|}}^i$ , where  $|m_{j,k}^i|$  denotes the total number of characters present in the entity mention. For entity mention containing multiple tokens, we join these tokens with a space in between tokens. Every character will have corresponding vector representation in a lookup table for characters. The character sequence is then fed one by one to a LSTM encoder, and the final output is used as a feature representation for entity mention  $m_{j,k}^i$ . We denote this process by a function  $F_m : \mathcal{M} \rightarrow \mathbb{R}^{D_m}$ , where  $D_m$  is the number of dimensions for mention representation. The whole process is illustrated in figure 4 (Mention representation).

**Context representation:** This representation captures information about the context surrounding the entity mention. Context representation is further divided into two parts, left and right context representation. The left context consists of a sequence of tokens within a sentence from the start of a sentence till the last token of entity mention. The right context consists of a sequence

of tokens from the start of entity mention till the end of a sentence. We use bi-directional LSTM encoders (Graves et al., 2013) to encode token level sequences of both context to a fixed dimensional vector. Formally, for an entity mention  $m_{j,k}^i$  present in a sentence  $s^i$ , decompose  $s^i$  into a sequence of tokens  $s_1^i, s_2^i, \dots, s_k^i$  for the left context, and  $s_j^i, s_{j+1}^i, \dots, s_{|s^i|}^i$  for the right context, where  $|s^i|$  denotes the number of tokens in the sentence. Every token will have a corresponding vector representation in a lookup tables for token. The token sequence is then fed one by one to a bi-directional LSTM encoder, and the final output will be used as feature representation. We denote this whole process by function  $F_{lc} : (\mathcal{M}, \mathcal{S}) \rightarrow \mathbb{R}^{D_{lc}}$  for computing left context and  $F_{rc} : (\mathcal{M}, \mathcal{S}) \rightarrow \mathbb{R}^{D_{rc}}$  for computing right context.  $D_{lc}$  and  $D_{rc}$  are the number of dimensions for the left context and the right context representation, respectively. The whole process is illustrated in figure 4 (Left and right context representation).

The context representation described above is slightly different from what was proposed in (Shimaoka et al., 2016), here we include entity mention tokens within both left and right context, to explicitly encode context relative to an entity mention.

In the end, we concatenate entity mention and its context representation into a single  $D_f$  dimensional vector, where  $D_f = D_m + D_{lc} + D_{rc}$ . This complete process is denoted by a function

$F : (\mathcal{M}, \mathcal{S}) \rightarrow \mathbb{R}^{D_f}$  given by:

$$F(m_{j,k}^i, s^i) = F_m(m_{j,k}^i) \oplus F_{lc}(m_{j,k}^i, s^i) \oplus F_{rc}(m_{j,k}^i, s^i) \quad (1)$$

where  $\oplus$  denotes vector concatenation. For brevity, we will now omit the use of subscript  $j, k$  from  $m_{j,k}^i$  and  $l_{j,k}^i$ , and will use  $f^i$  to denote feature representation for entity mention and its context obtained via equation 1.

### 3.4 Feature and label embeddings

Similar to Yogatama et al. (2015) and Ren et al. (2016), we embed feature representations and labels in a same dimensional space such that an object is embedded closer to the objects that share similar types than the objects that do not. Formally, we are trying to learn linear mapping functions  $\phi_{\mathcal{M}} : \mathbb{R}^{D_f} \rightarrow \mathbb{R}^{D_e}$  and  $\phi_{\mathcal{L}} : \mathbb{R}^{D_K} \rightarrow \mathbb{R}^{D_e}$ , where  $D_e$  is the size of embedding space. These mappings are given by:

$$\phi_{\mathcal{M}}(f^i) = f^{iT} U; \quad \phi_{\mathcal{L}}(l_t^i) = l_t^{iT} V \quad (2)$$

where,  $U \in \mathbb{R}^{D_f \times D_e}$  and  $V \in \mathbb{R}^{D_K \times D_e}$  are projection matrices for features representations and type labels respectively and  $l_t^i$  is one-hot vector representation for label  $t$ .

We assign a score to each label type  $t$  and feature vector as a dot product of their embeddings. Formally, we denote a score as:

$$s(f^i, l_t^i) = \phi_{\mathcal{M}}(f^i) \cdot \phi_{\mathcal{L}}(l_t^i) \quad (3)$$

### 3.5 Optimization

We use two different loss functions to model *clean* and *noisy* entity mentions. For *clean* entity mentions, we use a hinge loss function. The intuition is simple: maintain a margin, centered at zero, between positive and negative type scores. The scores are computed by similarity between an entity mention and label types (eq. 3). Hinge loss function has two advantages. First, it intuitively separates positive and negative labels during inference. Second, it is independent of data dependent parameter. Formally, for a given entity mention  $m^i$  and its label  $l^i$  we compute the associated loss as given by:

$$L_c(m^i, l^i) = \sum_{t \in \gamma} \max(0, 1 - s(m^i, l_t^i)) + \sum_{t \in \bar{\gamma}} \max(0, 1 + s(m^i, l_t^i)) \quad (4)$$

where  $\gamma$  and  $\bar{\gamma}$  are set of indices that have positive and negative labels respectively.

For *noisy* entity mentions, we propose a variant of a hinge loss where, like  $L_c$ , score for all negative labels should go below  $-1$ . However, for positive labels, as we don't know which labels are relevant to entity mention's local context, we propose that the maximum score from the set of given positive labels should be greater than one. This maintains a margin between all negative types and the most relevant positive type. Formally, *noisy* label loss,  $L_n$  is defined as:

$$L_n(m^i, l^i) = \sum_{t \in \bar{\gamma}} \max(0, 1 + s(m^i, l_t^i)) + \max(0, 1 - s(m^i, l_{t^*}^i)); \quad t^* = \arg \max_{t \in \gamma} s(m^i, l_t^i) \quad (5)$$

Again, using this loss function makes it intuitive to set a threshold of zero during inference.

These loss functions are different from the loss functions used in (Yogatama et al., 2015; Ren et al., 2016) in a way that, we make strict absolute criteria to distinguish between positive and negative labels. Whereas in (Yogatama et al., 2015; Ren et al., 2016) positive labels should have a higher score than negative labels. As their scoring is relative, the final result varies on the threshold used to separate positive and negative labels.

To train the partitioned dataset together, we formulate the joint objective problem as:

$$\min_{\theta} O = \sum_{m \in \mathcal{M}_c} L_c(m, l) + \sum_{m \in \mathcal{M}_n} L_n(m, l) \quad (6)$$

where  $\theta$  is the collection of all model parameters that needs to be learned. To jointly optimize the objective  $O$ , we use Adam (Kingma and Ba, 2014), a stochastic gradient-based optimization algorithm.

### 3.6 Inference

For every entity mention in set  $\mathcal{M}$  from  $\mathcal{D}_{test}$ , we perform a top-down search in the given type hierarchy  $\Psi$ , and estimate the correct type path  $\Psi_*$ . Starting from the tree root, we recursively compute the best type among node's children by computing its score with obtained feature representations. We select the node that has maximum score among other nodes. We continue this process till a leaf node is encountered or the score associated

with a node falls below an absolute threshold zero. The threshold is fixed across all datasets used.

### 3.7 Transfer learning

We want to investigate, whether the feature representations learnt for an entity mention are useful. We study what contribution these feature representations make to an existing feature engineering based method such as AFET. We learn the proposed model on one training dataset, namely Wiki dataset, which has the highest number of entity mentions among other datasets and use this model to generate representations that is  $F(m_{j,k}^i, s^i)$  for another training and testing data. These representations, which are  $D_f$  dimensional vectors, are used as feature for an existing state-of-the-art model, AFET, in place of the hand-crafted features that were originally used. AFET model is then trained using these feature representations. We call this as feature level transfer learning. On the other hand, we also evaluate model level transfer learning, where we initialize weights of LSTM encoders for a new dataset with the weights learnt from the model trained on another dataset, namely Wiki dataset.

## 4 Experiments

### 4.1 Datasets used

We evaluate the proposed model on three publicly available datasets, provided in a pre-processed tokenized format by Ren et al. (2016). Statistics of the datasets used in this work are shown in Table 1. The details of the datasets are as follows:

**Wiki/FIGER(GOLD):** The training data consists of Wikipedia sentences and was automatically generated in distant supervision paradigm, by mapping hyperlinks in Wikipedia articles to Freebase. The test data, mainly consisting of sentences from news reports, was manually annotated as described in (Ling and Weld, 2012).

**OntoNotes:** OntoNotes dataset consists of sentences from newswire documents present in OntoNotes text corpus (Weischedel et al., 2013). DBpedia spotlight (Daiber et al., 2013) was used to automatically link entity mention in sentences to Freebase. For this corpus, manually annotated test data was shared by Gillick et al. (2014).

**BBN:** BBN dataset consists of sentences from Wall Street Journal articles and is completely manually annotated (Weischedel and Brunstein, 2005). Please refer to (Ren et al., 2016) for more details

Datasets	Wiki/FIGER(GOLD)	OntoNotes	BBN
# types	128	89	47
# training mentions	2690286	220398	86078
# testing mentions	563	9603	13187
% clean training mentions	64.58	72.61	75.92
% clean testing mentions	88.28	94.00	100
% pronominal testing mentions <sup>1</sup>	0.00	6.78	0.00
Max hierarchy depth	2	3	2

Table 1: Statistics of the datasets used in this work.

of the datasets.

### 4.2 Evaluation settings

#### 4.2.1 Baselines

We compared the proposed model with state-of-the-art entity classification methods<sup>2</sup>: (1) **FIGER** (Ling and Weld, 2012); (2) **HYENA** (Yosef et al., 2012); (3) **AFET-NoCo** (Ren et al., 2016): AFET without data based label-label correlation modeled in loss function; (4) **AFET-CoH** (Ren et al., 2016): AFET with hierarchy based label-label correlation modeled in loss function; (5) **AFET** (Ren et al., 2016); (6) **Attentive** (Shimaoka et al., 2016): An attentive neural network based model.

We compare these baselines with variants of our proposed model: (1) **our**: complete model; (2) **our-AIIC** assuming all mentions are *clean*; (3) **our-NoM** without mention representation.

#### 4.2.2 Experimental setup

We use Accuracy or Strict-F1 score, Macro-averaged F1 score, and Micro-averaged F1 score as metrics for evaluation. Existing methods for FETC use same measures (Ling and Weld, 2012; Yogatama et al., 2015; Shimaoka et al., 2016; Ren et al., 2016). We removed entity mentions that do not have any label in training as well as test set. We also remove entity mentions that have spurious indices (i.e entity mention length of 0).<sup>3</sup> For all the three datasets, we randomly sampled 10% of the test set, and use it as a development set, on which we tune model parameters. The remaining 90% is used for final evaluation. For all our experiments, we train each model using same hyperparameters five times and report their performance in terms of micro-F1 score on the development set as

<sup>1</sup>We considered an entity mention as pronominal, if all of its tokens have POS tag as pronoun.

<sup>2</sup>Whenever possible, the baselines result are reported from (Ren et al., 2016), otherwise we re-implemented baseline methods based on description available in corresponding papers.

<sup>3</sup>The code to replicate the work is available at <https://github.com/abhipef/fnet>

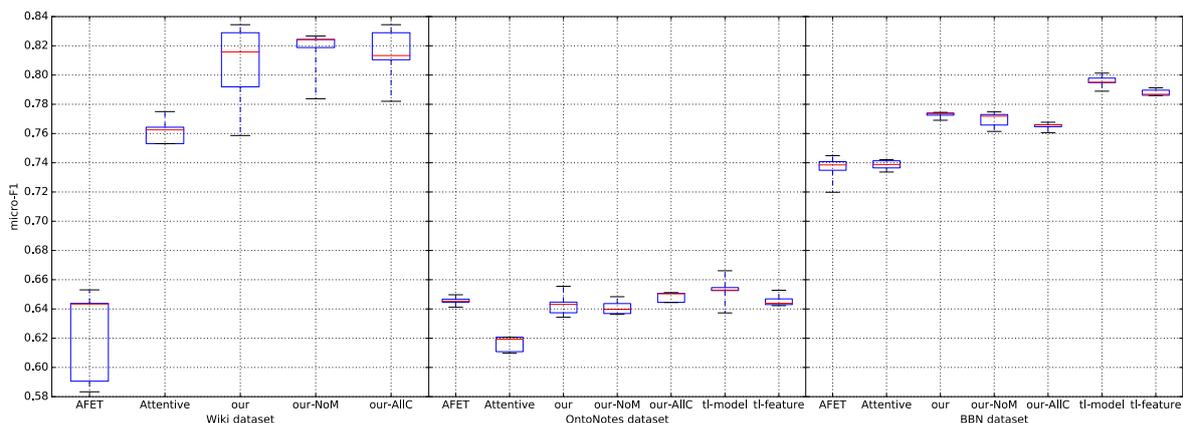

Figure 5: These box-plots show the performance of different baselines on validation set. The red line, boxes and whiskers indicate the median, quartiles and range.

shown in Figure 5. On Wiki dataset, we observed a large variance in performance as compared to other two datasets. This might be because of the fact that Wiki dataset has a very small development set. From each of these five runs, we pick the best performing model based on the development set and report its result on the test set.

**Hyperparameter setting:** All the neural network based models in this paper used 300 dimensional pre-trained word embeddings distributed by Pennington et al. (2014). The hidden-layer size of word level bi-directional LSTM was 100, and that of character level LSTM was 200. Vectors for character embeddings were randomly initialized and were of size 200. We use dropout with the probability of 0.5 on the output of LSTM encoders. The embedding dimension used was 500. We use Adam (Kingma and Ba, 2014) as optimization method with learning rate of 0.0005-0.001 and mini-batch size in the range of 800 to 1500. The proposed model and some of the baselines were implemented using TensorFlow<sup>4</sup> framework.

### 4.3 Transfer learning

In feature level transfer learning, we use the best performing proposed model trained on Wiki dataset to generate representations that is  $D_f$  dimensional vector for every entity mention present in the train, development, and test set of the BBN and the OntoNotes dataset. Figure 4 illustrates an example for the encoding process. Then we use these representations as a feature vector in place of the user-defined features and train the AFET

model. Its hyper-parameters were tuned on the development set. These results are shown in table 2 as **feature level transfer-learning**.

In model level transfer learning, we use the learnt weights of LSTM encoders from the best performing proposed model trained on Wiki dataset and initialize the LSTM encoders of the same model with these weights while training on BBN and OntoNotes datasets. These results are shown in table 2 as **model level transfer learning**.

### 4.4 Performance comparison and analysis

Table 2 shows the results of the proposed method, its variants and the baseline methods.

**Comparison with other feature learning methods:** The proposed model and its variants (**our-AIIC**, **our-NoM**) perform better than the existing feature learning method by Shimaoka et al. (2016) (**Attentive**), consistently on all datasets. This indicates benefits of the proposed representation scheme and joint learning of representation and label embedding.

**Comparison with feature engineering methods:** The proposed model performs better than the existing feature engineered methods (**FIGER**, **HYENA**, **AFET-NoCo**, **AFET-CoH**) consistently across all datasets on Micro-F1 and Macro-F1 evaluation metrics. These methods do not model label-label correlation based on data. In comparison with **AFET**, the proposed model outperforms AFET on Wiki and BBN dataset in terms of Micro-F1 evaluation metric. This indicates benefits of feature learning as well as data driven label-label correlation. We do a type-wise perfor-

Table 2: Performance analysis of entity classification methods on the three datasets.

mance comparison on OntoNotes dataset in subsection 4.5.

**Comparison with variants of our model:** The proposed model performs better on all dataset as compared to **our-AIIC** in terms of micro-F1 score. However, we find the performance difference on Wiki and OntoNotes dataset is not statistically significant. We investigated it further and found that across all three datasets, there exist only few entity types for which more than 85% of entity mentions are noisy. These types consist of approximately 3-4% of test set, and our model fails on these types (zero micro-F1 score). However, **our-AIIC** performs relatively well on these types. Examples of such types are: */building*, */person/political\_figure*, */GPE/STATE\_PROVINCE*. This indicates two limitations of the proposed model. First, the separating of clean and noisy mentions based on the hierarchy has its own inherent limitation of assuming labels within a path are correct. Second, our model learns better if more clean examples are available at the cost of not learning very noisy types. We will try to address these limitations in our future work. Compared with **our-NoM**, the proposed model performs slightly better across all datasets in terms of micro-F1 score.

**Feature level transfer learning analysis:** We observed 4.5% performance increase in micro-F1 score of AFET on BBN dataset, after replacing hand-crafted features with feature representations generated by the proposed model. This indicates usefulness of the learnt feature representations. However, if we repeat the same process with OntoNotes dataset, there is only a subtle change in performance. This is majorly because of the data distribution of OntoNotes dataset is different from

that of Wiki dataset. This issue is discussed in the next subsection.

**Model level transfer learning analysis:** In model level transfer learning, sharing knowledge from similar dataset (Wiki to BBN) increases the performance by 3.8% in terms of micro-F1 score. However, sharing knowledge from Wiki to OntoNotes dataset slightly increases the performance by 0.4% in terms of micro-F1 score.

#### 4.5 Case analysis: OntoNotes dataset

We observed three things; (i) all models perform relatively poor on OntoNotes dataset compared to their performance on other two datasets; (ii) the proposed model outperforms other models including AFET on the other two datasets, but gave worse performance on OntoNotes dataset; (iii) the two variants of transfer learning significantly improve performance of the proposed model on the BBN dataset but resulted in only a subtle performance change on OntoNotes dataset.

Statistics of the dataset (Table 1) indicates that presence of pronominal or other kinds of mentions are relatively higher in OntoNotes (6.78% in test set) than the other two datasets (0% in test set). Examples of such mentions are *100 people*, *It*, *the director*, etc. Table 3 shows 20 randomly sampled entity mentions from test set of OntoNotes datasets. Some of these mentions are very generic and likely to be dependent on

<sup>\*</sup>These results are from (Ren et al., 2016) that also uses 10% of the test set as development set and the remaining for evaluation.

<sup>‡</sup>We used the publicly available code distributed by Ren et al. (2016).

<sup>†</sup>All of these results are on exact same train, development and test set.

previous sentences. As all the methods use features solely based on the current sentence, they fail to transfer cross-sentence boundary knowledge. Removing pronominal mentions from test set increases the performance of all feature learning methods by around 3%.

Table 3: 20 randomly sampled entity mentions present in the test set of OntoNotes dataset.

Next we analyse where the proposed model is failing as compared to AFET. For this, we look at type-wise performance for the top-10 most frequent types in the OntoNotes test dataset. Results are shown in Table 4. Compared to AFET, the proposed model performs better in all types except *other* in the top-10 frequent types. The *other* type, which is dominant in test set (42.6% of entity mentions are of type *other*) and is a collection of multiple broad subtypes such as *product*, *event*, *art*, *living\_thing*, *food*. Performance of AFET significantly drops (*AFET-NoCo*) when data-driven label-label correlation is ignored, which indicates that modeling data-driven correlation helps. However, as shown in Figure 2a, the use of label-label correlation depends on appropriate values of parameters which vary from one dataset to another.

Label type	Support	our			AFET

## 5 Conclusion and Future Work

In this paper, we propose a neural network based model for the task of fine-grained entity classification. The proposed model learns representations for entity mention, its context and incorporate label noise information in a variant of non-parametric hinge loss function. Experiments show that the proposed model outperforms existing state-of-the-art models on two publicly available datasets without explicitly tuning data dependent parameters.

Our analysis indicates the following observations. First, OntoNotes dataset has a different distribution of entity mentions compared with other two datasets. Second, if data distribution is similar, then transfer learning is very helpful. Third, incorporating data-driven label-label correlation helps in the case of labels of mixed types. Fourth, there is an inherent limitation in assuming all labels to be clean if they belong to the same path of the hierarchy. Fifth, the proposed model fails to learn label types that are very noisy.

Future work could analyse the effect of label noise reduction techniques on the proposed model, revisiting the definition of clean and noisy labels and modeling label-label correlation in a principled way that is not dependent on dataset specific parameters.

## Abstract

To extract structured representations of newsworthy events from Twitter, unsupervised models typically assume that tweets involving the same named entities and expressed using similar words are likely to belong to the same event. Hence, they group tweets into clusters based on the co-occurrence patterns of named entities and topical keywords. However, there are two main limitations. First, they require the number of events to be known beforehand, which is not realistic in practical applications. Second, they don't recognise that the same named entity might be referred to by multiple mentions and tweets using different mentions would be wrongly assigned to different events. To overcome these limitations, we propose a non-parametric Bayesian mixture model with word embeddings for event extraction, in which the number of events can be inferred automatically and the issue of lexical variations for the same named entity can be dealt with properly. Our model has been evaluated on three datasets with sizes ranging between 2,499 and over 60 million tweets. Experimental results show that our model outperforms the baseline approach on all datasets by 5-8% in F-measure.

## 1 Introduction

Event extraction from texts is to automatically extract key information of events such as what happened to whom, when and where. Previous research mainly focused on news articles, the best and abundant source of newsworthy events. With the increasing popularity of social media platforms, events are also reported and discussed in

Table 1: An example of several tweets describing the same event about “*Space shuttle Atlantis landed at Kennedy Space Center in Florida on 2011/07/08*”.

---

Boom! #shuttle #Atlantis is back!

---

The shuttle is down, welcome back Atlantis, goodbye shuttle program.

---

Atlantis lands safely in Florida, marking the end of NASA's 30-yr space shuttle programme.

---

Space shuttle Atlantis lands at Kennedy space center, ending NASA's 30-year shuttle program.

---

social media apart from news articles. It was reported in (Petrovic et al., 2013) that even 1% of public Twitter stream covers 95% of all events on newswire. Extracting events from social media makes it possible to quickly understand what is being discussed. It can be further integrated into downstream applications such as tracking the public's viewpoints towards a certain event. However, due to the difficulty in acquiring annotated data for training and the short and informal text commonly appeared in social media, traditional approaches (Grishman et al., 2005; Tanev et al., 2008; Piskorski et al., 2008) to event extraction from news articles are no longer applicable in social media data. Nevertheless, one important characteristic of social media data is that for most newsworthy events, there might be a high volume of redundant messages referring to the same event. An example of several tweets describing one event is given in Table 1.

Approaches to event extraction from social media have largely explored the redundancy characteristic (Xia et al., 2015; Popescu et al., 2011; Abdelhaq et al., 2013). Most of the previous methods aim to discover new or previously unidenti-

fied events without extracting structured representations of events. Ritter et al. (2012) presented a system called TwiCal to extract and categorize events from Twitter. The strength of association between each named entity  $y$  and date  $d$  is measured based on the number of co-occurring tweets in order to form a binary tuple  $\langle y, d \rangle$  to represent an event. However, TwiCal relies on a supervised sequence labeler trained on tweets annotated with event mentions for the identification of event-related phrases.

Assuming that each tweet message  $m \in \{1..M\}$  is assigned to one event instance  $e$ , while  $e$  is modeled as a joint distribution over the named entities  $y$ , the date/time  $d$  when the event occurred, the location  $l$  where the event occurred and the event-related keywords  $k$ , Zhou et al. (2014; 2015) proposed an unsupervised Bayesian model called latent event model (LEM) for event extraction from Twitter. However, LEM requires the number of events to be known beforehand, which is not realistic in practical applications. To address this limitation, in this paper, a non-parametric mixture model for event extraction is proposed, in which the number of events is inferred automatically from data. Moreover, the lexical variation of the same named entity, for example, “Charles” and “The Prince of Wales”, if identified properly, could be exploited to help in detecting the same event described in tweets with different mentions. To this end, we further extend the non-parametric mixture model to incorporate word embeddings generated using neural language modelling.

The main contributions of the paper are summarized below:

- We propose a non-parametric approach called the Dirichlet Process Event Mixture Model (DPEMM) to extract structured events information. It avoids the problem of pre-setting the number of events, a common issue in latent Dirichlet allocation (LDA) based approaches.
- We extend DPEMM by incorporating word embeddings to deal with the issue of using multiple mentions to refer to the same named entity.
- The proposed approaches have been evaluated on three datasets and a significant improvement on F-measure compared to the baseline approach is observed.

## 2 Related Work

Research on event extraction of tweets can be divided into domain-specific and open domain approaches. Domain-specific approaches typically focus on one particular type of events. For example, Panem et al. (2014) proposed an algorithm to extract attribute-value pairs and map such pairs to manually generated schemas for natural disaster events. Evaluation was carried out on 58,000 tweets for 20 events and the system can fill such event schemas with an F-measure of 60%. TSum4act (Nguyen et al., 2015) was designed for disaster responses based on tweets and has been evaluated on a dataset containing 230,535 tweets. Anantharam et al. (Anantharam et al., 2014) focused on extracting city events by solving a sequence labeling problem. Evaluation was carried out on a real-world dataset consisting of event reports and tweets collected over four months from San Francisco Bay Area.

Open domain event extraction approaches are not limited to a specific event type or topic. Benson et al. (2011) proposed a structured graphical model which simultaneously analyzed individual messages, clustered, and induced a canonical value for each event. Popescu et al. (2011) focused on detecting events involving known entities from Twitter. Experimental results showed that events centered on specific entities can be extracted with 70% precision and 64% recall. Liu et al. (2012) worked on social events extraction for social network construction using a factor graph by harvesting the redundancy in tweets. Experiments were conducted on manually annotated data set and results showed that it achieved a gain of 21% in F-measure. In (Abdelhaq et al., 2013), a system called EvenTweet was constructed to extract localized events from a stream of tweets in real-time. The extracted events are described by start time, location and a number of related keywords. Armengo et al. (2015) proposed a model named Tweet-SCAN based on hierarchical Dirichlet process to detect events from geo-located tweets. To extract more information, a system called SEEFT (Wang et al., 2015) used links in tweets and combined tweets and linked articles to identify events. Xia et al. (2015) proposed a framework combining text, image and geo-location information to detect events with low spatial and temporal deviation.

Our proposed method belongs to the open do-

main category. Different from the previous methods, our model can automatically identify the number of events in the corpus and deal with lexical variations of named entities using word embeddings generating from neural language modelling.

### 3 Methodology

Our proposed model for event extraction is based on a typical non-parametric mixture model, Dirichlet Process Mixture Model (DPMM) (Green and Richardson, 2001; Ishwaran and Zarepour, 2002) in which the number of active clusters is automatically learned from the data. We first give a brief introduction to DPMM. In DPMM, observation  $x_i$  is assumed to be derived from the following model:

$$\begin{aligned}\pi|\alpha &\sim \text{Dirichlet}(\alpha/K, \dots, \alpha/K) \\ c_i|\pi &\sim \text{Multinomial}(\pi) \\ \phi_k|G_0 &\sim G_0 \\ x_i|c_i, \{\phi_k\}_{k=1}^K &\sim F(\phi_{c_i})\end{aligned}$$

where  $K$  denoting the number of components in the mixture model and can go to infinity,  $\pi$  is the mixture weights of each component,  $\phi_k$  is the parameter of the  $k$ th component,  $c_i$  denotes the index of components,  $F(\phi_{c_i})$  denotes the distribution of  $x_i$  with parameter  $\phi_{c_i}$ . In this model,  $\pi$  can be generated by stick-breaking model (Pitman, 2002) and Chinese restaurant process (Aldous, 1985).

Suppose that all the observations are generated by DPMM and the variable of observation  $x_i$  is  $\theta_i$ , which has the following conditional distribution:

$$\theta_i|\theta_1, \dots, \theta_{i-1} \sim \sum_{k=1}^K \frac{n_k}{i-1+\alpha} \delta_{\phi_k} + \frac{\alpha}{i-1+\alpha} G_0$$

where  $\phi_1, \dots, \phi_k$  are the distinct values of  $\theta$ ,  $n_k$  is the number of observations that belong to component  $k$ ,  $\delta_{\phi_k}$  is a probability measure concentrated on  $\phi_k$ , which returns 1 when  $\theta_i = \phi_k$ ,  $G_0$  is the base probability measure and generates new  $\phi$  with probability  $\frac{\alpha}{i-1+\alpha}$ .

#### 3.1 Dirichlet Process Event Mixture Model (DPEMM)

We propose a Dirichlet Process Event Mixture Model (DPEMM) in which each event is represented as a 4-tuple  $\langle y, l, k, d \rangle$ , where  $y$  stands for non-location named entity,  $l$  for location,  $k$  for

event-related keyword and  $d$  for date. It is worth noting that  $y, l, k$  is not atomic and could be a set by itself. One event can have multiple named entities, locations or keywords. Also, some elements of the 4-tuple might be absent if no associated information can be found in tweets. Assuming that the data contains an infinite number of events and each event is modeled as a joint distribution over  $y, l, k$  and  $d$ , the model can be viewed as a Bayesian mixture model.

The generative process of the proposed model is given below.

- Draw event distribution  $\pi \sim \text{Dirichlet}(\frac{\alpha}{K}, \dots, \frac{\alpha}{K})$ .
- For each event  $e$ , draw multinomial distribution  $\theta_e \sim \text{Dirichlet}(\beta)$ ,  $\psi_e \sim \text{Dirichlet}(\eta)$ ,  $\omega_e \sim \text{Dirichlet}(\lambda)$ ,  $\phi_e \sim \text{Dirichlet}(\gamma)$ .
- For each tweet  $\mathbf{t}$ :
  - Draw an event from event distribution  $e \sim \text{Multinomial}(\pi)$ .
  - For each non-location named entity occurred in  $\mathbf{t}$ , choose a named entity  $y \sim \text{Multinomial}(\theta_e)$ .
  - For each location occurred in  $\mathbf{t}$ , choose a location  $l \sim \text{Multinomial}(\psi_e)$ .
  - For each keyword occurred in  $\mathbf{t}$ , choose a keyword  $k \sim \text{Multinomial}(\omega_e)$ .
  - For each date occurred in  $\mathbf{t}$ , choose a date  $d \sim \text{Multinomial}(\phi_e)$ .

Here,  $K$  is the number of events and can go to infinity. To estimate the parameters of the model, we employ Markov chain sampling methods (Neal, 2000). As  $K$  goes to infinity, we cannot represent the infinite number of  $\theta_e, \psi_e, \omega_e$  and  $\phi_e$  explicitly. Therefore, we perform Gibbs sampling for only those parameters that are currently associated with some observations. Gibbs sampling for the event label  $e_i$  of tweet  $i$  is based on the following conditional probabilities:

If  $e_i$  is assigned with a previously seen event  $e$ ,

$$\begin{aligned}P(e_i = e|e_{-i}, s_i, t_{-i}) &= b \frac{n_e^{-i}}{n-1+\alpha} \\ &\prod_{y \in y_i} \int F_y(\theta_e) dH_y(\theta_e) \prod_{l \in l_i} \int F_l(\psi_e) dH_l(\psi_e) \\ &\prod_{k \in k_i} \int F_k(\omega_e) dH_k(\omega_e) \prod_{d \in d_i} \int F_d(\phi_e) dH_d(\phi_e)\end{aligned}$$

If  $e_i$  is assigned with a new event,

$$P(e_i = e_{new} | e_{-i}, s_i, d_i, t_{-i}) = b \frac{\alpha}{n-1+\alpha} \prod_{y \in y_i} \int F_y(\theta) dG_0(\theta) \prod_{l \in l_i} \int F_l(\psi) dG_0(\psi) \prod_{k \in k_i} \int F_k(\omega) dG_0(\omega) \prod_{d \in d_i} \int F_d(\phi) dG_0(\phi)$$

, where  $b$  is the normalizing constant that makes the probabilities sum to 1,  $e_{-i}$  is the event assignment of all the other tweets excluding the data from  $i$ th tweet,  $s_i$  is the four-tuple  $\langle y_i, l_i, k_i, d_i \rangle$ ,  $n$  is the total number of tweets,  $n_e^{-i}$  is the number of tweets assigned with event label  $e$  excluding the current assignment,  $F_y(\theta_e)$  is the multinomial distribution over non-location named entities with prior  $\theta_e$ ,  $F_l(\psi_e)$  over locations with  $\psi_e$ ,  $F_k(\omega_e)$  over keywords with  $\omega_e$ , and  $F_d(\phi_e)$  over dates with  $\phi_e$ .  $H_y(\theta_e)$  is the posterior distribution of parameters based on the prior  $G_0(\theta_e) \sim \text{Dirichlet}(\beta)$  and all observations  $y_j$  for which  $j \neq i$  and  $e_j = e$ , and similarly for  $H_l(\psi_e)$ ,  $H_k(\omega_e)$  and  $H_d(\phi_e)$ .

We then derive the following formulae:

If  $e_i$  is assigned with a previously seen event  $e$ ,

$$P(e_i = e | e_{-i}, s_i, t_{-i}) = b \frac{n_e^{-i}}{n-1+\alpha} \prod_{y \in y_i} \frac{n_{e,y}^{-i} + \beta}{\sum_{t=1}^Y (n_{e,y,t}^{-i} + \beta)} \prod_{l \in l_i} \frac{n_{e,l}^{-i} + \eta}{\sum_{t=1}^L (n_{e,l,t}^{-i} + \eta)} \prod_{k \in k_i} \frac{n_{e,k}^{-i} + \lambda}{\sum_{t=1}^K (n_{e,k,t}^{-i} + \lambda)} \prod_{d \in d_i} \frac{n_{e,d}^{-i} + \gamma}{\sum_{t=1}^D (n_{e,d,t}^{-i} + \gamma)}$$

If  $e_i$  is assigned with a new event  $e'$ ,

$$P(e_i = e' | e_{-i}, s_i, t_{-i}) = b \frac{\alpha}{n-1+\alpha} \prod_{y \in y_i} \frac{1}{Y} \prod_{l \in l_i} \frac{1}{L} \prod_{k \in k_i} \frac{1}{K} \prod_{d \in d_i} \frac{1}{D}$$

, where the superscript  $-i$  denotes a count excluding data from  $i$ th tweet,  $n_{e,y}^{-i}$ ,  $n_{e,l}^{-i}$ ,  $n_{e,k}^{-i}$ , and  $n_{e,d}^{-i}$  denotes the occurrence count of non-location  $y$ , location  $l$ , keyword  $k$  and date  $d$  in event  $e$ , respectively.  $t_{-i}$  denotes all other tweets.  $\beta, \eta, \lambda, \gamma$  are the hyperparameters and are set to the same value 1 in the experiments in the paper.

### 3.2 DPEMM With Word Embeddings

In the proposed model described above, each distinct word is treated separately without consider-

ing their semantic relations. However, the knowledge of semantic relations of words might be useful for event extraction. For example, ‘‘Putin’’ and ‘‘The President of Russia’’ are two different mentions referring to the same person. Knowing such knowledge would help to cluster the following two tweets together, ‘‘*President of Russia attended the opening ceremony of the 119th session of the International Olympic Committee.*’’ and ‘‘*Putin took part in the presentation of Sochi, at the 119th of the IOC.*’’, and hence identify a single event. Moreover, there might exist partitive relations between two location names. For example, Croydon is a part of London. The information will help to identify the same event described as happened in Croydon and London and subsequently improve the accuracy of event extraction.

To incorporate such information about semantic relations between words, we propose another model by employing word embeddings to describe the semantic relations among  $y$  or  $l$ , which is called DPEMM-WE. Word embedding for each word is often represented in a vector form. In the embedded hyperspace, words that are more semantically or syntactically similar to each other are located closer. We use neural language modeling (Collobert et al., 2011) to learn word representations by discriminating the legitimate phrase from incorrect phrases. Given a sequence of words  $p = (w_1, w_2, \dots, w_d)$  with window size  $d$ , the goal of the model is to discriminate the sequence of words  $p$  (the correct phrase) from a random sequence of words  $p^r$ . Thus, the objective function of the model is to minimize the ranking loss with respect to parameters  $\theta$ :

$$\sum_{p \in \mathfrak{p}} \sum_{r \in \mathfrak{R}} \max(0, 1 - f_\theta(p) + f_\theta(p^r)) \quad (1)$$

, where  $\mathfrak{p}$  is the set of all possible text sequences with  $d$  words coming from the corpus  $U$ ,  $\mathfrak{R}$  is the dictionary of words,  $p^r$  denotes the window of words obtained by replacing the central word of  $p$  by the word  $r$  and  $f_\theta(p)$  is the score of  $p$ . The dataset for learning the language model can be constructed by considering all the word sequences in the corpus. Positive examples are the word sequences from the corpus, while negative examples are the same word sequence with the central word replaced by a random one.

Different from DPEMM, in DPEMM-WE, non-location named entities  $y$  and locations  $l$  are as-

sumed to follow Gaussian distribution to incorporate word embeddings and their prior distributions are assumed to follow Normal-Inverse-Wishart (NIW) distribution, which is conjugated with Gaussian distribution. The probability density function is

$$\begin{aligned} NIW(\mu, \Sigma | \mu_0, \lambda, \Psi, \nu) \\ = \mathcal{N}(\mu | \mu_0, \frac{1}{\lambda} \Sigma) \mathcal{W}^{-1}(\Sigma | \Psi, \nu) \end{aligned}$$

$$\mathcal{N}(\mu | \mu_0, \frac{1}{\lambda} \Sigma) = \frac{e^{-\frac{1}{2}(\mu - \mu_0)^T (\Sigma / \lambda)^{-1} (\mu - \mu_0)}}{\sqrt{|2\pi \Sigma / \lambda|}}$$

$$\mathcal{W}^{-1}(\Sigma | \Psi, \nu) = \frac{|\Sigma|^{\frac{\nu}{2}}}{2^{\frac{\nu p}{2}} \Gamma_p(\frac{\nu}{2})} |\Sigma|^{-\frac{\nu+p+1}{2}} e^{-\frac{1}{2} \text{tr}(\Psi \Sigma^{-1})}$$

where  $\Sigma$  and  $\Psi$  are  $p \times p$  positive definite matrices and  $\Gamma_p(\cdot)$  is the multivariate gamma function. The graphical model of DPEMM-WE is shown in Figure 1.

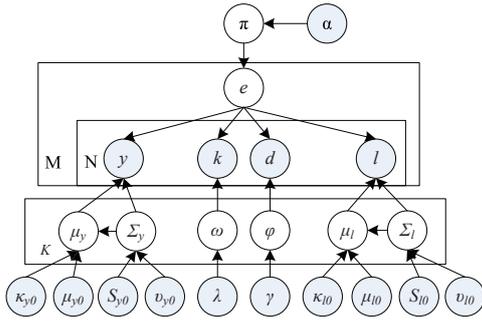

Figure 1: Plate notation of the graphical model DPEMM-WE.

The generative process of DPEMM-WE is given below.

- Draw event distribution  $\pi \sim \text{Dirichlet}(\frac{\alpha}{K}, \dots, \frac{\alpha}{K})$ .
- For each event, draw Gaussian distribution  $\theta_e \sim \text{NIW}(\beta)$ ,  $\psi_e \sim \text{NIW}(\eta)$ ; draw Multinomial distribution  $\omega_e \sim \text{Dirichlet}(\lambda)$ ,  $\phi_e \sim \text{Dirichlet}(\gamma)$ .
- For each tweet  $\mathbf{t}$ :
  - Draw an event from event distribution  $e \sim \text{Multinomial}(\pi)$ .
  - For each named entity occurred in  $\mathbf{t}$ , choose a named entity  $y \sim \text{Gaussian}(\theta_e)$ .

- For each location occurred in  $\mathbf{t}$ , choose a location  $l \sim \text{Gaussian}(\psi_e)$ .
- For each keyword occurred in  $\mathbf{t}$ , choose a keyword  $k \sim \text{Multinomial}(\omega_e)$ .
- For each date occurred in  $\mathbf{t}$ , choose a date  $d \sim \text{Multinomial}(\phi_e)$ .

, where  $\beta = (\kappa_{y0}, \mu_{y0}, \nu_{y0}, S_{y0})$ ,  $\theta_e = (\mu_y, \Sigma_y)$ ,  $\eta = (\kappa_{l0}, \mu_{l0}, \nu_{l0}, S_{l0})$ ,  $\psi_e = (\mu_l, \Sigma_l)$ .

Similar to DPEMM, parameters of the model can be estimated by Gibbs sampling. The sampling equation is given as below:

If  $e_i$  is assigned with a previously seen event  $e$ ,

$$\begin{aligned} P(e_i = e | e_{-i}, s_i, t_{-i}) &= b \frac{n_e^{-i}}{n - 1 + \alpha} \\ &\prod_{y \in y_i} \int p(y | \theta) p(\theta | \nu_{e,y0}, \kappa_{e,y0}, \mu_{e,y0}, S_{e,y0}, t_{-i}) d\theta \\ &\prod_{l \in l_i} \int p(l | \psi) p(\psi | \nu_{e,l0}, \kappa_{e,l0}, \mu_{e,l0}, S_{e,l0}, t_{-i}) d\psi \\ &\prod_{k \in k_i} \int p(k | \omega) p(\omega | \lambda, t_{-i}) d\omega \\ &\prod_{d \in d_i} \int p(d | \phi) p(\phi | \gamma, t_{-i}) d\phi \end{aligned}$$

If  $e_i$  is assigned with a new event  $e'$ ,

$$\begin{aligned} P(e_i = e' | e_{-i}, s_i, t_{-i}) &= b \frac{\alpha}{n - 1 + \alpha} \\ &\prod_{y \in y_i} \int p(y | \theta) p(\theta | \nu_{e',y0}, \kappa_{e',y0}, \mu_{e',y0}, S_{e',y0}) d\theta \\ &\prod_{l \in l_i} \int p(l | \psi) p(\psi | \nu_{e',l0}, \kappa_{e',l0}, \mu_{e',l0}, S_{e',l0}) d\psi \\ &\prod_{k \in k_i} \int p(k | \omega) p(\omega | \lambda) d\omega \prod_{d \in d_i} \int p(d | \phi) p(\phi | \gamma) d\phi \end{aligned}$$

, where  $\theta$  and  $\psi$  denote parameter  $(\mu, \Sigma)$ .

As

$$\begin{aligned} \int \mathcal{N}(x | \theta) NIW(\theta | \nu, \kappa, \mu, S) d\theta = \\ \mathcal{F}(\nu - D + 1, \mu, \frac{S(\kappa + 1)}{\kappa(\nu - D + 1)}) \end{aligned}$$

the parameters of entities'  $\mathcal{F}$  distribution are

given as:

$$\begin{aligned}
\kappa_{e,y} &= \kappa_{y0} + N_e \\
\nu_{e,y} &= \nu_{y0} + N_e \\
\mu_{e,y} &= \frac{\kappa_{y0}\mu_{y0} + N_e\bar{v}_{e,y}}{\kappa_{e,y}} \\
S_{e,y} &= S_{e0} + C_{e,y} \\
&\quad + \frac{\kappa_{e0}N_e}{\kappa_{e,y}}(\bar{v}_{e,y} - \mu_{e0})(\bar{v}_{e,y} - \mu_{e0})^T \\
\bar{v}_{e,y} &= \frac{\sum_{y \in e} v_y}{N_e} \\
C_{e,y} &= \sum_{y \in e} (v_y - \bar{v}_{e,y})(v_y - \bar{v}_{e,y})^T
\end{aligned}$$

, where  $v_y$  means the word embedding of entity  $y$ . The parameters of locations'  $\mathcal{T}$  distribution can be calculated similarly.

### 3.3 Post-Processing

DPEMM or DPEMM-WE essentially outputs tweet clusters where each cluster represents one event. To further extract structured representation of an event, such as named entities, locations, dates and keywords, from each cluster, we simultaneously look into the probabilities of each event element returned by our models and their co-occurrence frequencies. We assumed that non-location named entities were the most important since an event is usually operated by somebody or something. If an event happened in someplace like "A bomb attack was happened in London", the location is the most important. Therefore, we first select the top 3 non-location named entities ranked by the probability  $\theta_e$ . For each non-location named entity  $y$ , its occurrence frequency needs to exceed  $T_y$ . If no such entities exist, the top 3 locations ranked by the probability  $\psi_e$  are chosen; otherwise, the location  $l$  is chosen based on its co-occurrences with the selected non-location named entities. After that, keywords  $k$  are chosen among the top 10  $\omega_e$ . Only those keywords with correlation coefficients with the chosen named entities and locations exceeding  $T_c$  are selected. Then date  $d$  is chosen in a similar way. Here, we define the correlation coefficient between  $a$  and  $b$  as  $Corr(a, b) = \log \frac{\#(a,b)}{\#(b)}$ , where  $\#(a, b)$  denotes the co-occurrence count of  $a$  and  $b$  in the same tweet within a tweet cluster and  $\#(b)$  denotes the occurrence count of  $b$  in all tweets within a tweet cluster. In our experiments, we set the thresholds  $T_y = 0.2, T_c = 0.4$ .

If the entity or location is in the form of word embeddings, its occurrence frequency is calculated as the occurrence frequencies of all the neighboring words which have cosine similarity values greater than 0.85. The rationale behind our post-processing step is that although tweets have been filtered in the pre-processing step, tweet clusters generated by the proposed models still contain noisy event elements. As such, we select event elements from tweet clusters not only based on their probability distributions given by the proposed models but also taking into account their co-occurrences in each tweet cluster.

## 4 Experiments

We evaluate the proposed models on three datasets. Dataset I is the First Story Detection (FSD) dataset (Petrovic et al., 2013) containing 2,499 tweets manually annotated with 27 events. These tweets were published between 7th July and 12th September 2011, covering a range of categories such as accidents and science discoveries. Considering that events mentioned in a very few tweets are less likely to be significant, we remove events mentioned in less than 15 tweets and are left with 2,453 tweets annotated with 20 events. Dataset II and III were collected from tweets published in the month of December in 2010 using the Twitter streaming API. Dataset II consists of 6,297 tweets manually annotated with 73 events. All the annotated events in Dataset II are mentioned in at least 15 tweets. Dataset III contains 60 millions unlabelled tweets. We chose LEM (Zhou et al., 2014), the state-of-art approach based on Bayesian modelling for event extraction, as the baseline to compare with the proposed model. For all datasets, pre-processing is done as described in *baseline* (Zhou et al., 2014). A named entity tagger<sup>1</sup> specifically built for Twitter is used for extracting named entities including locations from tweets. A Twitter Part-of-Speech tagger (Gimpel et al., 2011) is used for POS tagging and only words tagged with nouns, verbs or adjectives are kept as candidate keywords. Word embeddings are trained on Dataset III (60 million tweets) using Word2Vec<sup>2</sup>. In this model, a word is used as an input to a log-linear classifier with continuous projection layer and the objective is to predict its neighboring words.

<sup>2</sup><http://code.google.com/p/word2vec/>

We train DPEMM, DPEMM-WE and LEM on an IBM 3850 X5 Linux server equipped with 1.86 Ghz processor and 8 GB DDR3 RAM. The number of Gibbs sampling iterations is set to 1,000 for LEM for all the datasets. For DPEMM, it converges in 16 iterations on Dataset I and 20 iterations on Dataset II and III. While for DPEMM-WE, it converges in 20 iterations on both Dataset II and III.

#### 4.1 Experimental Results

To evaluate the performance of the proposed approaches, we calculate *precision*, *recall*, and *F-measure* on Dataset I and II and only *precision* on Dataset III since it is hard to know exactly how many events are mentioned in such a large dataset. The *precision* is defined based on the following criteria: 1) Do the entity  $y$ , location  $l$  and the date  $d$  refer to the same event? 2) Are the keywords  $k$  in accord with the event that other extracted elements  $y$ ,  $l$ ,  $d$  refer to and are they informative enough to tell us what happened? If the extracted events does not have any keyword, such events are considered as incorrect.

The performance comparison of event extraction results is presented in Table 2. It can be observed that the proposed DPEMM achieves better performance on all the three datasets compared to the baseline approach, with the improvement in F-measure being 6.1% and 7.7% on Dataset I and II, respectively. After incorporating word embeddings into DPEMM, the proposed DPEMM-WE further improves upon DPEMM slightly by 1.45% in F-measure on Dataset II, but more significantly by 4.16% in precision on Dataset III. It verifies our hypothesis that the knowledge about the semantic relations of entities and locations could potentially improve the performance of event extraction. We also compared the proposed models with K-means on Dataset I to justify whether these proposed generative models are better than traditional clustering methods based on co-occurrence. The feature set was constructed by organizing the words in four categories such as  $y$ ,  $l$ ,  $k$ ,  $d$  and concatenating the four one-hot feature sets together.

It is worth noting that we did not apply DPEMM-WE on Dataset I because this dataset is very small, consisting of less than 2500 tweets. It is thus unreliable to learn word embeddings from such a small dataset. It is also hard to pre-train word embedding from extra dataset like Wikipedia

Table 2: Comparison of the performance of event extraction on the three datasets.

Dataset I			
Method	Precision(%)	Recall(%)	F-measure(%)
K-means	91.23	55.40	68.93
LEM	79.17	85.00	81.98
DPEMM	<b>86.21</b>	<b>90.00</b>	<b>88.06</b>
Dataset II			
Method	Precision(%)	Recall(%)	F-measure(%)
LEM	62.35	68.49	65.28
DPEMM	70.80	75.34	73.00
DPEMM-WE	<b>71.15</b>	<b>78.08</b>	<b>74.45</b>
Dataset III			
Method	Precision(%)	Number of correctly Events	
LEM	68.25	215	
DPEMM	68.60	342	
DPEMM-WE	<b>72.76</b>	<b>353</b>	

corpus for Dataset I because some words in social media are informal and some words were only mentioned in some specific time slots such as “Dream Act”. Also, word embeddings learned from Dataset III are not beneficial for event extraction in Dataset I since tweets collected in these two datasets were in different periods and a large number of words in Dataset I cannot be found in Dataset III. For example, more than 20% named entities in Dataset I can not be found in the word vocabulary constructed based on Dataset III.

Examples of events extracted by DPEMM and DPEMM-WE are shown in Table 3. It can be observed that the extracted results from DPEMM-WE contain more detailed and accurate information describing the events. For example, for the first event, DPEMM-WE is able to extraction the location information while DPEMM failed to do so. For the third event, DPEMM-WE gives more accurate location information compared to DPEMM. It might attribute to the advantage of incorporating word embeddings which are able to map semantically similar words into nearby locations in the embedding hyperspace. As such, although two tweets might contain different mentions of named entities and locations, they might still be clustered together if these named entities or locations have similar word embeddings.

We observed that the precision achieved by DPEMM on Dataset I is significantly better than LEM on Dataset I and II while similar on Dataset III. We found that DPEMM tended to generate many but smaller clusters compared to LEM. As dataset III is huge, DPEMM might generate some small clusters which do not contain enough information to describe a correct event.

Table 3: Examples of extracted events based on DPEMM and DPEMM-WE.

Event	Method	Entities	Locations	Keywords	Date
1	DPEMM	Biden	-	inevit marriage gay say	2010-12-24
	DPEMM-WE	Biden, Obama	WhiteHouse	marrige gay inevit say	2010-12-24
2	DPEMM	Charles	London	car protest attack contain	2010-12-09
	DPEMM-WE	Charles, Camilla	London, UK	protest car demonstrators attack	2010-12-09
3	DPEMM	-	London	snow close airport ice	2010-12-18
	DPEMM-WE	-	Europ, London, Gatwick	snow delay runaway airport	2010-12-18

	DPEMM-WE	DreamAct, Harry, Reid	Senate	vote pass debate bill	2010-12-09
5	DPEMM	WorldCup	Russia	announce will host chose	2010-12-03
	DPEMM-WE	WorldCup, FIFA	Russia, Qatar	news host win will	2010-12-03

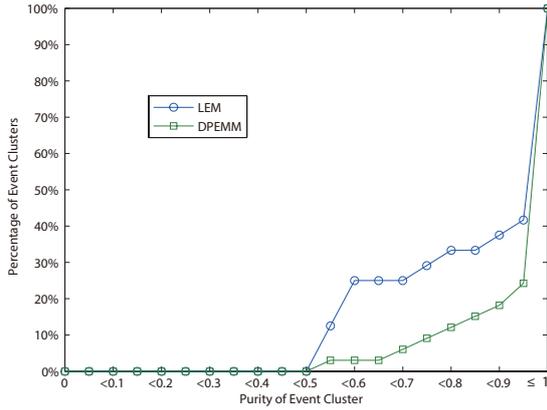

Figure 2: Purities of the clusters on Dataset I.

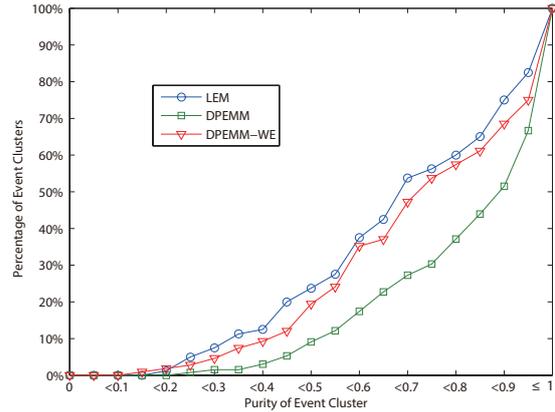

Figure 3: Purities of the clusters on Dataset II.

## 4.2 Quality of Clusters

As the proposed approaches essentially group tweets into different clusters with each cluster corresponding to an event, we conduct experiments to explore the quality of clusters by a measure of purity, which is defined as  $P_e = \frac{n_e}{n}$ , where  $n_e$  denotes the number of tweets describing the event  $e$  extracted from a cluster and  $n$  denotes the total number of tweets in the cluster. Since it is difficult to calculate the purity on Dataset III, we only report the results on Dataset I and Dataset II as shown in Figure 2 and 3 respectively.

Each point  $(x, y)$  in the figures denotes the percentage  $y$  of the clusters whose purity is less than  $x$ . Obviously, if the curve is steeper, it means that the percentage of the clusters with low purity is smaller and the quality of the clusters is better. It can be observed that DPEMM achieves the best quality of cluster on both Dataset I and Dataset II, whose precision is lower than DPEMM-WE. Specifically, on Dataset I, more than 80% of clusters generated by DPEMM has the purity value greater than 0.9, compared to only 70% in LEM. It might be attributed to the property of DPEMM

that the cluster is generated dynamically without a preset number of clusters. On Dataset II, both DPEMM and DPEMM-WE achieve better clustering results compared to LEM. However, the purity of clusters generated by DPEMM is slightly higher than that generated by DPEMM-WE. This is somewhat contrary to our prior belief. By further analyzing the results, we found that as more tweets are clustered together using DPEMM-WE, more noisy information such as some named entities with similar word embeddings which are not related to the events is introduced. We present an example of the tweet clusters describing the same event generated by DPEMM and DPEMM-WE in Figure 4. For each method, we use a histogram to indicate the number of tweets which share the same event elements. Regions highlighted in dark or light red colors indicate that the corresponding tweets are event-related. Regions highlighted in blue denote the corresponding tweets are not event-related. It can be observed that the purity of the cluster generated by DPEMM is 91% which is better than DPEMM-WE's 63%. However, the size of the cluster returned by DPEMM is smaller and it failed to extract the location information.

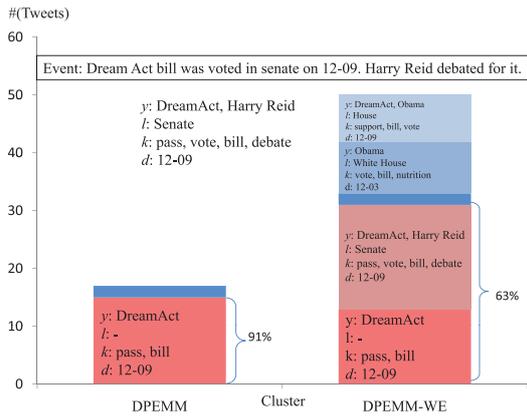

Figure 4: Example tweet clustering results generated by DPEMM and DPEMM-WE.

On the contrary, DPEMM-WE generated a larger cluster and for some tweets, it successfully extracted the location “Senate”. However, more spurious tweets are included because “Harry Reid” is close to both “DreamAct” and “Obama”, and “White House” is close to “Senate” in the word embedding space. Therefore, although DPEMM-WE gives better extraction results overall compared to DPEMM as shown in Table 2, it returns lower purity results because of some noisy information introduced through word embeddings.

## 5 Conclusions and Future Work

In this paper, we have proposed a model based on the Dirichlet Process mixture model to extract structured event information from social media data. Different from previous approaches for event extraction which require setting the number of events beforehand, it can infer the number of events automatically from data. It is specifically appealing for processing large-scale social media data. Moreover, considering different mentions of names could refer to the same person (and similarly for other named entities such as location), we have proposed to incorporate word embeddings into DPEMM so as to more effectively capture semantically similar words. Experiments have been conducted on three datasets and the proposed approaches achieve better performance on all the datasets in comparison with the baseline approach. In the future, we plan to investigate more effective way in reducing the noise introduced by word embeddings and incorporate emotion information into the proposed models to simultaneously ex-

tract public opinions of the extracted event.

## Abstract

End-to-end relation extraction refers to identifying boundaries of entity mentions, entity types of these mentions and appropriate semantic relation for each pair of mentions. Traditionally, separate predictive models were trained for each of these tasks and were used in a “pipeline” fashion where output of one model is fed as input to another. But it was observed that addressing some of these tasks jointly results in better performance. We propose a single, joint neural network based model to carry out all the three tasks of boundary identification, entity type classification and relation type classification. This model is referred to as “All Word Pairs” model (AWP-NN) as it assigns an appropriate label to each word pair in a given sentence for performing end-to-end relation extraction. We also propose to refine output of the AWP-NN model by using inference in Markov Logic Networks (MLN) so that additional domain knowledge can be effectively incorporated. We demonstrate effectiveness of our approach by achieving better end-to-end relation extraction performance than all 4 previous joint modelling approaches, on the standard dataset of ACE 2004.

## 1 Introduction

The task of relation extraction (RE) deals with identifying whether any pre-defined *semantic relation* holds between a pair of *entity mentions* in the given sentence. Pure relation extraction techniques (Zhou et al., 2005; Jiang and Zhai, 2007; Bunescu and Mooney, 2005; Qian et al., 2008) assume that for a sentence, gold-standard entity

mentions (i.e. boundaries as well as types) in it are known. In contrast, end-to-end relation extraction deals with plain sentences without assuming any knowledge of entity mentions in them. The task of end-to-end relation extraction consists of three sub-tasks: i) identifying boundaries of entity mentions, ii) identifying entity types of these mentions and iii) identifying appropriate semantic relation for each pair of mentions. First two sub-tasks correspond to the Entity Detection and Tracking task defined by the the Automatic Content Extraction (ACE) program (Doddington et al., 2004) and the third sub-task corresponds to the Relation Detection and Characterization (RDC) task. ACE standard defined 7 entity types<sup>1</sup>: PER (person), ORG (organization), LOC (location), GPE (geopolitical entity), FAC (facility), VEH (vehicle) and WEA (weapon). It also defined 7 coarse level relation types<sup>2</sup>: EMP-ORG (employment), PER-SOC (personal/social), PHYS (physical), GPE-AFF (GPE affiliation), OTHER-AFF (PER/ORG affiliation), ART (agent-artifact) and DISC (discourse).

Traditionally, the three sub-tasks of end-to-end relation extraction are carried out serially in a “pipeline” fashion. In this case, the errors in any sub-task affect subsequent sub-tasks. Another disadvantage of this “pipeline” approach is that it allows only one-way *information flow*, i.e. the knowledge about entities is used for identifying relations but not vice versa. Hence to overcome this problem, several approaches (Roth and Yih, 2004; Roth and Yih, 2002; Singh et al., 2013; Li and Ji, 2014) were proposed which carried out these sub-tasks jointly rather than in “pipeline” manner.

We propose a new approach which combines

---

Table 1: Expected output of end-to-end relation extraction system for entity mentions

the powers of Neural Networks and Markov Logic Networks to jointly address all the three sub-tasks of end-to-end relation extraction. We design the “All Word Pairs” neural network model (AWP-NN) which reduces solution of these three sub-tasks to predicting an appropriate label for each word pair in a given sentence. End-to-end relation extraction output can then be constructed easily from these labels of word pairs. Moreover, as a separate prediction is made for each word pair, there may be some inconsistencies among the labels. We address this problem by refining the predictions of AWP-NN by using inference in Markov Logic Networks so that some of the inconsistencies in word pair labels can be removed at the sentence level.

The specific contributions of this work are : i) modelling boundary detection problem by introducing a special relation type WEM and ii) a single, joint neural network model for all three sub-tasks of end-to-end relation extraction. The paper is organized as follows. Section 2 provides a detailed problem definition. Section 3 describes our AWP-NN model in detail, followed by Section 4 which describes how the predictions of AWP-NN model are revised using inference in MLNs. Section 5 provides experimental results and analysis. Finally, we conclude in Section 6 with a short note on future work.

## 2 Problem Definition

Given a sentence as an input, an end-to-end relation extraction system should produce a list of entity mentions within it. For each entity mention, its boundaries and entity type should be identified. Also, for each pair of valid entity mentions, it should decide whether any pre-defined semantic relation holds between them.

Consider the sentence : His<sub>0</sub> sister<sub>1</sub> Mary<sub>2</sub> Jones<sub>3</sub> went<sub>4</sub> to<sub>5</sub> the<sub>6</sub> United<sub>7</sub> Kingdom<sub>8</sub> .<sub>9</sub> Here, end-to-end relation extraction should produce the output as shown in the tables 1 and 2.

Entity Mention Pair	Relation Type
His, sister	PER-SOC
His, Mary Jones	PER-SOC
sister, United Kingdom	PHYS
Mary Jones, United Kingdom	PHYS

## 3 All Word Pairs Model (AWP-NN)

We propose a single, joint model for addressing all three sub-tasks of end-to-end relation extraction : i) identifying boundaries of entity mentions, ii) identifying entity types of these mentions and iii) identifying appropriate semantic relation for each pair of mentions. We refer to this model as AWP-NN, i.e. All Word Pairs model using Neural Networks. Here, annotations of all these three sub-tasks can be represented by assigning an appropriate label to each pair of words. It is not necessary to assign label to all possible word pairs; rather  $i^{th}$  word is paired with  $j^{th}$  word only when  $j \geq i$ . AWP-NN model is motivated from the table representation idea proposed by Miwa and Sasaki (2014) but differs significantly from it in following ways:

1. boundary identification is modelled with the help of a special relation type (WEM) instead of BIO (**B**egin, **I**nside, **O**ther) encoding or BILOU (**B**egin, **I**nside, **L**ast, **U**nit, **O**ther) encoding
2. neural network model for prediction of appropriate label for each word pair instead of structured prediction

Labels predicted by the AWP-NN model for each word pair can then be used to construct the end-to-end relation extraction output as described in tables 1 and 2.

Consider the example sentence from Section 2. Table 3 shows true annotations of all word pairs in this sentence as required for training the AWP-NN model. Labels used for these annotations can be grouped into the following 5 logical clusters:

1. PER, ORG, GPE, LOC, FAC, VEH and WEA : Represent entity type of *head word* of an entity mention when both the words in a word pair are the same
2. OTH : Represents words which are not head words of any entity mention and both the words in a word pair are the same

Table 3: Annotation of all word pairs as per the AWP-NN model

3. EMP-ORG, PHYS, OTHER-AFF, EMP-ORG-R, PHYS-R, OTHER-AFF-R<sup>3</sup>, PER-SOC, GPE-AFF and ART : Represent relation type between *head words* of any two entity mentions
4. NULL : Indicates that no pre-defined semantic relation exists between the words in the word pair
5. WEM (Within Entity Mention) : Indicates that the words in the word pair belong to the same entity mention and one of the word is the *head word* of that mention

### 3.1 Features for the AWP-NN model

Previous work (Zhou et al., 2005; Jiang and Zhai, 2007; Bunescu and Mooney, 2005; Qian et al., 2008) in relation extraction establishes the importance of both lexical and syntactic features. Hence, we designed features to capture information about word sequences, POS tags and dependency structure. As each word pair constitutes a separate instance for classification, features are of three types: i) features characterizing individual word in a word pair, ii) features characterizing properties of both the words at a time and iii) features based on feedback, i.e. predictions of preceding instances.

#### 3.1.1 Individual word features

These features are generated separately for both the words in a word pair.

1. Word itself and its POS tag
2. Previous word and previous POS tag
3. Next word and next POS tag
4. Parent / Governor of the word in the dependency tree, the corresponding dependency relation type and POS tag of the parent

<sup>3</sup>EMP-ORG-R, PHYS-R and OTHER-AFF-R correspond to relation types EMP-ORG, PHYS and OTHER-AFF in the reverse direction, respectively.

#### 3.1.2 Word pair features

These features are generated for a word pair (say  $\langle W_i, W_j \rangle$ ) as a whole.

1. Words distance (WD): Number of words in the sentence between the words  $W_i$  and  $W_j$
2. Tree distance (TD): Number of words on the path leading from  $W_i$  to  $W_j$  in the sentence's dependency tree
3. Common Ancestor (CA): Lowest common ancestor of the two words in the dependency tree
4. Ancestor Position (AP): It indicates the position of the common ancestor with respect to the two words of a word pair. Different possible positions of the ancestor are - left of  $W_i$ ,  $W_i$  itself, between  $W_i$  and  $W_j$ ,  $W_j$  itself and right of  $W_j$ .
5. Dependency Path ( $DP_1, DP_2, \dots, DP_K$ ): Sequence of dependency relation types (ignoring directions) on the dependency path leading from  $W_i$  to  $W_j$  in the sentence's dependency tree.

#### 3.1.3 Feedback features

These features are based on predictions of the preceding instances. Unlike other sequence labelling problems such as Named Entity Recognition where each word gets a label and there is natural order / sequence of instances (i.e. words), there is no natural order / sequence of instances (i.e. word pairs) for AWP-NN model. Hence, for each instance we identify its two preceding instances and define two corresponding feedback features ( $FB_1$  and  $FB_2$ ). Let  $\langle W_i, W_j \rangle$  be an instance representing a word pair in a sentence having  $N$  words such that  $1 \leq i, j \leq N$  and  $i \leq j$ . There are following two cases for identifying two preceding instances of  $\langle W_i, W_j \rangle$ :

- If  $i = j$  then both the preceding instances are same i.e.  $\langle W_{i-1}, W_{i-1} \rangle$ . Feedback features:  $FB_1 = FB_2 = \text{LabelOf}(\langle W_{i-1}, W_{i-1} \rangle)$
- If  $i < j$  then the preceding instances are

$\langle W_i, W_i \rangle$  and  $\langle W_j, W_j \rangle$ . Feedback features:  $FB_1 = \text{LabelOf}(\langle W_i, W_i \rangle)$  and  $FB_2 = \text{LabelOf}(\langle W_j, W_j \rangle)$

Label predictions of the preceding instances are then represented using one-hot encoding and used as features. During training, true labels of the preceding instances are used but while decoding, the predicted labels of these instances are used. Hence during decoding, predictions for word pairs of the form  $\langle W_i, W_i \rangle$  (diagonal word pairs in the table 3) are obtained first, starting from  $i = 1$  to  $N$ . Predictions of other word pairs can be obtained later, as predictions of their preceding instances would then be available.

### 3.2 Architecture of the AWP-NN model

Figure 1 shows various major components in the architecture of the AWP-NN model.

#### 3.2.1 Embedding Layers

Most of the features used by the model are discrete in nature such as words, POS tags, dependency relation types and ancestor position. These discrete features have to be mapped to some numerical representation and *embedding* layers are used for this purpose. We have employed following embedding layers to represent various types of features:

**Word embedding layer:** It maps each word to a real-valued vector of some fixed dimensions. We initialize this layer with the *pre-trained* 100 dimensional GloVe word vectors<sup>4</sup> learned on Wikipedia corpus. All the different features which are expressed in the form of words ( $W_1, W_2, NW_1, PW_1, NW_2, PW_2, Pa_1, Pa_2$  and  $CA$  in the figure 1) share the *same* word embedding layer. During training, the initial embeddings get *fine-tuned* for our supervised classification task.

**POS embedding layer:** It maps each distinct POS tag to some real-valued vector representation. All the different features which are expressed in the form of POS tags ( $T_1, T_2, NT_1, PT_1, NT_2, PT_2, PaT_1$  and  $PaT_2$  in the figure 1) share the *same* embedding layer.

**Dependency relation type embedding layer:** It maps each distinct dependency relation type to some real-valued vector representation. Both the features based on dependency types ( $DR_1, DR_2, DP_1, \dots, DP_K$  in the figure 1) also share the *same* embedding layer.

**AP embedding layer:** It maps each distinct ancestor position to some real-valued vector representation.

**WD/TD embedding layer:** Even though word distance (WD) and tree distance (TD) are numerical features, we used embeddings to represent each distinct value for them as range of values of these features is large. It was observed to be better than directly providing them as inputs to the neural network.

In our experiments, we used 20 dimensions for POS embeddings, 40 for dependency relation type embeddings and 5 dimensions for AP, WD and TD embeddings. Unlike word embeddings these were initialized randomly during training.

#### 3.2.2 Hidden Layers

First hidden layer is divided in 3 parts. First two parts of 60 nodes each are connected to only the features capturing first and second word, respectively. These nodes are expected to capture higher level abstract features of both the words separately. In order to force these two parts to learn similar abstract features, the weights matrix is shared among them. The third part of the first hidden layer consisting of 500 nodes is connected to all the input features except dependency path, i.e. individual word features of two words, word pair features and feedback features. Output of this part is further given as input to the second hidden layer of 250 units. Output of the second hidden layer is fed to the final softmax layer. Also, outputs of the first two parts of the first hidden layer are directly connected to the final softmax layer. As the dependency path is represented as a sequence of dependency relation types, it is fed to a separate LSTM layer. Output of the LSTM layer is directly connected to the final softmax layer. Softmax layer consists of 19 nodes, each representing one of the possible prediction label described earlier.

## 4 Inference using Markov Logic Networks

Pawar et al. (2016) presented an approach for end-to-end relation extraction which uses Markov Logic Networks (MLN) (Richardson and Domingos, 2006) to obtain *globally consistent* output by combining *local* outputs of individual classifiers. They developed separate classifiers for identifying mention boundaries, predicting entity types and

<sup>4</sup><http://nlp.stanford.edu/projects/glove/>

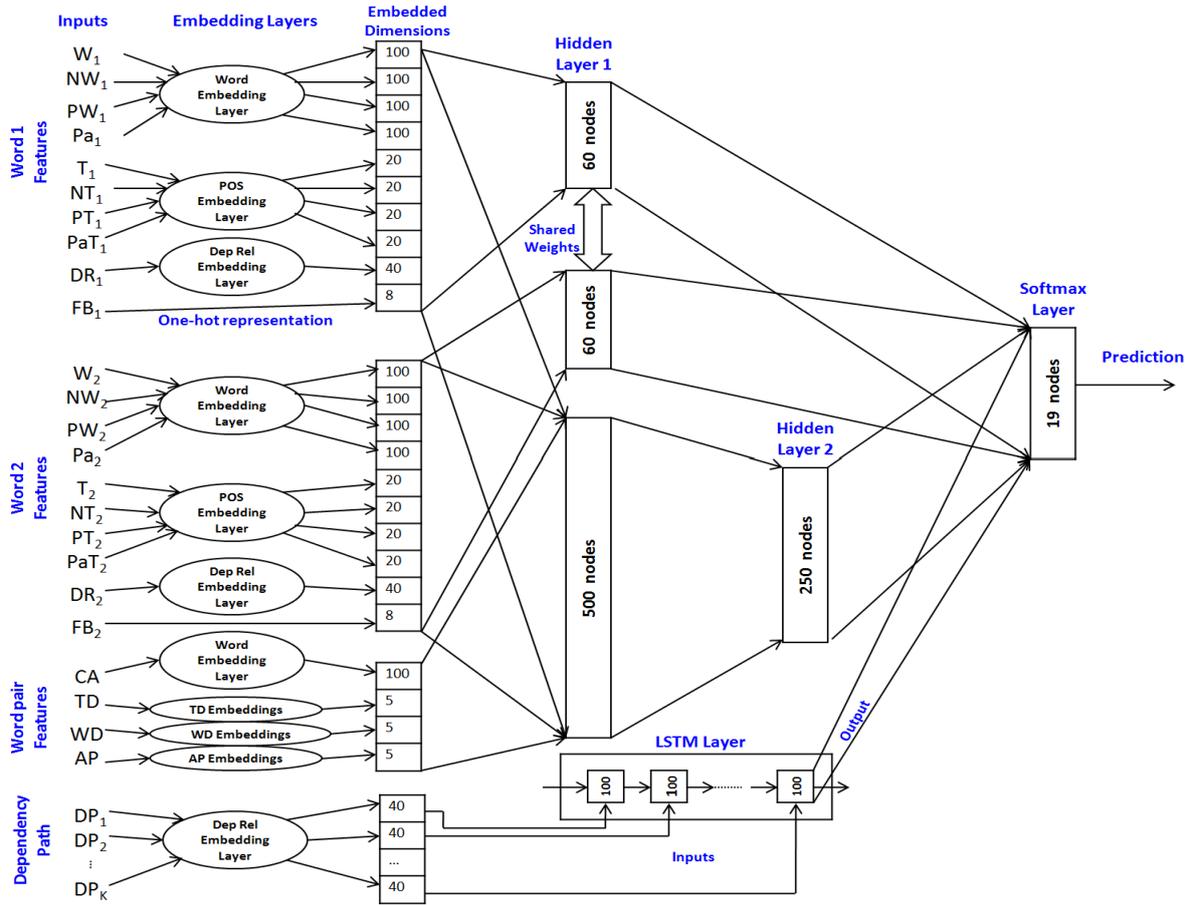

Figure 1: AWP-NN model architecture for predicting appropriate label for the given word pair. ( $W_1, W_2$ : words in the word pair;  $NW_1, PW_1, NW_2, PW_2, NT_1, PT_1, NT_2, PT_2$ : next and previous words/POS tags of  $W_1$  and  $W_2$ ;  $Pa_1, DR_1, Pa_2, DR_2$ : parents and corresponding dependency relation types of  $W_1$  and  $W_2$  in the dependency tree;  $PaT_1, PaT_2$ : POS tags of the parents of  $W_1$  and  $W_2$ ;  $FB_1, FB_2$ : Predictions of the preceding instances;  $CA$ : Lowest common ancestor of  $W_1$  and  $W_2$  in the dependency tree;  $TD$ : Tree distance;  $WD$ : Words distance;  $AP$ : Ancestor position;  $DP_1, DP_2, \dots, DP_K$ : Sequence of dependency relation types on the dependency path leading from  $W_1$  to  $W_2$ ; Embedding layers for words, POS and dependency relations are shown separately for clarity, but are shared throughout the network.

predicting relation types. Outputs of these classifiers may be inconsistent. E.g., if PER-SOC relation is predicted by the local relation classifier for an entity pair and the local entity classifier predicts entity type as ORG for one of the entity mentions, then there is an inconsistency. Because PER-SOC relation can only exist between two PER entity mentions. Such domain knowledge can be easily incorporated in the form of first-order logic rules in MLN. For each sentence, predictions of individual classifiers are represented in an MLN as first-order logic rules where weights of these rules are proportional to the prediction probabilities. The consistency constraints among the relation types and entity types can be represented in the form of first-order logic rules with infinite weights. Now,

the inference in such an MLN generates a globally consistent output with maximum weighted satisfiability of the rules.

AWP-NN is a single joint model which captures boundaries of mentions, their types and relations among them. As the same parameters are shared for all entity as well as relation type predictions, we expect the model to learn dependencies among relation and entity types. However, as it makes separate predictions for each word pair, there might be some inconsistencies among the labels as described above. We adopt the MLN-based approach of Pawar et al. (2016) for handling these inconsistencies and generate a globally consistent output. For this adoption, we consider the AWP-NN predictions for the words pairs where a word

<p><b>Domains:</b> Let <math>N</math> be the number of words in the sentence in consideration.</p> $word = \{1, 2, \dots, N\}, etype = \{PER, ORG, LOC, GPE, WEA, FAC, VEH, OTH\}$ $rtype = \{EMPORG, GPEAFF, OTHERAFF, PERSOC, PHYS, ART, NULL, WEM\}$
<p><b>Evidence Predicates:</b>  <math>ET(word, etype) : \text{AWP-NN predictions for word pairs } \langle W_i, W_j \rangle \text{ where } i = j</math>  <math>RT(word, word, rtype) : \text{AWP-NN predictions for word pairs } \langle W_i, W_j \rangle \text{ where } i &lt; j</math></p>
<p><b>Query Predicates:</b>  <math>ETFinal(word, etype) : \text{Global predictions for word pairs } \langle W_i, W_j \rangle \text{ where } i = j</math>  <math>RTFinal(word, word, rtype) : \text{Global predictions for word pairs } \langle W_i, W_j \rangle \text{ where } i &lt; j</math></p>
<p><b>Some examples of generic rules:</b></p> $RTFinal(x, y, EMPORG) \wedge ETFinal(x, PER) \Rightarrow (ETFinal(y, ORG) \vee ETFinal(y, GPE)).$ $RTFinal(x, y, PERSOC) \Rightarrow (ETFinal(x, PER) \wedge ETFinal(y, PER)).$

Table 4: Domains and Predicates used for constructing MLN for any given sentence

is paired with itself (diagonal entries in table 3), as *entity* type predictions. Whereas all other word pairs where a word is paired with any subsequent word in the sentence, are considered as *relation* type predictions. Table 4 describes the domains and predicates required for generating an MLN for any given sentence. Unlike Pawar et al. (2016) which considers all predicted mentions in their *entity* domain, we consider all words in our *word* domain. But to keep the size of the MLN in check, we keep only those words in the *word* domain which are part of *interesting* word pairs. A word pair is an *interesting* word pair, if it can potentially represent a relation i.e. if AWP-NN model assigns a probability more than some threshold (say 0.01) for any non-NULL relation type. All the *generic rules* (with infinite weights) described in (Pawar et al., 2016) are used for imposing constraints among the relation and entity types. Also, we added following additional *generic rules* for specifying constraints for our *WEM* relation type, which captures information about mention boundaries.

$$RTFinal(x, y, WEM) \Rightarrow (ETFinal(x, OTH) \vee ETFinal(y, OTH)).$$

$$RTFinal(x, y, WEM) \Rightarrow (!ETFinal(x, OTH) \vee !ETFinal(y, OTH)).$$

By definition, the WEM relation holds between a head word of an entity mention and other words of that entity mention. Additionally, head word of an entity mention is labelled with appropriate entity

label and other words are labelled with entity type OTH. The above rules state that if there is WEM relation between two words  $x$  and  $y$  then at least one of them should have label OTH and at least one of them should have entity type label, i.e. a label from domain *etype* other than OTH.

Similarly, all the *sentence-specific rules* (with finite weights proportional to AWP-NN prediction probabilities) described in (Pawar et al., 2016) are also generated for representing predictions of the AWP-NN model. We use *Constant Multiplier* (CM) as the weights assignment strategy. Following rule would be generated for each entity type  $E$  (from *etypes*) for each word pair  $\langle W_i, W_j \rangle$ , with the weight  $10 \cdot Pr_{AWP-NN}(E|\langle W_i, W_j \rangle)$  where  $E_{max}$  is the predicted entity type with the highest probability:

$$ET(i, E_{max}) \Leftrightarrow ETFinal(i, E)$$

Similarly, following rule would be generated for each relation type  $R$  (from *rtypes*) for each word pair  $\langle W_i, W_j \rangle$ , with the weight  $10 \cdot Pr_{AWP-NN}(R|\langle W_i, W_j \rangle)$  where  $R_{max}$  is the predicted relation type with the highest probability:

$$RT(i, R_{max}) \Leftrightarrow RTFinal(i, R)$$

Using these *generic* and *sentence-specific* rules, an MLN is constructed for each sentence. The best values of *ETFinal* and *RTFinal* (query predicates) for each word pair are obtained by using the

inference in this MLN with *ET* and *RT* as evidence predicates based on AWP-NN’s predictions.

## 5 Experimental Analysis

### 5.1 Dataset

ACE 2004 dataset (Dodgington et al., 2004) is the most widely used dataset<sup>5</sup> for reporting relation extraction performance. We use this dataset to demonstrate effectiveness of our approach for end-to-end relation extraction using AWP-NN model and MLN inference. We perform 5-fold cross-validation on this dataset where the folds are formed at the document level. We follow the same assumptions made by (Chan and Roth, 2011; Li and Ji, 2014; Pawar et al., 2016), which are - ignore the DISC relation, do not consider implicit relations (resulting due to intra-sentence co-references) as false positives and use coarse-level entity and relation types.

**Direction of Relations:** Out of 6 coarse-level relation types that we are considering, we need not model direction for relation types PER-SOC, GPE-AFF and ART. Because in case of these relations, given the entity types of their arguments, the direction of relation is not necessary or becomes implicit. As PER-SOC is a social relation between two PER entity mentions, the direction is not necessary. For GPE-AFF, as entity type of one of the arguments is always GPE, the direction becomes implicit. Also, the relation type ART always holds between an agent (PER, ORG or GPE) and an artifact (FAC, WEA or VEH), hence the direction is implicit. Whereas for relation like EMP-ORG which also represents subsidiary relationship between two ORG entity mentions, it is important to model the relation direction explicitly. Consider following sentence fragments:

- ..the fisheries section of the Gulf Coast Research Laboratory..
- ..company that owned Road & Track..

Here, EMP-ORG relation exists between ORG entity mentions `fisheries section` and `Gulf Coast Research Laboratory`. Whereas, EMP-ORG-R relation holds between `that` and `Road & Track`.

Hence, we consider 9 distinct relation types: EMP-ORG, EMP-ORG-R, PHYS, PHYS-R, OTHER-AFF, OTHER-AFF-R, PER-SOC,

<sup>5</sup>We haven’t yet acquired a more recent ACE 2005 dataset

GPE-AFF and ART. Hence, the overall dataset contained 4074 instances<sup>6</sup> of valid relation types.

### 5.2 Implementation details

We used Keras (Chollet, 2015) for implementing our AWP-NN model. The model was trained for 40 epochs using batch size of 64 instances. We used *Dropout* (Srivastava et al., 2014) for regularization with probability 0.5 for hidden layers and 0.1 for embedding layers. We used the tool *Alchemy*<sup>7</sup> for MLN inference. The value of K (maximum length of dependency path, see Figure 1) was set to be 4, hence all word pairs having length of dependency path more than 4 were assumed to have NULL label.

### 5.3 Results

Table 5 shows the comparative performances (in terms of micro-F1 measure) for various approaches. The results are divided in three different sections:

1. **only entity extraction:** It includes boundary identification as well as entity type classification.
2. **only relation extraction:** It includes relation type classification for each pair of predicted entity mentions. It is a relaxed version of end-to-end relation extraction problem where correct relation label for an entity mention pair is counted as a true positive even if entity types of one or both the mentions are identified incorrectly.
3. **entity+relation extraction:** It is end-to-end relation extraction which includes boundary identification, entity type classification and relation type classification. Here, correct relation label for an entity mention pair is counted as a true positive only if boundaries and entity types of both the mentions are identified correctly.

It can be observed in the table 5 that end-to-end relation extraction performance of our AWP-NN model is better than all the 4 previous approaches (Chan and Roth, 2011; Li and Ji, 2014; Pawar et al., 2016; Miwa and Bansal, 2016) on the ACE 2004 dataset. However, the AWP-NN+MLN approach which uses MLN inference to revise AWP-NN predictions during decoding, achieves the best performance.

<sup>6</sup>279 instances of type DISC were not considered. Additionally, 21 relation instances were not contained in a single sentence as per our sentence detection algorithm.

<sup>7</sup><https://alchemy.cs.washington.edu/>

Approach	Entity Extraction			Relation Extraction			Entity+Relation		
	P	R	F	P	R	F	P	R	F

Table 5: Performance of various approaches on the ACE 2004 dataset. The numbers are micro-averaged and obtained after 5-fold cross-validation. Actual folds used by each algorithm may differ.

### 5.3.1 Statistical Significance

As neural networks are initialized randomly, if we train a neural network model multiple times, different predictions are obtained each time. Hence, it is important to establish the statistical significance of the performance. We train our AWP-NN model 30 times independently and obtain 30 different values for precision, recall and F1 score. The numbers shown in table 5 are average values over these 30 runs. Also, in order to establish that the F1 score of AWP-NN model is significantly higher than the best previous F1 score of 48.4% (by Miwa and Bansal (2016)), we conduct one tailed one sample t-test. Here, mean and standard deviation of sample of 30 F1 scores by AWP-NN are 49.3 and 0.44, respectively. This leads to p-value of  $1.23 \times 10^{-12}$ , hence establishing the statistical significance of AWP-NN’s performance.

## 5.4 Analysis of results

### 5.4.1 Effect of using MLN

We analyzed the effect of using MLN by observing the individual sentences where errors of AWP-NN were being corrected by MLN. As an example, consider the following sentence:

Lemieux<sub>0</sub> rescued<sub>1</sub> his<sub>2</sub> team<sub>3</sub> from<sub>4</sub> bankruptcy<sub>5</sub> last<sub>6</sub> season<sub>7</sub> by<sub>8</sub> exchanging<sub>9</sub> deferred<sub>10</sub> salary<sub>11</sub> for<sub>12</sub> an<sub>13</sub> ownership<sub>14</sub> stake<sub>15</sub> .<sub>16</sub>

End-to-end relation extraction output produced by the AWP-NN model for this sentence is shown in the tables 6 and 7. Only error in this output is that entity type of the mention `team` should be `ORG` instead of `PER` as it refers to some professional team. After MLN inference, the entity type of `team` is corrected to `ORG`. This happens because of high-confidence `EMP-ORG` relations between `Lemieux` and `team` and between `his` and `team`. As both `Lemieux` and `his` are of type

`PER` with high confidence, global inference using `MLN`<sup>8</sup> forces type of `team` to be `ORG` to ensure compatibility of relation and entity types.

Entity Mention	Boundaries	Entity Type
Lemieux	(0, 0)	PER
his	(2, 2)	PER
team	(3, 3)	PER

Table 6: End-to-end relation extraction output (entity mentions) produced by the AWP-NN model

Entity Mention Pair	Relation Type
Lemieux, team	EMP-ORG
his, team	EMP-ORG

Table 7: End-to-end relation extraction output (relations) produced by the AWP-NN model

The AWP-NN model was able to outperform (see table 5) all 4 previous approaches without the help of MLN. One reason behind this may be that the AWP-NN model itself was sufficient to learn most of the dependencies among the entity and relation types. However, MLN helped to improve the performance of AWP-NN by 0.6 F1. Though considerable improvement was observed in the precision value, the recall improvement was not significant. In other words, MLN was observed to be more effective for reducing false positives than false negatives.

### 5.4.2 Difficult to identify entities

We observed that for some entity mentions, it is very difficult to identify their entity types as the key information required for identification lies outside the current sentence. Currently, our approach does not use any information outside the sentences, such as document level co-reference

<sup>8</sup>Detailed MLN rules & inference results for this sentence can be found at: [www.cse.iitb.ac.in/~sachinpawar/MLN/sentence.html](http://www.cse.iitb.ac.in/~sachinpawar/MLN/sentence.html)

information. Usually these difficult to classify entity mentions are pronoun mentions. Some examples are as follows:

1. Though, I think that if they could stifle the entire peace process at the moment, then that is what they'd like to do.
2. It is a partially victory for both sides.

Here, in the first sentence, it is difficult to identify (even for humans) whether entity type of they is PER (e.g. set of leaders) or GPE (e.g. countries). Also, in the second sentence, entity type of sides can be any of PER, ORG or GPE depending on the context. In future, we plan to capture document level information for correctly predicting types of such mentions.

## 6 Related Work

There have been multiple lines of research for jointly modelling and extracting entities and relations. Integer Linear Programming (ILP) based approaches (Roth and Yih, 2004; Roth and Yih, 2007) were the earliest ones. Here, various local decisions are associated with suitable “cost” values and they are represented using an integer linear program. The optimal solution to this integer linear program provides the best global output. Another significant lines of research were Probabilistic Graphical Models (Roth and Yih, 2002; Singh et al., 2013), Card-pyramid parsing (Kate and Mooney, 2010) and Structured Prediction (Li and Ji, 2014; Li et al., 2014; Miwa and Sasaki, 2014).

Four previous approaches (Miwa and Sasaki, 2014; Li and Ji, 2014; Pawar et al., 2016; Miwa and Bansal, 2016) are the most similar to our approach in the sense that they all address the problem of end-to-end relation extraction without assuming gold-standard entity mention boundaries like the earlier approaches. Our idea of labelling “all word pairs” is similar to the table representation idea of Miwa and Sasaki (2014). The major difference is that they identify boundaries of mentions through BIO encoding of labels whereas we try to capture boundaries by treating them as an additional relation type WEM. Also, they perform structured prediction with beam search to find optimal label assignment to the table, whereas we opt for neural network based classification. The idea of using MLNs to incorporate domain knowl-

edge and perform joint inference to obtain globally consistent output was proposed by Pawar et al. (2016). The current state-of-the-art approach for end-to-end relation extraction is by Miwa and Bansal (2016), who employ LSTM-RNN based model for addressing this problem.

## 7 Conclusion and Future Work

We proposed a novel approach for end-to-end relation extraction which carries out its all three sub-tasks (identifying entity mention boundaries, their entity types and relations among them) jointly by using a neural network based model. We proposed a “All Word Pairs” neural network model (AWP-NN) which reduces solution of these three sub-tasks to predicting an appropriate label for each word pair in a given sentence. End-to-end relation extraction output is then constructed from these labels of word pairs. We further improved output of the AWP-NN model by using inference in Markov Logic Networks so that some of the inconsistencies in word pair labels can be removed at the sentence level.

We demonstrated effectiveness of our approaches (AWP-NN and AWP-NN+MLN) on the standard dataset of ACE 2004. They outperformed all 4 previously reported joint modelling approaches (Chan and Roth, 2011; Li and Ji, 2014; Pawar et al., 2016; Miwa and Bansal, 2016) for end-to-end relation extraction. Since all three sub-tasks share the same AWP-NN model parameters, many inter-task dependencies are captured effectively by the AWP-NN itself (without MLN) and this can be validated by the fact that AWP-NN itself performs better than all other joint models. However, MLN certainly helps to further improve the end-to-end relation extraction performance by correcting some errors in predictions of the AWP-NN model.

In future, we plan to incorporate some additional features (e.g. document level co-reference information) in the AWP-NN model for improving its performance further. Also, deeper analysis of the errors is required to have a better understanding about which characteristics are better captured by the AWP-NN model as compared to the MLN and vice versa. This will help these two to complement each other in a better way.

### Abstract

We introduce automatic verification as a post-processing step for entity linking (EL). The proposed method *trusts* EL system results collectively, by assuming entity mentions are mostly linked correctly, in order to create a semantic profile of the given text using geospatial and temporal information, as well as fine-grained entity types. This profile is then used to automatically *verify* each linked mention individually, i.e., to predict whether it has been linked correctly or not. Verification allows leveraging a rich set of global and pairwise features that would be prohibitively expensive for EL systems employing global inference. Evaluation shows consistent improvements across datasets and systems. In particular, when applied to state-of-the-art systems, our method yields an absolute improvement in linking performance of up to 1.7 *F1* on AIDA/CoNLL'03 and up to 2.4 *F1* on the English TAC KBP 2015 TEDL dataset.

### 1 Introduction

Entity linking (EL) is the task of automatically linking mentions of entities such as persons, locations, or organizations to their corresponding entry in a knowledge base (KB). The task is generally approached by generating a set of candidate entities<sup>1</sup> for a given mention and then ranking those candidates. Approaches differ in whether they rank a mention's candidates independently of the candidates of other mentions ("local inference") or

whether they rank all candidates of all mentions simultaneously by incorporating a global coherence measure into the optimization goal ("global inference").

While linguistically well-founded in the concept of lexical cohesion (Halliday and Hasan, 1976), global inference approaches (Kulkarni et al., 2009; Hoffart et al., 2011a) do not scale well with number of mentions and number of candidate entities. In contrast, local approaches do not suffer from scalability issues, since they only optimize the similarity between mention context and candidate KB entry text (Bunescu and Paşca, 2006; Cucerzan, 2007), usually also including a popularity prior<sup>2</sup> (Milne and Witten, 2008; Spitzkovsky and Chang, 2012). Recent local approaches achieve state-of-the-art results by using convolutional neural networks to capture similarity at multiple context sizes (Francis-Landau et al., 2016), but, by definition, fail to take global coherence into account.

To avoid the trade-off between the efficiency of local inference on the one hand and the coherence benefits of global inference on the other, we propose a two-stage approach: In the first stage, candidate entities are ranked by a fast, local inference-based EL system. In the second stage these results are used to create a semantic profile of the given text, derived from rich data the KB contains about the top-ranked candidates. Since the linking precision of current EL systems is relatively high, we trust that this profile is reasonably accurate and leverage it to measure the cohesive strength between a given candidate entity and the other linked entities mentioned in the text. We then automatically verify the first stage results by classifying entity links as correct if they display high coherence, and as wrong if there are only weak or no cohesive

\*The majority of this work was done during an internship at Microsoft Research Asia.

<sup>1</sup>We use *entity* to refer to both real-word entities and to their corresponding entries in the KB.

<sup>2</sup>Also referred to as *commonness prior* by some authors.

ties to the semantic profile. Verification results can be used in at least three ways:

1. To increase linking precision by filtering out all entity links classified as wrong;
2. To rerank candidate entities by the class probability estimated by the verifier, i.e., prefer candidates that were predicted as correct with higher probability; or
3. To employ a more sophisticated EL system to re-link all entity links classified as wrong, using the entity links deemed correct as additional context.

In this work we investigate options 1. and 2., and make the following contributions:

- We propose automatic verification as a post-processing step for EL systems;
- We propose global coherence features based on notions of entity type coherence, geographic coherence, and temporal coherence;
- We show how these novel features, as well as features developed in prior work, can be used to verify EL results; and
- We show that automatic verification consistently improves linking performance in an evaluation across two datasets and seven different EL systems.

## 2 Method

We cast entity linking verification as a supervised classification task. Given EL system output on a training set with gold standard linked entity annotations, we extract global, pairwise, and local features and train a classifier to predict whether a given mention has been linked correctly by the EL system.

In the standard EL setting, global inference is an NP-hard problem, since all combinations of all candidate entities of all mentions are considered simultaneously. In our proposed automatic verification setting, however, taking only the top candidate entities into account allows us to employ knowledge-rich, global coherence features that would be prohibitively expensive otherwise.

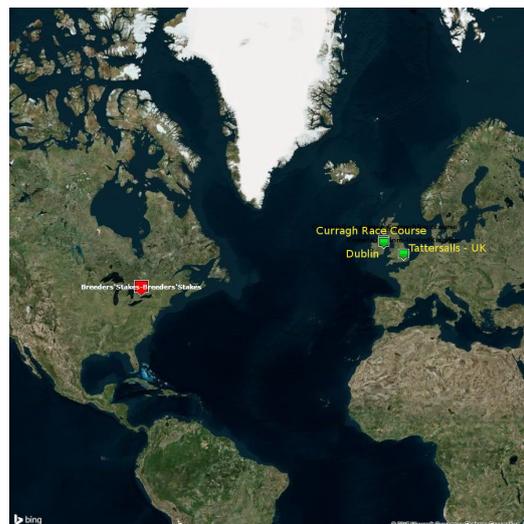

Figure 1: Example showing a geographical outlier: Breeder’ Stakes (red, in Canada) and contextual entities located in Ireland and the UK (green).

### 2.1 Aspects of Global Coherence

Global coherence captures how well a candidate entity fits into the overall semantic profile of a text. Current global inference approaches optimize a single coherence measure, most commonly a measure of general semantic relatedness such as the Milne-Witten distance (Milne and Witten, 2008), or keyphrase overlap relatedness (KORE) (Hoffart et al., 2012).

In contrast, verification allows employing many global coherence features, which we categorize according to four aspects of coherence: geographical coherence and temporal coherence, which to our knowledge have not been used before in EL, as well as entity type coherence and the general semantic relatedness mentioned above.

#### 2.1.1 Geographic Coherence

Entities mentioned in a text tend to be geographically close or clustered around very few locations. We use this observation to identify geographic outliers as potential entity linking mistakes.

For example, consider the mention *Breeders Stakes* in the following excerpt (CoNLL 1112testa):

DUBLIN 1996-08-31 Result of the Tattersalls Breeders Stakes , a race for two-year-olds run over six furlongs at The Curragh ...

*DUBLIN, Tattersalls* (a company doing business in the UK and Ireland), and *The Curragh* (a

horse race track in Ireland) clearly situate the text in Ireland (cf. Figure 1). However, some current EL systems link *Breeder Stakes* to the Wikipedia article about the Canadian horse race of the same name, since the Irish race does not have a Wikipedia article and other evidence<sup>3</sup> suggests a strong match.

We aim to identify these kinds of errors by first querying locations (Table 1) of all linked mentions in the document, and then performing geographic outlier detection<sup>4</sup>. This yields a binary feature indicating whether a candidate entity is a geographic outlier or not.

Since outliers are rare and hence the resulting features sparse, we also add a feature for the average geographic distance  $\bar{d}(e, D)$  of a candidate entity  $e$  to all other entities in document  $D$ :

$$\bar{d}(e, D) = \frac{\sum_{e' \in D \setminus e} d(e, e')}{|D| - 1}$$

where  $d(e, e')$  is the geographic distance between entities  $e$  and  $e'$ , and  $|D|$  is the number of entities

<sup>3</sup>Specifically, high context-similarity due to the appositive *race*, and an almost perfect string match between mention and Wikipedia title.

<sup>4</sup>We use an ensemble of standard outlier detection algorithms provided by the ELKI clustering toolkit (Achter et al., 2011).

mentioned in  $D$ . This feature is based on the intuition that a candidate entity which is geographically closer to other entities is more likely to be correct than a distant one.

Geographic scope varies across documents. For example, entities mentioned in a text about world politics will be geographically more distant than entities in a text about a local business). As a scale-invariant distance measure  $s(e, D)$ , we divide the average distance  $\bar{d}(e, D)$  by the average distance between all other entities:

$$s(e, D) = \bar{d}(e, D) / \frac{\sum_{e', e'' \in D \setminus e} d(e', e'')}{|e', e'' \in D \setminus e|}$$

### 2.1.2 Temporal Coherence

Applying the notion of coherence to the temporal dimension, we observe that entities mentioned in a text tend to be temporally close or clustered around a few points in time.

Entities are associated with temporal ranges with a *begin*, i.e. the point in time at which the entity comes into existence, and an *end*, i.e. the point in time at which the entity ceases to exist. Using the same approach as in geographical outlier detection, we perform temporal outlier detection on all *begin* and *end* times associated with linked entities in the given text, and declare a candidate entity as a temporal outlier if both its *begin* and *end* were detected as outliers.

Since temporal outliers are rare, we also add a feature aiming to capture temporal proximity and distance in a softer fashion with higher coverage; by calculating the total overlap  $T(e, D)$  between the temporal range  $t(e)$  of a candidate entity  $e$ , and the known temporal ranges of all other linked entities in the document  $D$ :

$$T(e, D) = \sum_{e' \in D \setminus e} |t(e) \cap t(e')|$$

where  $|t(e) \cap t(e')|$  is the length of the overlap between the temporal ranges of entities  $e$  and  $e'$ .<sup>5</sup>

Analogously to the geographic distance feature, we take temporal proximity, i.e. a large overlap with other temporal ranges, as evidence for a correctly linked entity, and temporal distance, i.e. only small or no overlap with other temporal

<sup>5</sup>We also extract this feature normalized by the number of entity mentions in the document, but did not see any effect. This is likely due to little variation in the number of entities per document for which the KB contains temporal information.

ranges, as evidence for a linking mistake. Temporal ranges are queried from the KB using the predicates shown in Table 2.

The final feature using temporal information checks whether an entity’s temporal ranges contains the document’s creation date. This feature is based on the intuition that, especially in the news genre, an existing entity is more likely to be mentioned than an entity that has already ceased to exist or did not exist at the time of writing. The document creation date is either trivially obtained if metadata is present, or heuristically by using the first date found in the document text by the Heidelberg Time temporal tagger (Strötgen and Gertz, 2010).

### 2.1.3 Entity Type Coherence

Frequency statistics of the types of entities mentioned in a text are an indicator of what the text is about. For example, looking at the entity type distribution shown in Table 3, we can tell that the corresponding text appears to be about rugby teams. Unlike other methods for representing the “aboutness” of a text, such as topic models, entity type statistics are grounded in the KB, thus offering a simple method of measuring the relatedness between entities in terms of their types via the similarity of their type distributions.

Specifically, we model entity type coherence between a given candidate entity  $e$  and all other linked entities in document  $D$  as the cosine similarity of the respective type distributions. Type frequencies are TF-IDF weighted, in order to discount frequent types (e.g. `:base:tagit:concept`) and give more importance to salient types occurring in the document (e.g. `:base.rugby.rugby_club`):

$$coh_{type}(e, D) = sim(types(e), tfidf(types(D)))$$

where  $sim$  is the cosine similarity,  $types(e)$  a binary vector indicating the types of entity  $e$ , and  $types(D)$  a vector whose entries are occurrence counts of entity types in document  $D$ , which are weighted by  $tfidf$ .

TF-IDF	Count	Type
1115.67	2	<code>:base.rugby.rugby_club</code>
243.62	3	<code>:organization.organization</code>
231.76	2	<code>:base.schemastaging.sports_team_extra</code>
183.49	2	<code>:sports.sports_team</code>
56.34	2	<code>:base.tagit.concept</code>

Table 3: Entity type distribution in a document about rugby, sorted by type TF-IDF.

### 2.1.4 Semantic Relatedness

Measures of generic semantic relatedness are a standard feature in global inference systems. We add features for the average and maximum semantic relatedness  $SemRel(e, D)$  of a candidate entity  $e$  with respect to all other entities  $e'$  mentioned in document  $D$ , using two semantic relatedness measures:

$$SemRel_{max}(e, D) = max_{e' \in D \setminus e} SemDist(e, e')$$

$$SemRel_{avg}(e, D) = avg_{e' \in D \setminus e} SemDist(e, e')$$

where  $max$  and  $avg$  are the maximum and average operators.  $SemDist$  denotes either the Milne-Witten Distance (Milne and Witten, 2008), which defines relatedness of Wikipedia entries in terms of shared incoming article links, or the Normalized Freebase Distance (Godin et al., 2014), an adaptation of the Milne-Witten Distance to Freebase entities.

## 2.2 Pairwise Features

**Semantic relation:** Given a pair consisting of a candidate entities and an entity mention in its context, we add a feature encoding whether a (and if yes which) semantic relation exists between the two entities. We add different features depending on the type of context in which the entity pair occurs: in the same sentence, within a fixed token window, and within the same noun phrase. For example, in the noun phrase *German Chancellor Angela Merkel*, we find a `wasBornIn` and a `isLeaderOf` relation between YAGO entities `ANGELA_MERKEL`<sup>6</sup> and `GERMANY`. We expect this feature to be sparse, but strong evidence for both arguments of the identified relation being linked correctly. We record the relation type, as some relations tend to be more informative than others, e.g., the `playsFor` relation, which holds between players and sports teams,

<sup>6</sup>In this work, `SMALL_CAPS` denote both real-world entities and their corresponding entries in the knowledge base.

should provide stronger evidence than the less specific `isCitizenOf` relation, which holds between citizens and countries.

**Person name consistency:** Having observed that some local inference systems tend to make the mistake of linking a full name mention (e.g. “John Smith”) to one entity, and a coreferent surname-only mention (“Smith”) to a different one, we add a binary feature that indicates whether a candidate entity assigned to a partial person name mention agrees with its unambiguous full name antecedent.

### 2.3 Local Features

Since the global and pairwise features do not have high enough coverage to provide evidence for all linked candidate entities, we employ local features that are devised to capture similarity between a candidate entity and its textual context. As these features are commonly used in EL systems, we only give brief descriptions for completeness.

**Popularity prior:** The prior probability of the candidate entity given its mention, obtained from the CrossWikis dictionary (Spitkovsky and Chang, 2012). This feature aims to cover unambiguous and almost unambiguous mentions.

**Entity type agreement:** A binary feature indicating whether the candidate entity type, as found in the KB agrees with the named entity type, as determined by the NER system during preprocessing.

**Keyphrase match:** Knowledge bases contain various sources of key phrases, such as labels and aliases of semantic types, or salient noun phrases in description texts, e.g., noun phrases occurring in the first, defining sentence of a Wikipedia article. We add a binary feature indicating whether a known keyphrase occurs in the context of a given candidate entity.

**Demonym match:** This binary feature indicates whether a mention is a demonym of its linked entity, e.g., the mention text *French* is a demonym match for the entity FRANCE.

**Mention-entity string match:** Finally, we extract features from the string similarity between a mention and the known labels and aliases of a candidate entity. The similarity measures include exact match, case-insensitive match, head match, match with stop words filtered, fuzzy string match, Levenshtein distance, and abbreviation pattern matches, as well as different combinations of these.

Dataset	CoNLL	TAC15
Entity Type	99.2	98.5
Geographic	62.9	41.5
Temporal	87.6	79.4

Table 4: KB coverage of our proposed global coherence features. Shown are the percentages of in-KB mentions in each dataset for which the KB (YAGO or Freebase) contains the required information for each coherence feature set.

## 3 Experiments

We evaluate our automatic verification method by applying it to the entity linking results produced by seven systems on two standard datasets: CoNLL, which consists of 1393 Reuters news articles annotated with Wikipedia links by Hoffart et al. (2011a) and TAC15, which comprises 315 news articles and discussion forum texts annotated with Freebase links for the TAC KBP 2015 TEDL shared task (Ji et al., 2015).

The KB coverage for each of our proposed global coherence features on these two datasets is shown in Table 4. YAGO and Freebase contain entity type information for almost all in-KB entities mentioned in the two datasets. Geographic data is available for 62.9 percent on CoNLL, but only for 41.5 percent of entities mentioned in TAC15. This difference is likely due to the large fraction of documents from the sports genre in CoNLL. These documents include match result tables mentioning a large number of sports teams, which can be easily located via their cities and stadiums. Temporal information is present for most entities.

Our evaluation uses results of the following EL systems:

**AIDA** (Hoffart et al., 2011a): This system globally optimizes a graph-based model incorporating three factors: a popularity prior, the context similarity of mention and candidate entity, and coherence modeled via general semantic relatedness measures. We use the AIDA system output on the CoNLL dataset as provided by the Wikilinks project.<sup>7</sup>

**SPOTL** (Daiber et al., 2013): DBpedia Spotlight is a local inference system. We use results obtained from the Spotlight webservice.<sup>8</sup>

<sup>7</sup>[https://github.com/wikilinks/conll103\\_nel\\_eval](https://github.com/wikilinks/conll103_nel_eval)

<sup>8</sup><https://github.com/dbpedia-spotlight/>

**FL** (Francis-Landau et al., 2016): This local inference system models mention and entity context with a convolutional neural network (CNN). The CNN captures semantic similarity of a given mention’s context at different granularities (small context window, paragraph, document) and the entity context derived from the entity’s Wikipedia page.

**PH** (Perschina et al., 2015): This global inference system applies Personal PageRank to a graph whose nodes represent candidate entities and whose edges indicate if a link between the corresponding Wikipedia articles exists. PH achieves the best CoNLL performance among the systems in our evaluation.

**TAC-1** (Heinzerling and Strube, 2015): This system uses local and pairwise inference in an easy-first, incremental rule-based approach. Features are based on popularity priors, contextual occurrence of keywords, entity type, and relational evidence.

**TAC-2** (Sil et al., 2015): This system employs a global inference approach which partitions a document into sets of mentions that appear near each other. The partitioning is motivated by the intuition that a given mention’s immediate context provides the most salient information for disambiguation, and drastically reduces the search space during global optimization.

**TAC-3** (Dai et al., 2015): This local inference system models mentions and entity context with a CNN and word embeddings.

The systems were chosen for their popularity (AIDA, SL), performance on CoNLL (FL, PH), and performance on TAC15 (TAC systems). Unless stated otherwise, we use system output provided by authors for CoNLL systems, and provided by the workshop organizers for TAC15 systems.<sup>9</sup> Our evaluation does not include (Globerston et al., 2016) and (Yamada et al., 2016), who report better performance on CoNLL than PH, but were unable to make system output available.

### 3.1 Setup and Implementation Details

Feature extraction is implemented as a UIMA pipeline (Ferrucci and Lally, 2004); using the Stanford CoreNLP (Manning et al., 2014) UIMA components provided by DKPro (Eckart de Castilho and Gurevych, 2014) for text segmentation, POS tagging, and named entity recogni-

tion; DKPro WSD (Miller et al., 2013) for modeling entity mentions and links, and using Freebase (Bollacker et al., 2008) and YAGO (Hoffart et al., 2011a) as knowledge bases.

After feature extraction, we train a random forest classifier<sup>10</sup> for each dataset, one using FL system results for the CoNLL development set (216 documents) and one using TAC-1 results for the TAC15 training set (168 documents).

For evaluation, we apply the verifier trained on FL CoNLL development results to the test set results of the FL and AIDA systems, and a verifier trained on PH training data to the PH test set results. For the test set output of TAC systems 1-3 we apply the verifier trained on the TAC15 training set output of TAC-1.

As metric we use `strong_link_match` as implemented by the Wikilinks project for the CoNLL dataset, and the official NIST scorer (Hachey et al., 2014) for TAC15. This metric measures precision, recall, and  $F1$  of matching entity links and mention spans.

### 3.2 Results and Discussion

Evaluation results are shown in Table 5. Our method improves the linking performance of all evaluated EL systems. The impact is most noticeable for the systems that only use local and pairwise inference, namely FL (+1.9  $F1$ ), TAC-1 (+2.4  $F1$ ), TAC-3 (+1.1  $F1$ ). The improved TAC-1 result (68.1 $F1$ ) is the best published linking score on the TAC15 dataset.

Improvements are smaller for the global inference systems, AIDA, HP, and TAC-2. In contrast to Ratnov et al. (2011), who report only a very small increase in linking performance when incorporating global features into a local inference-based system, our results indicate that global features are useful and lead to considerable improvements.

As expected, improvements are caused by increased precision, due to filtering out likely linking mistakes. The fact that this increase is not accompanied by a commensurate decrease in recall, shows that our method predicts wrong linking decisions with high accuracy.

On TAC15, we observe considerable improvements in linking precision of up to 10.4 percent.

	TAC-3	68.0	<b>55.6</b>	61.1	<b>77.6</b>	52.0	<b>62.2</b>	+9.6	-3.2	+1.1

Table 5: Results on CoNLL and TAC15 test sets. *Baseline* shows performance of the original systems, *After verification* shows performance after application of our automatic verification method, and  $\Delta$  shows the corresponding change. Bold font indicates best results for each metric and system.

On CoNLL, the precision increase is less pronounced, arguably owing to the already higher baseline precision, which leaves less room for improvement. Since EL is usually performed as part of a larger task, such as knowledge base completion, search, or as part of a more comprehensive entity analysis system (Durrett and Klein, 2014), good precision is highly desirable in order to minimize error propagation to other system components and downstream applications.

### 3.3 Candidate Reranking

We resort to the binary decision of either retaining or removing an entity linked by an EL system if no candidate entities and no meaningful confidence scores are available. This is the case for the output of many EL systems, such as the systems participating in the TAC KBP TEDL 2015 challenge.

In case the EL system outputs not only the top-ranked candidate entity, but also lower-ranked ones, we can apply our verification method to all candidates and rerank them according to their probability of being correct. For example, if the EL system linked a mention to candidate entity  $e_1$  over candidate  $e_2$ , but verification assigns a higher probability of being correct to  $e_2$ , we rerank  $e_2$  over  $e_1$ . Since we assume that the document’s semantic profile derived from EL results is sufficiently accurate, we do not recreate it after reranking a candidate.

Reranking the candidate entities produced by the FL system on the CoNLL test set, this achieves a similar increase in  $F1$ , but with a different precision-recall trade-off (Table 6): We observe highest precision at the cost of a lower recall for

System	Prec	Rec	F1
FL baseline	85.3	85.2	85.2
FL filter	<b>89.2</b>	84.7	<b>86.9</b>
FL rerank	87.9	<b>85.6</b>	86.7

Table 6: Comparison of filtering and candidate entity reranking performance on the CoNLL test set.

filtering, while reranking increases both precision and recall.

### 3.4 Ablation Study

We conduct an ablation study to assess the impact of the proposed global coherence features on prediction performance. Applying backward elimination (John et al., 1994), we iteratively remove one feature set and successively eliminate the feature set with the largest impact (Figure 2).

Surprisingly, the string similarity features have a large effect across all three systems. This suggests that current systems do not optimally utilize string similarity when selecting and ranking candidate entities for a given mention.

Our proposed global coherence features are among the top features for all systems. This contradicts prior findings by Ratnov et al. (2011) and shows that global coherence has a considerable impact on EL performance. We believe that this is due to our proposed coherence features being more informative than the generic semantic relatedness measures used in prior work. While ablation indeed shows a relatively low importance of semantic relatedness features (cf. SemRel in Figure 2), further research is required to test this hypothesis.

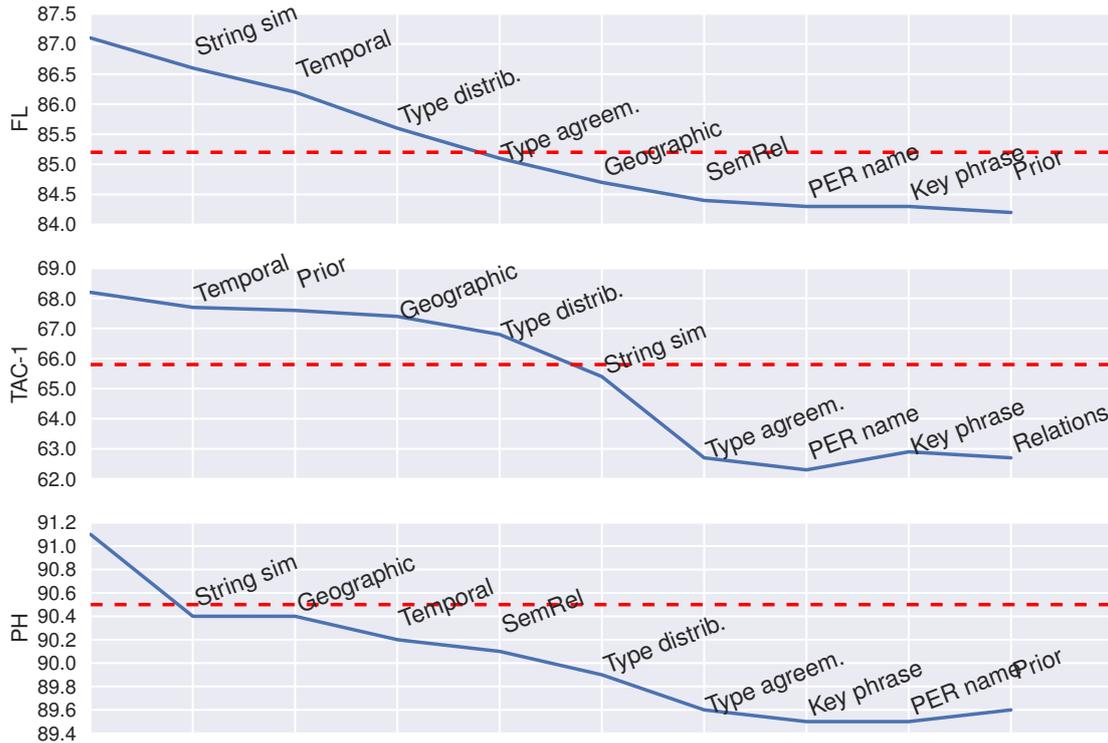

Figure 2: Feature set ablations for the FL, TAC-1, and PH systems. The solid blue lines show the performance impact in terms of `strong_link_match F1` incurred from eliminating feature sets. The red dashed line indicates baseline performance without verification.

### 3.5 Automatic Verification on Noisy Text

The TAC15 dataset consists of different text genres: clean newswire articles, and noisy discussion forum threads. Analysis of verification performance on these two genres reveals that verification has the biggest impact on noisy text (Table 7, bottom), while the improvement is smaller for two systems on clean text, and even slightly negative for one system, namely the global inference system TAC-2 (Table 7, top).

## 4 Related Work

Global coherence has been successfully employed for EL in a number of seminal works (Kulkarni et al., 2009; Hoffart et al., 2011b; Han et al., 2011), and more recently by Moro et al. (2014), Pershina et al. (2015), and Globerson et al. (2016), among others. These approaches maximize global coherence based on a general notion of semantic relatedness, while considering a fixed number of candidate entities for each mentions. Our approach differs from these in in two regards. Firstly, we introduce specific aspects of coherence, namely entity type coherence, geographic coherence, and tem-

poral coherence. While these aspects are limited to certain entities, such as entities with a clearly defined location and temporal range, our experiments showed that features based on these notions of coherence are useful on the types of texts found in common datasets. Secondly, in our verification setting, these rich coherence measures can be efficiently incorporated since their computation is linear in the number of entities mentioned in a document, while they would be prohibitively expensive in the global inference EL setting.

Entity types have been used in prior work. Cucerzan (2007) maximizes the agreement of Wikipedia categories associated with candidate entities. Due to intractability of the resulting global optimization problem, the agreement of the candidate entities for a given mention is maximized with respect to all categories of all candidate entites of all other mentions, and hence includes many wrong categories. Our approach is more precise, since verification allows using only the types of the top-ranked candidate entities. Sil and Yates (2013) also employ entity types, but only maximize type agreement of entity mentions in a small context window. In contrast, our ap-

	TAC-3	73.8	<b>52.4</b>	61.3	<b>84.7</b>	49.9	<b>62.8</b>	10.9	-2.5	1.5

Table 7: Verification on different text genres. See caption of Table 5 for details.

proach uses global context and hence allows capturing long-distance relations.

Post-processing of EL system output has been approached as an ensembling task (Rajani and Mooney, 2016). In this setting, a meta-classifier combines the output of different EL systems on a given dataset, taking into account features such as system confidence scores, past system performance, and number of systems agreeing with a given decision. Our approach differs from ensembling, since we post-process the output of a single system, using rich semantic features. In contrast, ensembling requires multiple system outputs and relies on meta-information about system performance and decision confidence. Combining these two post-processing methods is an interesting problem for future work and could lead to further improvements, since the two methods rely on different types of information.

## 5 Conclusions and Future Work

We have introduced automatic verification as a post-processing step for entity linking (EL). Our method uses the output of an existing EL system to create a semantic profile of the given text using entity types, as well as geographic and temporal information. Due to the high precision achieved by state-of-the-art EL systems, this profile is a sufficiently accurate representation of the text’s main topic, and further situates the text temporally and geographically. This profile is then used to automatically verify each linked mention individually, i.e., to predict whether it has been linked correctly or not. Verification allows leveraging a rich set of global and pairwise features that would be prohibitively expensive for EL systems employing global inference. Evaluation showed consistent improvements when applying our method to seven different EL systems on two different datasets.

Our main goal in future work is the better integration of our approach with existing EL systems. Most notably, some EL systems produce meaningful confidence scores, which we currently disregard. We expect further improvements from incorporating various confidence measures into the verification process. Automatic verification could also be used in an easy-first setting to identify likely correct decisions made by a fast and simple EL system, and then perform the remaining decisions with a more sophisticated system. Since our features make use of coreference information in the form of person name agreement, as well as entity types, another line of future research is expanding our proposed entity linking verification method to entity analysis (Durrett and Klein, 2014), which models entity linking, coreference, and entity typing as a joint task.

## Acknowledgments

We thank Matthew Francis-Landau, Maria Pershina, as well as the TAC KBP 2015 organizers for providing system output, and the anonymous reviewers for providing helpful feedback. This work has been supported by the German Research Foundation as part of the Research Training Group “Adaptive Preparation of Information from Heterogeneous Sources” (AIPHES) under grant No. GRK 1994/1.

## Abstract

This paper investigates how to improve performance on information extraction tasks by constraining and sequencing CRF-based approaches. We consider two different relation extraction tasks, both from the medical literature: dependence relations and probability statements. We explore whether adding constraints can lead to an improvement over standard CRF decoding. Results on our relation extraction tasks are promising, showing significant increases in performance from both (i) adding constraints to post-process the output of a baseline CRF, which captures “domain knowledge”, and (ii) further allowing flexibility in the application of those constraints by leveraging a binary classifier as a pre-processing step.

## 1 Introduction

With the number of articles indexed by MEDLINE/PubMed exceeding one million articles per year<sup>1</sup>, manual consumption of published medical literature is no longer practical and researchers are increasingly turning to automated techniques to quickly identify and process relevant medical knowledge (e.g., literature-based discovery (Hristovski et al., 2006)). Our overall project’s objective is to semi-automate the construction of decision support models by generating probabilistic graphical models of medical conditions and their associated risks based on the academic literature (Deleris et al., 2013). An essential task in this project consists of extracting from medical papers any relations mentioning (i) dependence or independence between variables and (ii) probability

<sup>1</sup><https://mbr.nlm.nih.gov/Background.shtml>

statements indicating the strength of a relationship. For both types of relations, we have approached the entity extraction step as a sequence labeling problem. We then rely on a set of rules to construct relations from the entities extracted. This paper focuses specifically on the entity extraction step which we describe in more detail in the following section. We then proceed in Section 3 with details about our suggested constraint enforcement procedures. Section 4 reports details about the experiments, with numerical results reported and discussed in Section 5.

## 2 Dependence Relation and Probability Statement Extraction

### 2.1 Dependence Relation Extraction

The first task concerns identifying dependence relations between pairs of potential variables mentioned in text. Dependence and independence here are to be understood as defined by probability theory where  $A$  depends on  $B$  iff  $\Pr(A) \neq \Pr(A|B)$ . As independence statements seldom occur in the literature, we focus predominantly on dependence in this paper and define independence as the negation of dependence. Our choice to use the term “dependence” to describe the task may lead to some ambiguity in the NLP world yet from a probability perspective, it is a precise characterization. Thus we caution the reader that our use of the word “dependence” is exclusively related to its meaning in probability theory. We structure dependence relations as being composed of two variables (variable  $A$  and variable  $B$ ) which are interchangeable, one influence term  $I$  and an optional negation.<sup>2</sup> As an example, from the sentence “For endometrial cancer, body mass index represents a major modifiable risk factor; about half of all cases in

<sup>2</sup>Negation enables us to capture independence though we ignore that last element for the remainder of the paper.

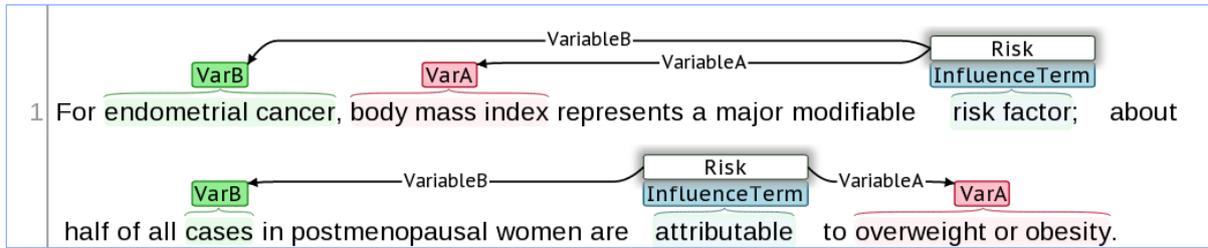

Figure 1: Dependence relation example in brat (Stenetorp et al., 2012)

postmenopausal women are attributable to overweight or obesity,” we extract two structured relations. The first involves variable  $A$ , *body mass index*, variable  $B$ , *endometrial cancer*, and an influence term, *risk factor*, and the second has a variable  $A$ , *overweight or obesity*, variable  $B$ , *cases* and influence term, *attributable* (see Figure 1).

## 2.2 Probability Statement Extraction

The second task focuses on extracting probability statements composed of probability terms (numbers) along with variables  $A$  (the conditioned variable) and  $B$  (the conditioning variable). Together they form a conditional probability statement, i.e.,  $\Pr(A|B) = x$ . For instance, from the sentence “Malaysian women have a one in 20 chance of developing breast cancer in their lifetime,” we want to extract the probability number, *one in 20*; the variable  $A$ , *developing breast cancer in their lifetime*; and the variable  $B$ , *Malaysian women*, which could be represented as  $\Pr(\textit{developing breast cancer in their lifetime}|\textit{Malaysian women}) = 0.05$ .

## 2.3 Insights into the Extraction Task

Probability terms, and to a lesser extent influence terms, are fairly regular and therefore more easily classified, while risk variables  $A$  and  $B$  are heterogeneous and exhibit a broad semantic variety. “1977-1990”, “breast cancer”, “homozygous carriers”, “> or = 10 years”, and “younger than age 35” are some examples of different variables taken from our corpus.

Risk variable identification presents multiple challenges. Consider the example “Carriers of the AC haplotype, which represents the variant alleles of both SNPs, were at an increased risk (OR = 1.41, 95% CI 1.09-1.82).” We have an odds ratio probability term “OR = 1.41” and two variables. However, determining the boundaries of the variables is not straightforward. Should the condition-

ing variable be the whole subject including the relative clause, only “Carriers of the AC haplotype,” or even simply “AC haplotype”? We sidestep this issue in our current work because these variables will later be clustered and aggregated into variable groups, e.g., a variable group “breast cancer” could include mentions of “breast cancer”, “ER+”, “breast carcinoma” and others.

Finally, the distinction between variables  $A$  and  $B$  is essential when constructing a probabilistic statement (while not significant for dependence extraction) but it can be problematic to distinguish the two when extracting them from text. Overall, the variable identification task has proved quite challenging. In fact, our interest in exploring constraints is motivated by preliminary results which hinted, as we will explain in more details in the next section, that, provided a probability number or an influence term is detected, we should further encourage the algorithm to search for the other associated variables.

## 3 Methodology

We approach the entity extraction (probability term and variables on one side, influence terms and variables on the other side) as a sequence labeling problem. We want to identify the best sequence of labels  $y$  for a sequence of tokens  $x$  comprising a sentence. The labels in our vocabulary are  $O$  (“outside”),  $A$  (variable  $A$ ),  $B$  (variable  $B$ ) and, depending on the specific task,  $P$  (probability term) or  $I$  (influence term). We initially propose using conditional random fields (CRF) (Lafferty et al., 2001) for this task as they have been successful for other related NLP sequence labeling tasks (Sha and Pereira, 2003; Settles, 2004). We start with a linear-chain CRF:

$$\Pr(y|x) = \frac{1}{Z_x} \exp\left(\sum_{t=1}^T \sum_k \lambda_k f_k(y_{t-1}, y_t, x_t)\right)$$

---

**Algorithm 1** Dependence Extraction Constraints

---

**if** influence term  $> 0$  **then**  
    ensure at least one  $A$  and one  $B$  label  
**else if**  $A > 0$  **then**  
    ensure at least one  $B$  label  
**else if**  $B > 0$  **then**  
    ensure at least one  $A$  label  
**end if**

---

where  $T$  is the number of observations indexed by  $t$ ,  $k$  indexes the feature function  $f_k$  and weight  $\lambda_k$ , and  $Z_x$  normalizes over the entire input sequence,  $Z_x = \sum_y \exp(\sum_{t=1}^T \sum_k \theta_k f_k(y_{t-1}, y_t, x_t))$ .

The CRF performs satisfactorily leading to higher precision classification of the labels than recall. However, it is not able to capture some information that we know to be true. For instance, for these corpora, if there is a labeled influence or probability term, 92% and 99% of the time, respectively, there are co-occurring variables in the same sentence. Thus for probability statement extraction, if we have a sentence with a detected probability term, which can be reliably classified (with  $F_1$  scores around 74), then we want to enforce the presence of both variables  $A$  and  $B$ .  $B$  is theoretically optional, as it is possible to find marginal probability, i.e., statements with an empty conditioning set. In practice, given our domain, we choose to impose the presence of at least one  $B$  label for each sentence with a  $P$  label. By contrast, for a sentence without a probability term, we want to discard such output altogether. In the case of dependence statement extraction, the situation is similar, if we detect an influence term or a variable, we want to force the system to find the other relevant pieces of the relations. The constraints we apply to each of our two tasks are summarized in structured language in Algorithm 1 and Algorithm 2.

While it is straightforward to discard sentences that do not contain a given label, constraining the output with statements to enforce the presence of at least one type of label given the presence of another label, is less obvious. We address it by complementing the initial classification with further steps to enforce the constraints. We have previously explored different approaches, varying in complexity, for finding the most likely sequence while applying these constraints (Deleris and Jochim, 2016). Here we settle on the constrained approach inspired by Culotta and McCal-

    ensure no labeled entities  
**else**  
    ensure at least one  $A$  and one  $B$  label  
**end if**

---

lum (2004) that uses posterior conditional probability in the CRF decoding.

### 3.1 Notation

We denote by  $y$  a vector of labels associated with observations  $x$  (tokens). Let  $T$  be the number of observations  $(x_1, \dots, x_T)$  then  $y$  also contains  $T$  elements  $(y_1, \dots, y_T)$  which we index by  $t$  and  $y_t \in \{A, B, P, I, O\} \forall t = 1 : T$ .

Let  $y^* = \operatorname{argmax}_y \Pr(y|x)$  denote the output of applying Viterbi decoding to our observations  $x$ . To describe the proposed extensions, we then introduce the following variables:  $t_P = \{t \in [1 : T] : y_t^* = P\}$ , the indexes in the initial output corresponding to the label  $P$ .  $t_I = \{t \in [1 : T] : y_t^* = I\}$ , the indexes in the initial output corresponding to the label  $I$ .  $t_A = \{t \in [1 : T] : y_t^* = A\}$ , indexes corresponding to the label  $A$ .  $t_B = \{t \in [1 : T] : y_t^* = B\}$ , indexes corresponding to the label  $B$ . Finally we denote by  $t_O$  the set of unspecified indexes, i.e.,  $t_O = \{t \in [1 : T] : y_t^* = O\}$ .

Our **baseline** method is simply to evaluate the classifier performance based on  $y^*$ . As we mentioned above, our specific context for probability statement extraction leads us to discard all labels in a sentence that does not contain any  $P$  label. We thus implement this constraint in our baseline as a simple post-processing filter on the CRF output. Specifically, for probability statement extraction, for a sentence such that  $|t_P| = 0$ , then we define a modified output  $y^B$  ( $B$  standing here for Baseline) where  $y_t^B = O \forall t = 1 : T$ , else we keep the original output so that  $y_t^B = y_t^* \forall t = 1 : T$ .

### 3.2 CRF-Driven Constraints

Our chosen method to enforce constraints takes into account current knowledge (i.e., initial decoding from CRF) when estimating probabilities of labels by conditioning posterior probabilities on the presence of label  $A$  and  $B$  based on current observations. Specifically, if only  $A$  missing, i.e.,

$|t_A| = 0$  then we search

$$t_A^* = \operatorname{argmax}_{t \in t_O} \varphi_t(s) \quad (1)$$

and we define  $y_t^C = A \forall t \in t_A^*$  and  $y_t^C = y_t^B \forall t \notin t_A^*$ .

In this method,  $\varphi$  represents the the posterior *conditional* probability given the observed locations of the required labels. In the case of probability statement extraction, we have:  $\varphi_t(s) = \Pr(y_t = s | x, y_{t_P} = P, y_{t_A} = A, y_{t_B} = B)$  for  $s \in \{A, B, P, O\}$ . In the case of dependence relation extraction, we have:  $\varphi_t(s) = \Pr(y_t = s | x, y_{t_I} = I, y_{t_A} = A, y_{t_B} = B)$  for  $s \in \{A, B, I, O\}$ .

Similar procedures are applied when  $B$  is missing and when both labels are missing where we search jointly on the best locations for  $A$  and  $B$ .

One difficulty with this approach is the need to compute  $\varphi$ . For this purpose, we borrow from Culotta and McCallum (2004) who provide a method to compute the forward values  $\alpha_t(s) = \Pr(x_1, \dots, x_t, y_t = s)$  of the forward-backward algorithm when forced to conform to a subpath of constraints  $C = \langle s_t, s_{t+1}, \dots \rangle$ . These constraints specify for a subset of locations which states they must be in or not be in (negative constraints).

The original recursive approach to compute  $\alpha_t(s)$  is

$$\alpha_{t+1}(s) = \sum_{s'} \alpha_t(s') \exp \left( \sum_k \lambda_k f_k(s', s, x_{t+1}) \right) \quad (2)$$

The updated recursion equation proposed by Culotta and McCallum (2004) so as to compute  $\alpha'_t(s) = \Pr(x_1, \dots, x_t, y_t = s | C)$  is simply to apply Equation 2 when  $y_{t+1} = s$  conforms with  $C$  (including locations that are not constrained in any way in  $C$ ) and set  $\alpha'_{t+1}(s) = 0$  otherwise. Note that in (Culotta and McCallum, 2004), the indexes of the constraints included in  $C$  are assumed to be contiguous although the method also applies when they are not. In our case, for probability statement extraction, we will simply set  $C = \{y_{t_P} = P, y_{t_A} = A, y_{t_B} = B\}$ , again where at least one of the sets  $t_A$  or  $t_B$  is empty.

We similarly extend this method to compute constrained backward values  $\beta'_t(s) = \Pr(x_{t+1}, \dots, x_T | y_t = s, C)$  by proposing the modified backward recursion

$$\beta'_t(s) = \sum_{s'} \beta'_{t+1}(s') \exp \left( \sum_k \lambda_k f_k(s, s', x_{t+1}) \right) \quad (3)$$

when  $y_t = s$  conforms with  $C$  and set  $\beta'_{t+1}(s) = 0$  otherwise. Overall, this means that  $\varphi_t(s) = \Pr(y_t = s | x, y_{t_P} = P, y_{t_A} = A, y_{t_B} = B)$  can be expressed as follows:

$$\varphi_t(s) = \frac{\Pr(y_t = s, x | y_{t_P} = P, y_{t_A} = A, y_{t_B} = B)}{\Pr(x | y_{t_P} = P, y_{t_A} = A, y_{t_B} = B)} \quad (4)$$

This is the result of an application of Bayes rule along with the conditional independence assumptions of the CRF. In turn, we have that :

$$\varphi_t(s) = \frac{\alpha'_t(s) \beta'_t(s)}{\sum_{s'} \alpha'_T(s')} \quad (5)$$

The output  $y^C$  is guaranteed to contain at least one label  $A$  and one label  $B$ .  $t_A^*$  in Equation 1 will contain only one token while variables  $A$  and  $B$ , in reality, often span multiple tokens. Therefore, as an additional post-processing step, we run the Viterbi algorithm once more using the identified labels  $A, B$  and  $P$  as constraints. This may reveal longer spans with such labels.

### 3.3 Classifier-driven Constraints

As we report in Section 5, imposing constraints based on the initial CRF decoding improves recall more than it degrades precision and thus proves useful. We further explore whether adding flexibility to the process can help reduce the precision degradation. Indeed in the case of dependence relations, we observed that several influence terms are quite common in dependence relations but are still not found exclusively in these relations. In our dataset for instance, the most common influence term words are *associated* (142 occurrences in the training set), *association* (42), *risk* (36), and *increased* (22). Our one-step CRF-based approach may thus be misled by those common words into forcing the presence of a dependence relation.

Therefore, we introduce two separate binary classifiers to predict whether or not the sentence contains either a dependence relation or a probability statement. Our intuition is that the classifier will be a more reliable indicator of the presence of a relation than the entity extraction of either probability number or influence term. We make use of that prediction to determine if and how to apply the constraints. In fact, we apply a threshold on the confidence of the classifier in order to decide whether to enforce the constraints.

To coordinate the classification, the entity detection (baseline CRF) and the constraint enforce-

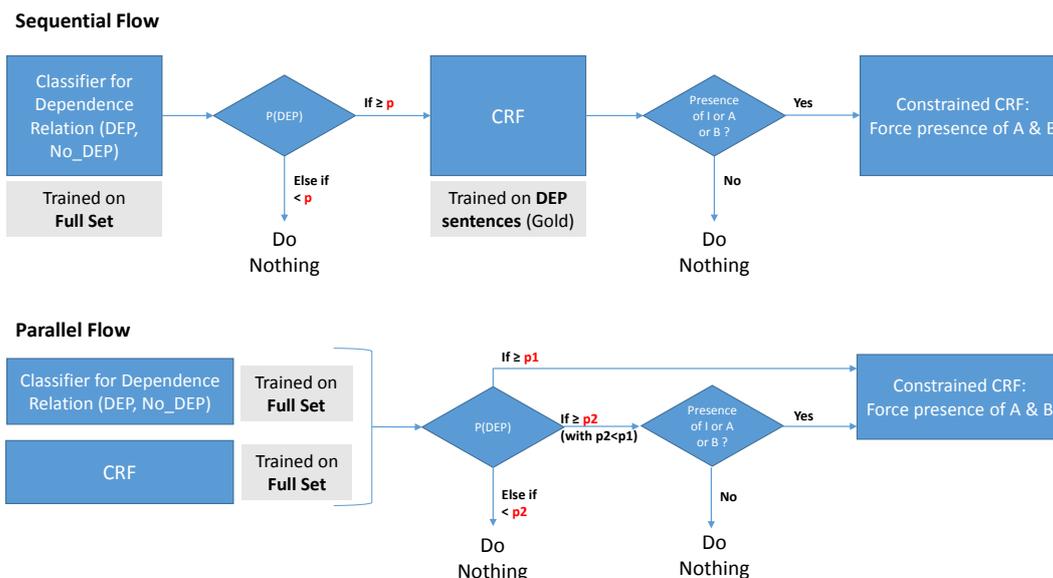

Figure 2: Description of Constraint Enforcement Flows

ment steps, we explore two kinds of flows as depicted in Figure 2 for dependence relation extraction. Both flows start with the binary classifier but evolve differently:

- In the *sequential flow*, if the confidence of the classifier is below a threshold  $p$  we simply discard the sentence. If it is above the threshold, then we process the sentence through the baseline CRF trained only on sentences containing relations in the ground truth. We then enforce our constraints, i.e., for the dependence case, discarding the sentence if no variable or influence term has been found but forcing the presence of variables if we detect an influence term or at least one variable.
- In the *parallel flow*, we implement the baseline CRF in parallel with the binary classifier. This implies that the baseline CRF is trained on the full set of sentences. Afterwards, if the confidence of the classifier is below  $p^2$ , we discard the sentence, if it is above  $p^1$  we enforce our constraints regardless of the Baseline CRF output. For intermediate cases, we only enforce constraints if we detect either an influence term or a variable.

## 4 Experiments

In this section we first describe the data used in our experiments and then cover the configuration

of the baseline CRF classifier along with the constrained configurations we test.

**Data for Dependence Statements.** The dependence dataset comes from 210 abstracts selected from PubMed based on a query about breast cancer. These 210 abstracts are split into 2144 sentences, of which 785 have a dependence relation. The dependence relations include 830 variables labeled  $A$  and 837 labeled  $B$ . The annotation also includes labels for *influence terms*, *modifiers* and *negation* (as mentioned in Section 2.1). The latter two are not considered here as they do not contribute to the dependence relations, but we do show results for influence terms as they are useful in constructing the dependence relations (although that is not covered in this paper).

**Data for Probability Statements.** The probability dataset is similarly constructed with 194 abstracts from PubMed that are related to breast cancer. The whole dataset has 2078 sentences, 376 of which, contain probabilistic statements, for example, “81% $p$  of stage III/IV breast cancers $B$  were positive for SNCG expression $A$ .” These sentences contain 652 probability terms, 446 variables  $A$ , and 467 variables  $B$ .

We split both datasets into train (70%) and test (30%) sets. Parameter tuning can be done by splitting the training set, however experiments shown in this paper do not require parameter tuning.

**Baseline CRF** We initially evaluate a baseline CRF model without constraints, implemented with Mallet (McCallum, 2002). The same feature set used in the baseline is used throughout our experiments. It is composed of standard features for sequence tagging: surface form, lemma, POS tag, word shape (i.e., is capitalized, has digit, etc.), and the arc label from a dependency parse. The CRF also extracts features from the previous position ( $t - 1$ ) and the following position ( $t + 1$ ) as well as bigram features combining the previous two positions ( $t - 2, t - 1$ ). We do not tune the features or regularization parameters in our experiments, but instead focus on the differences from applying constraints in decoding. The CRF training is the same for nearly all experiments and the important changes are in decoding and in how the constraints are applied, so tuning these parameters should not affect our results. The one exception to this is the sequential flow where the CRF classifier is trained only on sentences with relations. We use the default value for the Gaussian variance prior (10) and keep the same features across our experiments.

In addition to the baseline CRF we test three constraint settings: (i) **Default** refers to the decoding with the CRF driven enforcement of constraints described in Section 3.2; (ii) **Parallel** refers to the application of the Parallel flow which feeds the sentences into the CRF to identify entities and a binary classifier to determine if the sentence has a relation. The output of the binary classifier determines if and how the decoding constraints should be applied; and (iii) **Sequential** refers to the application of the sequential flow where the binary classifier first filters out noisy sentences followed by the use of a CRF trained on relation sentence data.

For the binary classifier, we make use of IBM’s Natural Language Classifier service<sup>3</sup> which relies on a Convolutional Neural Network combined with word embeddings (Feng et al., 2015). To clarify, the classifiers that we use, while using pre-trained word embedding (on general domain), are then only trained with our own training data.

**Evaluation criteria.** We evaluate our approach using standard metrics: precision, recall, and  $F_1$ . In addition, we consider different criteria for matching entities, i.e., token matches, exact entity matches, and “sloppy” matches (Olsson et al.,

2002). In Section 5 we report only our results for token matching since the trends are consistent for different matching criteria. Exact entity matching is unnecessarily strict for our application (e.g., in the context of our work “AC haplotype” is just as good as “Carriers of the AC haplotype”) and measuring performance by token makes the results easily interpretable.

## 5 Results

### 5.1 Binary Classifier

As mentioned in Section 3.3, we introduce a binary classifier to decide whether constraints should be applied or not (instead of relying only on the entity annotation of variables  $A$ ,  $B$ , and Influence or Probability terms). We need an accurate classifier to ensure that constraints are only applied when necessary. Our experiments show that the classifier achieves good results with accuracy for classifying dependence sentences of 82.2% and for probability statements, 95.3%.

### 5.2 Entity Extraction for Dependence Relations

We first look at the entity extraction results for dependence relations in Table 1. There is consistent improvement in  $F_1$  scores for variables  $A$  and  $B$  as we refine the application of constraints. The baseline CRF classifier has modest precision but much weaker recall and misses a number of variable  $A$  and  $B$  entities entirely. We are not particularly concerned about boundary errors with the CRF and they are relatively infrequent. On the other hand, the missed entities, i.e., the entity *false negatives*, are more detrimental to the results. In fact, of the 606 sentences in the test set, 253 should have some dependence relation annotation but 143 of these are missing a variable  $A$ , 143 are missing a variable  $B$ , and 84 are missing both. This result motivates our use of domain constraints.

Adding Default constraints leads to an increase in  $F_1$  as recall improves while precision drops. When the baseline CRF assigns any  $A$ ,  $B$ , or influence term, we force it to have both variables  $A$  and  $B$ , and essentially by forcing it we recover enough new variables (higher recall) to offset making some less confident prediction (lower precision). The application of these constraints depends on the quality of the Baseline predictions for  $A$ ,  $B$ , and Influence Term, and we note that that

Parallel	65.10%	55.70%	60.04
Sequential	64.86%	<b>56.38%</b>	<b>60.32</b>

Table 1: Entity extraction results for dependence relations.

even for influence terms our performance is moderate and inferior to that of the binary classifier.

The Parallel results display improvements to both precision and recall over the baseline. While Parallel recall for  $A$  and  $B$  is slightly below the numbers reached in Default, the 9% absolute increase in precision for both variables  $A$  and  $B$  leads to  $F_1$  improvements for both. By applying the binary classifier prediction before applying constraints, we remove some noisy sentences that contain spuriously labeled entities, which are not in a dependence relation; in the Parallel results there are 56 such sentences. For example, in the baseline experiment a lone variable  $B$ , *subsequent cancer occurrence*, is extracted from the sentence “It allowed for a correct estimation of the risk, and for investigating the time trend of the subsequent cancer occurrence.” The classifier correctly filters out this sentence and prevents the CRF from classifying what might be a valid variable  $B$  had there actually been a dependence relation.

Naturally, by filtering out sentences we also risk discarding some with dependence relations and thus affecting recall. In one example of this negative case, the baseline experiment labels only an influence term without variables  $A$  or  $B$ . The constraints applied for the Default constraint experiment assign the (correct) variable  $B$  and (incorrect) variable  $A$ . However, the classifier in the Par-

allel experiment mistakenly leads us not to label any entities in this sentence, thereby missing the relation.

We observe similar patterns for the Sequential results. The overall best  $F_1$  scores for variables  $A$  and  $B$  are due to the significant increases in recall. The main difference between Parallel and Sequential is the fact that the CRF is trained on a filtered set of sentences for Sequential compared to the full set for Parallel. The Sequential CRF, using filtered data, has a higher ratio of variables labeled  $A$  and  $B$  per word seen in training and this makes it more confident in predicting labels  $A$  and  $B$  in testing. This helps the Sequential flow recover several new entities which are missed by the baseline CRF. This also explains the higher recall but lower precision with respect to Parallel.

Although only variables  $A$  and  $B$  are necessary for dependence relations, we also report performance on influence terms, which contribute to the identification of dependence relations. For the influence terms, we observe that precision decreases with each experiment as recall increases. The binary classifier has a strong and positive effect on influence term extraction as we see an increase in recall and  $F_1$ . Recall for Parallel and Sequential increases by about 11% and 15% (absolute).

Table 1 shows Parallel results with  $p^1 = 0.5$  and  $p^2 = 0.5$  and Sequential results with  $p = 0.5$  (see Figure 2). We chose those parameter values as they correspond to the default for a binary classifier. In Section 5.4 we look more closely at the effects of  $p$ ,  $p^1$  and  $p^2$ .

### 5.3 Entity Extraction for Probability Statement

The probability results reported in Table 2 display similar trends as those for dependence relations, though we note a few differences as well. First the Baseline results are lower for variables  $A$  and  $B$ . This is due mainly to the heterogeneity of these variables (even with respect to the dependence relations) and to the smaller dataset. To illustrate how much more heterogeneous the variables are, the type-token ratio for variable  $A$  is 0.188 in the dependence training set and 0.392 in the probability training set, and the difference for variable  $B$  is similar, 0.224 vs. 0.448. The number of sentences in the dependence and probability corpora are similar but probability statements are less frequent than dependence relations and for the 620

	Precision	Recall	$F_{\beta=1}$

Parallel	<b>81.56%</b>	69.71%	75.17
Sequential	80.36%	<b>75.89%</b>	<b>78.06</b>

Table 2: Entity extraction results for probability statements.

sentences in the test set we only have 127 with probability annotation. Like with dependence relations, for probability statements we can motivate our constraints by looking at the large number of missed (i.e., false negative) entities. The baseline CRF misses variable  $A$  in 94 sentences with probability statements (i.e., about 74% of probability statements are missing variable  $A$ ). There are 78 probability sentences with a missed variable  $B$ , and 57 missing both.

By applying constraints to these missing variables we observe the largest increase in performance occurs from the Baseline to the Default setting, with improvements in precision, recall, and  $F_1$ . The Default constraints approach hinges on the CRF prediction of the probability term, which performs well. Because this prediction is already reliable, by contrast with the dependence relation extraction, there is less potential for improvement by applying the binary classifier. In fact, for Parallel, performance increases for variable  $A$  but decreases for variable  $B$ .

Training the CRF solely on probability statements, as is the case in Sequential, appears to have a greater impact than with dependence. As the proportion of sentences with no-relation in the probability dataset is higher than in the dependence dataset, filtering out the no-relations sentences removes more noise in the case of prob-

ability statement extraction. In turn, removing this noise improves the CRF performance, leading in particular to the improved performance for the probability term and consequently to improvements in the variable extraction with constraints.

#### 5.4 Improving Performance through Threshold Values

Performance was earlier reported for the Parallel and Sequential flow for  $p = p^1 = p^2 = 0.5$ , which represents the default threshold for binary classifiers. In this section, we look closer at the effect of these threshold values on performance.

There are no values for  $p$  that consistently lead to maximum  $F_1$  scores (Tables 3–7) and there is not space to show precision and recall results as well. However, as would be expected, the precision goes up as  $p^1$  and  $p^2$  increase, i.e., as we become more conservative in constraining the CRF output. On the other hand, recall drops with higher values of the  $p$  threshold as the CRF is not pushed to find previously missed variables  $A$  or  $B$ .

We do find lower  $p^2$  thresholds perform better for probability than dependence. This is likely because the probability constraints based on the CRF are still quite reliable. The classifier for dependence statements must be more strict in filtering sentences, using higher  $p^2$  thresholds, because the dependence constraints are less reliable.

The Sequential flow results are similar. The maximum  $F_1$  scores on the probability dataset come with  $p = 0.05$ , like  $p^2$  values for Parallel. The  $p$  threshold for variables  $A$  and  $B$  varies, also similar to  $p^2$  for Parallel, with better  $A$  results coming from a lower threshold and better  $B$  results with a higher threshold. However, more work needs to be done to see how we can best leverage classification in the Sequential and Parallel flows.

## 6 Related Work

Our work touches on several areas from constrained conditional models (Goldwasser et al., 2012) to biomedical entity extraction. The work most related to our approach for applying constraints with CRF decoding is (Culotta and McCallum, 2004; Roth and Yih, 2005; Kristjansson et al., 2004). Our solution for constraining CRF decoding borrows from Culotta and McCallum (2004) (which is also used by Kristjansson et al. (2004)). They use constraints for calculating the ‘forward’ values in the forward-backward algorithm and use this for estimating confidence at given states in the sequence. Our work applies constraints both forward and backward and uses these global constraints to force specific entities to be extracted. Roth and Yih (2005) also apply constraints to the CRF but instead of using Viterbi decoding as is done here they use Integer Linear Programming (ILP) to add constraints in decoding for semantic role labeling.

With respect to our overall objective of entity and relation extraction from the medical literature, a large proportion of the related work originates from BioNLP event extraction (Kim et al., 2009; Nédellec et al., 2013; Chaix et al., 2016; Deléger et al., 2016). These tasks are similar in that they

Table 7: Var. B  $F_1$  for Probability Parallel flow.

extract biomedical entities, analogous to our variables  $A$  and  $B$ , and the relations between entities (e.g., bio-molecular events).

The most similar entity extraction task to ours is from Fiszman et al. (2007). They are interested in extracting mentions of diseases and medical risk factors<sup>4</sup> from medical literature. They take a less statistical and more semantic approach to convert the biomedical text into a semantic representation using the UMLS Semantic Network.

## 7 Conclusions

In this paper we investigate how we can improve performance on information extraction tasks by constraining CRF-based approaches. We investigate two relation extraction tasks from the medical literature – dependence relations and probability statements – and show that by using our constrained CRF models we can get significant improvements over a CRF baseline. In future work we plan to build on these improvements and test constraints jointly applied to entity and relation extraction to improve our project’s construction of decision support models.

<sup>4</sup>Their *risks* and *disorders* appear to be subsets of variables  $A$  and  $B$ .

## Abstract

Enabling machines to read and comprehend unstructured text remains an unfulfilled goal for NLP research. Recent research efforts on the “machine comprehension” task have managed to achieve close to ideal performance on simulated data. However, achieving similar levels of performance on small real world datasets has proved difficult; major challenges stem from the large vocabulary size, complex grammar, and the frequent ambiguities in linguistic structure. On the other hand, the requirement of human generated annotations for training, in order to ensure a sufficiently diverse set of questions is prohibitively expensive. Motivated by these practical issues, we propose a novel curriculum inspired training procedure for Memory Networks to improve the performance for machine comprehension with relatively small volumes of training data. Additionally, we explore various training regimes for Memory Networks to allow knowledge transfer from a closely related domain having larger volumes of labelled data. We also suggest the use of a loss function to incorporate the asymmetric nature of knowledge transfer. Our experiments demonstrate improvements on Dailymail, CNN, and MCTest datasets.

## 1 Introduction

A long-standing goal of NLP is to imbue machines with the ability to comprehend text and answer natural language questions. The goal is still distant and yet generates tremendous amount of interest due to the large number of potential NLP applications that are currently stymied because of

their inability to deal with unstructured text. Also, the next generation of search engines are aiming to provide precise and semantically relevant answers in response to questions-as-queries; similar to the functionality of digital assistants like *Cortana* and *Siri*. This will require text understanding at a non-superficial level, in addition to reasoning, and, making complex inferences about the text.

As pointed out by Weston et al. (2016), the Question Answering (QA) task on unstructured text is a sound benchmark on which to evaluate machine comprehension. The authors also introduced *bAbI*: a simulation dataset for QA with multiple toy tasks. These toy tasks require a machine to perform simple induction, deduction, multiple chaining of facts, and, complex reasoning; which make them a sound benchmark to measure progress towards AI-complete QA (Weston et al., 2016). The recently proposed Memory Network architecture and its variants have achieved close to ideal performance, i.e., more than 95% accuracy on 16 out of a total of 20 QA tasks (Sukhbaatar et al., 2015; Weston et al., 2016).

While this performance is impressive, and is indicative of the memory network having sufficient capacity for the machine comprehension task, the performance does not translate to real world text (Hill et al., 2016). Challenges in real-world datasets stem from the much larger vocabulary, the complex grammar, and the often ambiguous linguistic structure; all of which further impede high levels of generalization performance, especially with small datasets. For instance, the empirical results reported by Hill et al. (2016) show that an end-to-end memory network with a single hop surpasses the performance achieved using multiple hops (i.e, higher capacity), when the model is trained with a simple heuristic. Similarly, Tapaswi et al. (2015) show that a memory network heavily overfits on the MovieQA dataset and

yields near random performance. These results suggest that achieving good performance may not always be merely a matter of training high capacity models with large volumes of data. In addition to exploring new models there is a pressing need for innovative training methods, especially when dealing with real world sparsely labelled datasets.

With the advent of deep learning, the state of art performance for various semantic NLP tasks has seen a significant boost (Collobert and Weston, 2008). However, most of these techniques are *data-hungry*, and require a large number of sufficiently diverse labeled training samples, e.g., for QA, training samples should not only encompass an entire range of possible questions but also have them in sufficient quantity (Bordes et al., 2015). Generating annotations for training deep models requires a tremendous amount of manual effort and is often too expensive. Hence, it is necessary to develop effective techniques to exploit data from a related domain in order to reduce dependence on annotations. Recently, Memory Networks have been successfully applied to QA and dialogue-systems to work with a variety of disparate data sources such as movies, images, structured, and, unstructured text (Weston et al., 2016; Weston, 2016; Tapaswi et al., 2015; Bordes et al., 2015). Inspired from the recent success of Memory Networks, we study methods to train memory networks with small datasets by allowing for knowledge transfer from related domains where labelled data is more abundantly available.

The focus of this paper is to improve generalization performance of memory networks via an improved learning procedure for small real-world datasets and knowledge transfer from a related domain. In the process, this paper makes the following major contributions:

- (i) A curriculum inspired training procedure for memory network is introduced, which yields superior performance with smaller datasets.
- (ii) The exploration of knowledge transfer methods such as pre-training, joint-training and the proposed curriculum joint-training with a related domain having abundant labeled data.
- (iii) A modified loss function for joint-training to incorporate the asymmetric nature of knowledge transfer, and also investigate the application of a pre-trained memory network on very small datasets such as MCTest dataset.

The remainder of the paper is organized as follows: Firstly, we provide a summary of related work in Section 2. Next in Section 3, we describe the machine comprehension task and the datasets utilized in our experiments. An introduction to memory networks for machine comprehension is presented in Section 4. Section 5 outlines the proposed methods for learning and knowledge transfer. Experimental details are provided in Section 6. We summarize our conclusions in Section 7.

## 2 Related Work

**Memory Networks** have been successfully applied to a broad range of NLP and machine learning tasks. These tasks include but are not limited to: performing reasoning over a simulated environment for QA (Weston et al., 2016), factoid and non-factoid based QA using both knowledge bases and unstructured text (Kumar et al., 2015; Hill et al., 2016; Chandar et al., 2016; Bordes et al., 2015), goal driven dialog (Bordes and Weston, 2016; Dodge et al., 2016; Weston, 2016), automatic story comprehension from both video and text (Tapaswi et al., 2015), and, transferring knowledge from one knowledge-base while learning to answer questions on a different knowledge base (Bordes et al., 2015). Recently, various other attention based neural models (similar to Memory Networks) have been proposed to tackle the machine comprehension task by QA from unstructured text (Kadlec et al., 2016; Sordoni et al., 2016; Chen et al., 2016). To the best of our knowledge, knowledge transfer from an unstructured text dataset to another unstructured text dataset for machine comprehension is not explored yet.

**Training deep networks** is known to be a notoriously hard problem and often the success of these techniques hinges upon achieving higher generalization performance with high capacity models (Blundell et al., 2015; Larochelle et al., 2009; Glorot and Bengio, 2010). To address this issue, *Curriculum learning* was firstly introduced by Bengio et al. (2009), which showed that training with gradually increasing difficulty leads to a better local minima, specially when working with non-convex loss functions. Although devising a universal curriculum strategy is hard, as even humans do not converge to one particular order in which concepts should be introduced (Rohde and Plaut, 1999) some notion of concept difficulty is normally utilized. With similar motivations, this pa-

per makes an attempt to exploit *curriculum learning* for machine comprehension with a memory network. Recently, curriculum learning has also been utilized to avoid negative transfer and make use of task relatedness for multi-task learning (Lee et al., 2016). Concurrently, Sachan and Xing (2016) have also studied curriculum learning for QA and unlike this paper, they do not consider learning and knowledge transfer on small real-world machine comprehension dataset in the setting of memory networks.

**Pre-training & word2vec:** Pre-training can often mitigate the issue that comes with random initialization used for network weights, by guiding the optimization process towards the basins of better local minima (Mishkin and Matas, 2016; Krahenbuhl et al., 2016; Erhan et al., 2010). An inspiration from the ripples created by the success of pre-training and as well as word2vec, this paper explores pre-training to utilize data from a related domain and also pre-trained vectors from word2vec tool (Mikolov et al., 2013). However, finding an optimal dimension for these pre-trained vectors and other involved hyper-parameters requires computationally extensive experiments.

**Joint-training / Co-training / Multi-task learning / Domain adaptation:** Previously, the utilization of common structures and similarities across different tasks / domains has been instrumental for various closely related learning tasks refereed as joint-training, co-training, multi-task learning and domain adaptation (Collobert and Weston, 2008; Liu et al., 2015; Chen et al., 2011; Maurer et al., 2016). To mitigate this ambiguity, in this paper, we limit ourselves to using “joint-training” and refrain from co-training, as unlike this work, co-training was initially introduced to exploit unlabelled data in the presence of small labelled data and two different and complementary views about the instances (Blum and Mitchell, 1998).

While this work looks conceptually similar, the proposed method tries to exploit information from a related domain and aims to achieve an asymmetric transfer only towards the specified domain, without any interest in the source domain, and hence should not be confused with the long-standing pioneering work on multi-task learning (Caruana, 1997). Another field of work that is related to this paper is on domain adaptation which appears to have two major related branches. The first branch is the recent work that has primar-

ily focused on unsupervised domain adaptation (Nguyen and Grishman, 2015; Zhang et al., 2015), and the other is the traditional work on domain adaptation which has focussed on problems like entity recognition and not on machine comprehension and modern neural architectures (Ben-David et al., 2010; Daume III, 2007).

### 3 Machine Comprehension : Datasets and Tasks Description

Machine comprehension is the ability to read and comprehend text, i.e., understand its meaning, and can be evaluated by tasks involving the answering of questions posed on a context document. Formally, a set of tuples  $(q, C, S, s)$  is provided, where  $q$  is the question,  $C$  is the context document,  $S$  is a list of possible answers, and,  $s$  indicates the correct answer. Each of  $q$ ,  $C$ , and  $S$  are sequence or words from a vocabulary  $V$ . Our aim is to train a memory network model to perform QA with small training datasets. We propose two primary ways to achieve this: 1) Improve the learning procedure to obtain better models, and 2) Demonstrate knowledge transfer from a related domain.

#### 3.1 Data Description

Several corpora have been introduced for the machine comprehension task such as MCTest-160, MCTest-500, CNN, Dailymail, and, Children Boot Test (CBT) (Richardson et al., 2013; Hermann et al., 2015; Hill et al., 2016). The MCTest-160 and MCTest-500 have multiple-choice questions with associated narrative stories. Answers in these datasets can be one of these forms: a word, a phrase, or, a full sentence.

The remaining datasets are generated using Cloze-style questions; which are created by deleting a word from a sentence and asking the model to predict the deleted word. A place-holder token is substituted in place of the deleted word which is also the correct answer (Hermann et al., 2015). We have created three subsets of CNN namely, CNN-11K, CNN-22K and CNN-55K from the entire CNN dataset, and Dailymail-55K from the Dailymail dataset. Statistics on the number of samples comprising these datasets is presented in Table 1.

#### 3.2 Improve Learning Procedure

It has been shown in the context of language modelling that presenting the training samples in an easy to hard ordering allows for shielding

	MCTest-160	MCTest-500	CNN-11K	CNN-22K	CNN-55K	Dailymail-55K
# Train	280	1400	11,000	22,000	55,000	55,000
# Validation	120	200	3,924	3,924	3,924	2,500
# Test	200	400	3,198	3,198	3,198	2,000
# Vocabulary	2856	4279	26,550	31,932	40,833	42,311
# Words $\notin$ Dailymail-55K	—	—	1,981	2,734	6,468	—

Table 1: Number of samples in training, validation, and, test samples in the MCTest-160, MCTest-500, CNN-11K, CNN-22K, CNN-55K, and, Dailymail-55K datasets; along with the size of vocabulary.

the model from very hard samples during training, yielding faster convergence and better models (Bengio et al., 2009). We investigate a curriculum learning inspired training procedure for memory networks to improve performance on the three subsets of the CNN dataset described below.

### 3.3 Demonstrate Knowledge Transfer

We plan to demonstrate knowledge transfer from Dailymail-55K to three subsets of CNN of varying sizes utilizing the proposed join-training method. For learning, we make use of smaller subsets of the CNN dataset. The smaller size of these subsets enables us to assess the performance boost due to knowledge transfer: As our aim is to demonstrate transfer when less labelled data is available, choosing the complete dataset would render gains from knowledge transfer as insignificant. We also demonstrate knowledge transfer for the case of MCTest dataset using embeddings obtained after training the memory network with CNN datasets.

## 4 End-to-end Memory Network for Machine Comprehension

End-to-end Memory Network is a recently introduced neural network model that can be trained in an end-to-end fashion; directly on the tuples  $(q, C, S, s)$  using standard back-propagation (Sukhbaatar et al., 2015). The complete training procedure can be described in the three steps: i) encoding the training tuples into the contextual memory, ii) attending context in memory to retrieve relevant information with respect to a question, and, iii) predicting the answer using the retrieved information. To accomplish the first step, an embedding matrix  $A \in \mathbb{R}^{p \times d}$  is used to map both question and context into a  $p$ -dimensional embedding space; by applying the following transformations:  $\vec{q} = A\Phi(q)$  and  $\{\vec{m}_i = A\Phi(c_i)\}_{i=1,2,\dots,n}$ . Where  $n$  is the number of items in context  $C$  and  $\Phi$  is a bag-of-words representation in  $d$ -dimensional space, where  $d$  is typically the size of the vocabulary  $V$ . In the

second step, the network senses relevant information present in the memory  $\vec{m}_i$  for query  $\vec{q}$ , by computing the attention distribution  $\{\alpha_i\}_{i=1,2,\dots,n}$ , where  $\alpha_i = \text{softmax}(\vec{m}_i^T \vec{q})$ . Thereafter,  $\alpha_i$  is used to aggregate the retrieved information into a vector representation  $\vec{r}_o$  by utilizing another memory  $\vec{r}_i$ ; as stated in Equation 1. The memory representation  $\vec{r}_i$  is also defined as  $\{\vec{r}_i = B\Phi(c_i)\}_{i=1,2,\dots,n}$  in a manner similar to  $\vec{m}_i$  using another embedding matrix  $B \in \mathbb{R}^{p \times d}$ .

$$\vec{r}_o = \sum_{i=1}^n \alpha_i \vec{r}_i \quad (1)$$

$$\hat{a}_i = \text{softmax}((\vec{r}_o + \vec{q})^T U\Phi(s_i)) \quad (2)$$

In the last step, prediction distribution  $\hat{a}_i$  is computed as in Equation 2, where  $U \in \mathbb{R}^{p \times d}$  is an embedding matrix similar to  $A$  and can potentially be tied with  $A$ , and  $s_i$  is one of the answers in  $S$ . Using the prediction step, a probability distribution  $\hat{a}_i$  over all  $s_i$  can be obtained and the final answer is selected as the one with the highest probability  $\hat{a}_i$  corresponding to the option  $s_i$ .

$$L(P, D) = \frac{1}{N_D} \sum_{n=1}^{N_D} a_n \times \log(\hat{a}_n(P, D)) + (1 - a_n) \times \log(1 - \hat{a}_n(P, D)) \quad (3)$$

To train a memory network, the cross-entropy loss function  $L$  between the true label distribution  $a_i \in \{0, 1\}^s$  (which is a one hot vector to indicate the correct label  $s$  in the training tuples) and the predicted distribution  $\hat{a}_i$  is used, as in Equation 3. Where  $P, D$  and  $N_D$  represent the set of model parameters to learn, training dataset, and the number of tuples in the training set respectively. Such an objective can be easily optimized using stochastic gradient descent (SGD). A memory network can easily be extended to perform several hops over the memory before predicting the answer. For details, we refer to Hill et al. (2016). However, we constrain this study to use a single-hop network in order to reduce number of

parameters to learn and also the chances of over-fitting; as we are dealing with small scale datasets.

**Self-Supervision** is a heuristic introduced to provide memory supervision and the rationale behind is that if the memory supporting the correct answer is retrieved than the model is more likely to predict the correct answer (Hill et al., 2016). More precisely, this is achieved by keeping a hard attention over memory while training, i.e.,  $m'_o = \text{argmax } \alpha_i$ . At each step of SGD, the model computes  $m'_o$  and updates only using those examples which do not select the memory  $m'_o$  having the correct answer in the corresponding  $c_i$ .

## 5 Proposed Methods

We attempt to improve the training procedure for Memory Networks in order to increase the performance for machine comprehension by QA with small scale datasets. Firstly, we introduce an improved training procedure for memory networks using curriculum learning which is termed as *Curriculum Inspired Training* (CIT) and offer details about this in Section 5.1. Thereafter, Section 5.2 explains joint-training method for knowledge transfer from an abundantly labelled dataset to another dataset with limited label information .

### 5.1 CIT: Curriculum Inspired Training

Curriculum learning makes use of the fact that model performance can be significantly improved if the training samples are not presented randomly but in such a way so as to make the learning task gradually more difficult by presenting examples in an easy to hard ordering (Bengio et al., 2009). Such a training procedure allows the learner to waste less time with noisy or hard to predict data when the model is not ready to incorporate such samples. However, what remains unanswered and is left as a matter of further exploration is how to devise an effective strategy for a given task?

$$SF(q, S, C, s) = \frac{\sum_{\text{word} \in \{q \cup S \cup C\}} \log(\text{Freq.}(\text{word}))}{\#\{q \cup S \cup C\}} \quad (4)$$

In this work, we formulate a curriculum strategy to train a memory network for machine comprehension. Formally, we rank training tuples  $(q, S, C, s)$  from easy to hard based on the normalized word frequency for passage, question, and context initially; using the score function (SF) mentioned in Equation 4 (i.e. easier passages have

more frequent words). The training data is then divided into a fixed number of chapters, with each successive chapter resulting in addition of more difficult tuples. The model is then trained sequentially on each chapter with the final chapter containing the complete training data. The presence of both the number of chapters and the fixed number of epochs per chapter makes such a strategy flexible and allows to be tailored to different data after optimizing the like other hyper-parameters.

$$L(P, D, en) = \frac{1}{N_D} \sum_{n=1}^{N_D} (a_n \times \log(\hat{a}_n(P, D)) + (1 - a_n) \times \log(1 - \hat{a}_n(P, D))) \times \mathbf{1}(en, c(n) \times epc) \quad (5)$$

The loss function used for curriculum inspired training varies with epoch number; as mentioned in Equation 5. Note, in Equation 5,  $en$  and  $c(n)$  represents the current epoch number and chapter number for  $n^{th}$  tuple assigned using rank allocated based on SF mentioned in Equation 4 respectively.  $epc$ ,  $P$ ,  $D$ , and  $\mathbf{1}$  is the number of epochs per chapter, model parameters, training set, and an indicator function which is one if first argument is  $\geq$  the second argument or else zero; respectively.

### 5.2 Joint-Training for Knowledge Transfer

While joint-training methods offer knowledge transfer by exploiting similarities and regularities across different tasks or datasets, the asymmetric nature of transfer and skewed proportion of datasets is usually not handled in a sound way. Here, we devise a training loss function  $\hat{L}$  to relieve both of these involved issues while doing joint-training with a target dataset (TD) with fewer training samples and a source dataset (SD) having label information for higher number of examples; as mentioned in Equation 6.

$$\hat{L}(P, TD, SD) = 2 \times \gamma \times L(P, TD) + 2 \times (1 - \gamma) \times L(P, SD) \times F(N_{TD}, N_{SD}) \quad (6)$$

Where  $\hat{L}$  represents the devised loss function for joint-training for transfer,  $L$  the cross-entropy loss function also mentioned earlier in Equation 3,  $\gamma$  is a weighting factor which varies between zero and one,  $F(N_{TD}, N_{SD})$  is an another weighting factor which is a function of number of samples in the target domain  $N_{TD}$  and in the source domain  $N_{SD}$ . The rationale behind  $\gamma$  factor is to control the relative update in the network due to

samples from source and target datasets; which permits biasing of the model performance towards one dataset.  $F(N_{TD}, N_{SD})$  factor can be independently utilized to mitigate the effect of skewed proportion in the number of samples present in both target and source domains. Note, maintaining both  $\gamma$  and  $F(N_{TD}, N_{SD})$  as separate parameters allows for restricting  $\gamma$  within (0,1) without any extra computation as described below.

### 5.3 Improved Loss Functions

This paper explores the following variants of the introduced loss function  $\hat{L}$  for knowledge transfer via joint-training:

1. Joint-training (Jo-Train):-  $\gamma = 1/2$  and  $F(N_{TD}, N_{SD}) = 1$ .
2. Weighted joint-training (W+Jo-Train):-  $\gamma = (0, 1)$  and  $F(N_{TD}, N_{SD}) = N_{TD}/N_{SD}$ .
3. Curriculum joint-training (CIT+Jo-Train):-  $L(P, TD)$  &  $L(P, SD)$  of Equation 6 are replaced by their analogous terms  $L(P, TD, en)$  &  $L(P, SD, en)$  generated using Equation 5;  $\gamma = 1/2$  and  $F(N_{TD}, N_{SD}) = 1$ .
4. Weighted curriculum joint-training (W+CIT+Jo-Train):-  $L(P, TD)$  &  $L(P, SD)$  of Equation 6 are replaced by analogous  $L(P, TD, en)$  &  $L(P, SD, en)$  generated using Equation 5;  $\gamma = (0, 1)$  and  $F(N_{TD}, N_{SD}) = N_{TD}/N_{SD}$ .
5. Source only (SrcOnly) :-  $\gamma = 0$ .

The  $F(N_{TD}, N_{SD})$  factor does not increase computation as it is not optimized for any of the cases. Jo-Train (Liu et al., 2015), SrcOnly and a method similar to W+Jo-Train (Daume III, 2007) have also been explored previously for other NLP tasks and models.

## 6 Experiments

We evaluate the performance on datasets introduced earlier in Section 3. We first present baseline methods, pre-processing and training details. In Section 6.3, we present results on CNN-11/22/55K, MCTest-160 and MCTest-50 to validate our claims mentioned in Section 1. All of the methods presented here are implemented in Theano (Bastien et al., 2012) and Lasagne (Dieleman et al., 2015) and are run on a single GPU (Tesla K40c) server with 500GB of memory.

### 6.1 Baseline Methods

We implemented Sliding Window (SW) and Sliding Window + Distance (SW+D)(Richardson et al., 2013) as baselines to compare against our experiments. Further, we augment SW (or SW+D) to incorporate distances between word vectors of the question and the context over the sliding window; in a manner similar to the way SW+D is augmented from SW by Richardson et al. (2013). These approaches are named based upon the source of pre-trained word vectors, e.g., SW+D+CNN-11K+W2V utilizes vectors estimated from both CNN-11K and word2vec pre-trained vectors<sup>1</sup>. In case of more than one source, individual distances are summed and utilized for final scoring. Results on MCTest for SW, SW+D, and their augmented approaches are reported using online available scores for all answers<sup>2</sup>.

**Meaningful Comparisons:** To ascertain that the improvement is due to the proposed training methods, and not merely because of addition of more data, we built multiple baselines, namely, initialization using word vectors from word2vec, pre-training, Jo-train, and SrcOnly. For pre-training and word2vec, words  $\in$  target dataset and  $\notin$  source dataset are initialized, by a uniform random sampling with the limits set to the extremes spanned by the word vectors in the source domain. *It is worth to note that the pre-training and Jo-train utilizes as much label information and data as other proposed variants of joint-training. Also, SrcOnly method is an indicative of how much direct knowledge transfer from source domain to target domain can be achieved without any learning.*

### 6.2 Pre-processing & Training Details

While processing data, we replace words occurring less than 5 times by <unk> token except for MCTest datasets. Additionally, all entities are included in vocabulary. All models are trained by carrying out the optimization using SGD with learning rate in  $\{10^{-4}, 10^{-3}\}$ , momentum value set to 0.9, weight decay in  $\{10^{-5}, 10^{-4}\}$ , and, max norm in  $\{1, 10, 40\}$ . We kept length of window equal to 5 for CNN / Dailymail datasets(Hill et al., 2016) and for MCTest datasets is chosen from  $\{3, 5, 8, 10, 12\}$ . For embedding size, we look for the optimal value in  $\{50, 100, 150, 200, 300\}$  for

Table 2: Train, validation and test percentage accuracy on CNN-11/22/55K datasets. § and ‡ indicate that the data used comes from either of CNN-11/22/55K and also from Dailymail-55K along with either of CNN-11/22/55K respectively. Random test accuracy on these datasets is 3.96% approximately.

CNN / Dailymail datasets. For CNN / Dailymail, we have trained memory network using a single batch with self-supervision heuristic (Hill et al., 2016). In case of curriculum learning, the number of chapters are optimized out of {3, 5, 8, 10} and number of epochs per chapter is set equal to  $\frac{2M}{M+1} \times \frac{ed_{ncl}}{ed_{cl}} \times EN$  which is estimated by equating to the number of network update found for the optimal case of non-curriculum learning. Here  $M$  and  $ed_{cl}$  represents the number of chapter and embedding size for curriculum learning, and  $ed_{ncl}$  &  $EN$  represents the optimal value found for embedding size and number of epochs without curriculum learning. We use early stopping with a validation set while training the network.

### 6.3 Results & Discussion

In this section, we present results to validate contributions mentioned in Section 1. Table 2 presents the results of our approaches along with results from baseline methods SW, SW+D, SW+W2V, and a standard memory network (MemNN). Results for CIT on CNN-11/22/55K (MemNN+CIT) show an absolute improvement of 2.96%, 1.31%, and, 1.00% respectively, when compared with the memory network (MemNN) (*contribution (i)*). Figure 1 shows that the CIT leads to better convergence when compared without CIT on CNN-11K.

As baselines for knowledge transfer from the Dailymail-55K dataset to CNN-11/22/55K datasets, Table 2 presents results for SW+Dailymail, memory network initialized with word2vec (MemNN+W2V), memory network trained on Dailymail (MemNN+SrcOnly), memory network initialized with pre-trained

embeddings from Dailymail (MemNN+Pre-train) and memory network jointly-trained with both Dailymail and CNN (MemNN+Jo-train) (*contribution (ii)*). Further, results show the knowledge transfer observed when MemNN+CIT+Jo-train and MemNN+W+Jo-Train are utilized to train Dailymail-55K with CNN-11/22/55K. On combining the MemNN+CIT+Jo-train with MemNN+W+Jo-Train (which is MemNN+W+CIT+Jo-Train), a significant and consistent improvement can be observed; as the performance goes up by 1.96%, 2.03%, and, 1.89% on CNN-11/22/55K respectively; when compared against the other competitive baselines (*contribution (ii) & (iii)*).

Results empirically support the major premise of this study, i.e., CIT and knowledge transfer from a related dataset with memory network can significantly improve the performance; improvements of 10.94%, 6.28%, and, 3.19% are observed with CNN-11/22/55K respectively when compared with the standard memory network. The improvement in knowledge transfer decreases as the amount of data in the target domain starts increasing from 11K to 55K, as the volume of data in the target domain starts becoming comparable to source domain, and is enough to achieve similar level of performance without knowledge transfer.

Previously, Chen et al. (2016) annotated a sample of 100 questions on CNN stories based on the type of capabilities required to answer the question. We report results for all 6 specific categories in Table 3. Even with CNN-11K and Dailymail-55K which is roughly 20% of the complete CNN dataset, the proposed methods achieve similar per-

Table 4: Knowledge transfer results on MCTest-160 and MCTest-500 datasets. One and Multi. indicates the questions that require one and multiple supporting facts. Random test accuracy is 25% here, as number of options are 4.

formance on 4 out of 6 categories, when compared to latest models ( $2^{nd}$  &  $3^{rd}$  last rows of Table 3).

On very small datasets such as MCTest-160 and MCTest-500, it is not feasible to train memory network (Smith et al., 2015), therefore, we explore the use of word vectors from the embedding matrix of a model pre-trained on CNN datasets. Here, the embedding matrix refers to the encoding matrix  $A$  used in the first step of memory network as mentioned in Section 4. SW+D+CNN-11/22/55K are the results when the similarity measures comes from SW+D as mentioned in Section 6.1 and also using the word vectors from encoding matrix  $A$  obtained after training on CNN-11/22/55K. From table 4, it is evident that performance improves as the amount of data increases in CNN domain (*contribution(iii)*). Further, on combining with word2vec distance (SW+D+CNN-11/22/55K+W2V), an improvement is observed.

## 7 Conclusion

Looking at the widespread applications of Memory Networks and the prohibitive data requirements for training them, this paper seeks to improve the performance of memory networks on small datasets in two different ways. Firstly, this paper introduces an effective CIT procedure for machine comprehension. Secondly, this paper explores various methods to exploit labelled data from closely related domains; in order to perform knowledge transfer and improve performance. Additionally, this paper suggests the use of a modified loss function to further incorporate the asymmetric nature of knowledge transfer. Beyond machine comprehension, we believe that the proposed methods are likely to achieve higher generalization for other tasks utilizing memory network style architectures, by virtue of the proposed CIT method and joint-training for knowledge transfer.

## Abstract

This paper presents a framework to understand negation in positive terms. Specifically, we extract positive meaning from negation when the negation cue syntactically modifies a noun or adjective. Our approach is grounded on generating potential positive interpretations automatically, and then scoring them. Experimental results show that interpretations scored high can be reliably identified.

## 1 Introduction

Negation is a complex phenomenon present in all human languages, allowing for the uniquely human capacities of denial, contradiction, misrepresentation, lying, and irony (Horn and Wansing, 2015). Acquiring and understanding negation poses unique challenges. For example, children acquire negation after learning to communicate in positive terms (Nordmeyer and Frank, 2013), and adults take longer to process sentences containing negation (Clark and Chase, 1972).

In any given language, humans communicate in positive terms most of the time, and use negation to express something unusual or an exception (Horn, 1989). But negation is ubiquitous (Morante and Sporleder, 2012): In scientific papers, 13.76% of sentences contain a negation (Szarvas et al., 2008); in product reviews, 19% (Councill et al., 2010); and in Conan Doyle stories, 22.23% (Morante and Daelemans, 2012).

From a theoretical perspective, it is accepted that negation has scope and focus, and that humans intuitively understand positive meanings from negation (Rooth, 1992; Huddleston and Pullum, 2002). For example, from (1) *John didn't earn a steady paycheck until he was 40 years old*, humans understand that (1a) *John earned unsteady paychecks before he was 40 years old*, and that

(1b) *John earned steady paychecks when he was 40 years old*. This kind of positive interpretations would benefit language understanding in general. For example, a question answering system would benefit from interpretation (1b) when answering question *Did John ever earn a steady paycheck?*

Within computational linguistics, automated approaches to extract positive meanings from negation target verbal negation (Section 3), i.e., when the negation cue is grammatically associated with a verb, as in (1). Verbal negation accounts only for a portion of all negations, e.g., out of all syntactic dependencies indicating a negation modifier (*neg* dependency) in OntoNotes (Hovy et al., 2006), 64.4% modify verbs, 19.6% nouns, 10.3% adjectives, and 5.7% other part-of-speech tags. Non-verbal negation also conveys positive meanings, e.g., from (2) *No media were allowed inside the venue* (*No* modifies noun *media*), humans understand that (2a) *Somebody* (e.g., *invited guests*) *were allowed inside the venue* and that (2b) *Media were allowed somewhere outside the venue* (presumably in a designated press area). Similarly, from (3) *She was not alive when she got to the Lafayette area* (*not* modifies adjective *alive*), humans understand that (3a) *She was dead when she got to the Lafayette area* and that (3b) *She was alive before she got to the Lafayette area*.

This paper presents new corpora and experimental results to extract positive interpretations from negation when the negation cue modifies a noun or adjective. The main contributions are: (1) analysis of negation in OntoNotes beyond verbal negation; (2) procedure to automatically generate potential positive interpretations from non-verbal negation, specifically, when the negation cue modifies a noun or adjective; (3) annotations validating and scoring potential interpretations according to their likelihood;<sup>1</sup> and (4) experimental results showing that the task can be automated.

<sup>1</sup>Available at <http://www.cse.unt.edu/~blanco/>

## 2 Terminology and Background

Negation can be expressed by verbs (e.g., *avoid* the highway), nouns (e.g. *lack* of knowledge), adjectives (e.g., it is *useless*), adverbs (e.g., *John never* drives on the highway), and others (van der Wouden, 1997). The primary negative prefixes in English are *in-*, *il-*, *im-*, *ir-*, *un-*, *non-*, *anti-* and *a-* (Garner, 2009, p. 563). We refer to the token, prefix or suffix that indicates negation (emphasized in the examples above) as *negation cue*. As we shall see, in this paper we target negations whose cue syntactically modifies a noun or adjective.

In philosophy and linguistics, it is generally accepted that negation conveys positive meanings (Horn, 1989). We use the term *positive interpretation* to refer to the positive meaning intuitively understood by humans when reading sentences that contain negation. Positive interpretations range from implicatures (Blackburn, 2008), to entailments. *Potential* positive interpretations are positive interpretations whose validity is unknown.

**Scope and Focus.** Negation is generally understood in terms of scope and focus. Scope is “the part of the meaning that is negated” and focus is “the part of the scope that is most prominently or explicitly negated” (Huddleston and Pullum, 2002). Scope and focus are not exclusive of negation. Among many others, there has been work on detecting the scope of uncertainty cues (Farkas et al., 2010), and other focus-sensitive phenomena include adverbs and conditionals (Rooth, 1985).

Consider statement (2) again, *No media were allowed inside the venue*. By definition, scope refers to “all elements whose individual falsity would make the negated statement strictly true”, and focus is “the element of the scope that is intended to be interpreted as false to make the overall negative true” (Huddleston and Pullum, 2002). If any of the truth conditions below were false, statement (2) would be true, thus the scope of the negation marked with *No* is (2a-2c):

- 2a. Some people were allowed somewhere.
- 2b. Media were allowed somewhere.
- 2c. Some people were allowed inside the venue.

Choosing the element of the scope which is the focus is more challenging than identifying the scope. A natural reading of statement (2) indicates that there were people (e.g., invited guests) allowed inside the venue, and that media were (probably) allowed in a press area outside (but not far from) the venue. The former positive inter-

pretation corresponds to choosing *Media* as focus, and the latter corresponds to choosing *inside* as focus. Statement (2) exemplifies two core properties of the work presented here: We choose several foci for a single negation, and as a result, reveal several positive interpretations per negation. Further, we see positive interpretations as probabilistic knowledge, i.e., knowledge that may be likely but not necessarily certain.

In general, the task of identifying foci and revealing positive interpretations is natural to humans, but hard to automate. Consider modified statement (2') *No media were allowed inside the venue to record the presentation*. The scope is conditions (2a-2c) and (2d) *Somebody was allowed to record the presentation*. The positive interpretations from (2') are different than from (2), e.g., *Media were allowed inside the venue, but they weren't allowed to record the presentation* can only be extracted from (2').

## 3 Previous Work

Within computational linguistics, most approaches to process negation target scope or focus detection. Generally speaking, there are corpora with scope annotations for all types of negations, but corpora with focus annotations are restricted to verbal negation, i.e., when the negation cue is grammatically associated with a verb.

**Scope of Negation.** There are two main corpora with scope of negation annotations: BioScope in the medical domain (Szarvas et al., 2008) and CD-SCO (Morante and Daelemans, 2012). The annotations schemas differ substantially; CD-SCO annotates negation cues, their scopes, and the negated events or properties. There have been several supervised proposals to detect the scope of negation using BioScope and CD-SCO (Morante and Daelemans, 2009; Velldal et al., 2012; Basile et al., 2012). Fancellu et al. (2016) present the best results to date with CD-SCO using neural networks. They also perform out-of-domain evaluation with new annotations on Wikipedia, and analyze the main sources of errors.

Outside BioScope and CD-SCO, Reitan et al. (2015) present a scope detector for negation in tweets, and use it for sentiment analysis.

As the examples throughout this paper show (e.g., Section 2), detecting the scope of negation is insufficient to reveal the positive interpretations we target in this work.

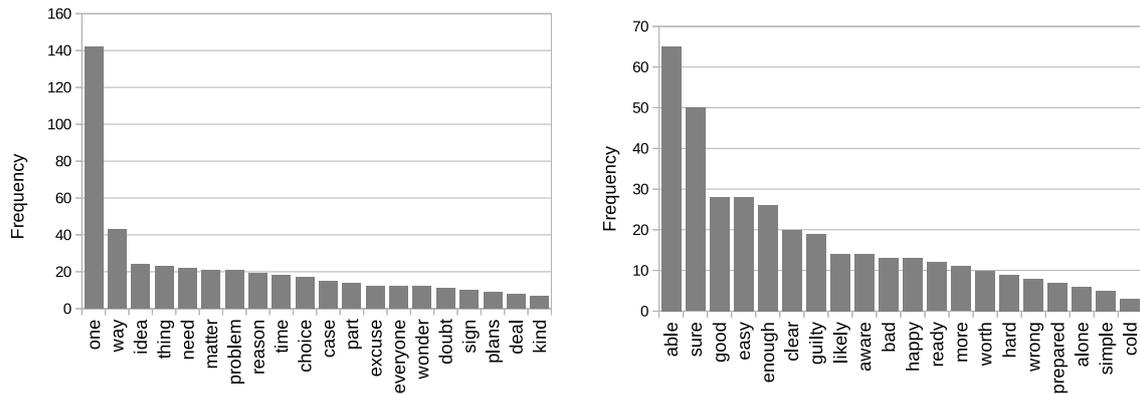

Figure 1: Most frequent nouns (left) and adjectives (right) tokens that are negated (*neg* dependency) in OntoNotes. Total number of noun and adjective tokens modified by a negation cue is 1,866 and 979.

### Focus of Negation and Positive Interpretations.

Identifying the focus of negation is equivalent to revealing positive interpretations—everything but the focus is actually positive. The definition of focus does not specify annotation guidelines, and most existing efforts are grounded on semantic roles. Blanco and Moldovan (2011) annotate focus on the negations marked with ARG-M-NEG role in PropBank (Palmer et al., 2005). They select a single focus per negation, specifically, they select the role that reveals the “most useful [positive] information.” Anand and Martell (2012) refine these annotations and differentiate positive interpretations arising from focus identification, scalar implicature and neg-raising predicates. Blanco and Sarabi (2016) propose a similar approach that scores the likelihood of several potential foci per negation. The main limitations of all these previous works is that selecting as focus a semantic role is only suitable when the negation cue modifies a predicate, and roles often yield coarse-grained interpretations. Sarabi and Blanco (2016) bypass these drawbacks by working with syntactic dependencies to refine coarse-grained interpretations.

All these previous efforts to reveal positive interpretations from negation target exclusively verbal negation, i.e., when the negation cue modifies a verb. While verbal negation is more frequent (64.4% of *neg* dependencies in OntoNotes, Section 4), in this paper we target two understudied yet important negations: when the negation cue modifies a noun or adjective (19.6% and 10.3% of *neg* dependencies). Our approach is not grounded on semantic roles but syntactic dependencies. Doing so allows us to tackle negation when the negation cue modifies nouns or adjectives.

## 4 Corpus Creation

We create a corpus of negations and their positive interpretations following three steps. First, we select negations whose negation cue syntactically modifies either a noun or adjective. Second, we automatically generate potential positive from those negations by manipulating syntactic dependencies and part-of-speech tags. Third, we gather manual annotations to validate and score potential interpretations. While asking annotators to suggest positive interpretations would potentially yield more natural interpretations, we found experimentally that a generate-and-rank approach yields higher quality annotations.

**Negation in OntoNotes.** Instead of building our corpus from plain text, we decided to work on top of OntoNotes (Hovy et al., 2006), a publicly available corpus including texts in several genres (news, transcripts, magazines, etc.).<sup>2</sup> OntoNotes includes, among other gold linguistic annotations, part-of-speech tags and parse trees. We transformed the parse trees into syntactic dependencies using Stanford CoreNLP (Manning et al., 2014).

We reduce the problem of finding negations to retrieving syntactic dependencies *neg*, which stands for negation modifier. Doing so ignores negation cues that are prefixes or suffixes (e.g., *unlimited*, *motionless*), but also simplifies the process. There are 9,507 *neg* syntactic dependencies in OntoNotes; 6,120 of them modify verbs (64.4%), 1,866 nouns (19.6%), 979 adjectives (10.3%), and 543 other part-of-speech tags (5.7%). Since verbal negation has been tackled

<sup>2</sup>We use the CoNLL-2011 Shared Task distribution (Pradhan et al., 2011), <http://conll.cemantix.org/2011/>

Noun			
	Negated statement	No condemned murderer has been granted clemency in California since nineteen sixty-seven.	
	Positive counterpart	[A] condemned murderer has been granted clemency in California since nineteen sixty-seven.	
	Relevant tokens	[A] condemned murderer has been granted clemency in California since nineteen sixty-seven.	
	Potential positive interpretations	Intpn. 1, root	[A] condemned murderer has been {some verb} clemency in California since nineteen sixty-seven, but not <i>granted</i> .
		Intpn. 2, nsubjpass	{Someone} has been granted clemency in California since nineteen sixty-seven, but not [ <i>a</i> ] <i>condemned murderer</i> .
Intpn. 3, dobj		[A] condemned murderer has been granted {something} in California since nineteen sixty-seven, but not <i>clemency</i> .	
Intpn. 4, prep		[A] condemned murderer has been granted clemency {somewhere} since nineteen sixty-seven, but not <i>in California</i> .	
Intpn. 5, prep		[A] condemned murderer has been granted clemency in California {at some point of time}, but not <i>since nineteen sixty-seven</i> .	
Adjective			
	Negated statement	But she was not alive when she got to the Lafayette area.	
	Positive counterpart	But she was alive when she got to the Lafayette area.	
	Relevant tokens	She was alive when she got to the Lafayette area.	
	Potential positive interpretations	Intpn. 1, root	She was {some adjective} when she got to the Lafayette area but not <i>alive</i> .
		Intpn. 2, nsubj	{Somebody} was alive when she got to the Lafayette area but not <i>she</i> .
Intpn. 3, advcl		She was alive {at some point of time} but not <i>when she got to the Lafayette area</i> .	

Table 1: Examples of negations and the steps to generate potential positive interpretations (the negated token is either a noun (top) or adjective (bottom)). We also indicate the dependency between a token in the potential focus and a token outside the potential focus.

before (Section 3), we focus on negation cues that modify nouns or adjectives. We use the term *negated token* to refer to the token that is syntactically modified by the negation cue. The most frequent negated tokens that are nouns or adjectives are plotted in Figure 1.

#### 4.1 Selecting Negations

Annotating all negations that modify a noun or adjective is outside the scope of this paper. To alleviate the annotation effort, we discard negations that belong to sentences that do not have at least one verb and one subject (*nsubj* or *nsubjpass* dependencies), and sentences that contain more than two negations, conditionals, questions or commas. Additionally, we skip negations if the negated token is the noun *one*, as scoring their potential positive interpretations is straightforward. Out of the

1,866 and 979 negation modifying nouns and adjectives, 635 and 320 pass the above filters. Out of these, we randomly select 309 and 75 respectively (approximately 50% and 25%).

#### 4.2 Generating Potential Positive Interpretations

We generate potential positive interpretations automatically using a deterministic procedure that manipulates part-of-speech tags and syntactic dependencies. The first step is to remove the negation cue to obtain the positive counterpart. Then, we use dependencies to select the tokens relevant to the negation—the main motivation is to select the eventuality to which the negation belongs. Finally, we generate potential interpretations using a battery of deterministic rules. Table 1 shows the output of each step with two sample negations.

**Selecting Relevant Tokens.** Negation may occur in sentences with multiple clauses. We simplify the original sentence and identify the eventuality to which the negation belongs by using the rules below. We defined these rules after analyzing several examples and the Stanford dependencies manual (de Marneffe and Manning, 2008).

When the negated token is a noun, we have two scenarios. Scenario (1) occurs when the negated token is the root or it has a *cop* dependency (*copula*) with the verb *to be*. In this case, we select all the dependents of the negated token.<sup>3</sup> Scenario (2) occurs when neither of the two rules above apply. In that case, we select all the dependents of the closest verb, where the closest verb is the first verb found when traversing the dependency tree from the negated token to the root. For example, we simplify *Article three says that no law shall prohibit any religious belief* to *No law shall prohibit any religious belief*.

When the negated token is an adjective, we select all the dependents of the negated token. For example, from *His estimate of 3.3% for third-quarter GNP is higher than the consensus because he believes current inventories aren't as low as official figures indicate*, we select *Current inventories aren't as low as official figures indicate*.

**Manipulating Dependencies to Generate Potential Positive Interpretations.** After removing the negation cue and selecting relevant tokens, we use syntactic dependencies to select potential foci. Once potential foci are identified, generating positive interpretations is straightforward: each focus yields one interpretation, where everything but the focus is positive. The main idea is to select as potential foci subtrees rooted at selected tokens.

When the negated token is a noun, we select as potential foci the subtrees rooted in all the direct dependents of the negated token in Scenario (1), and the subtrees rooted in all the direct dependents of the closest verb in Scenario (2). When the negated token is an adjective, we select as potential foci the subtrees rooted in all the direct dependents of the negated token. This strategy to select potential foci has a few exceptions to avoid foci that yield meaningless interpretations. Specifically, we discard potential foci:

- whose root has dependency *aux*, *auxpass*, *cop*, *poss*, *dep*, *prt* or *punct*;

<sup>3</sup>If the negated token is a noun and the root, this scenario is equivalent to selecting the whole sentence

- that consist of
  - the determiner *the*, *a*, *an*, *it* and *there*;
  - the adverbs *so*, *too*, *though*, *even*, *still*, *as*, *quite*, *either*, *however*, *any-more*, *moreover*, *therefore*, *furthermore*, *hence*, *thus*, *further*, *apparently*, *clearly*, *specifically*, *actually*, *fortunately*, and *unfortunately*;
  - a single token with part-of-speech tag TO, CC, UH, POS or IN.

These exceptions were defined after manual examination of several examples. For example, consider sentence *It's not just women and girls who are affected*. We avoid generating interpretations *It's just women and girls who {X} affected* (focus would be *are*, with dependency *aux*), and *It's just women {X} girls who are affected* (focus would be *and*, with part-of-speech tag *CC*).

After potential foci are selected, we generate potential positive interpretations by rewriting each focus with “someone / some people / something / etc.”, and appending “but not text\_of\_focus” at the end. Table 1 details the steps to generate potential positive interpretations.

### 4.3 Scoring Potential Interpretations

Once potential interpretations are generated automatically, we manually annotate them. The annotation interface shows the sentence containing the negation, the previous and next sentences as context, and one potential positive interpretation at a time. Annotators are asked *Given the text snippet below [previous sentence, sentence containing the negation and next sentence], do you think the statement [positive interpretation] is true?*, and must answer with a score ranging from 0 to 5, where 0 means *certainly no* and 5 means *certainly yes*. During pilot annotations, we found that certainty must be taken into account as forcing annotators to answer *yes* or *no* proved too restrictive. Note that some negations do not have any positive interpretation scored high, e.g., all interpretations from *Utter no words* receive a low score.

## 5 Corpus Analysis

Table 2 shows basic counts and statistics of the annotated potential positive interpretations. *Dependency* indicates the syntactic dependency between a token within the potential focus and a token outside the potential focus. The total number of potential positive interpretations is 777 when

	Negation, context (previous and next sentences) and all potential positive interpretations	Score
Noun	Context, previous sentence: Here’s what that judge said. Negation: The victim in this case is not a young child. Context, next sentence: He’s now sixteen years old.	
	- Interpretation 1: The victim in this case is a young {something}, but not <i>a child</i> .	2
	- Interpretation 2: {Something} is a young child, but not <i>The victim in this case</i> .	4
	- Interpretation 3: The victim in this case is a {some adjective} child, but not <i>young</i> .	5
Adjective	Context, previous sentence: She was alive when she left that nursing home. Negation: But she was not alive when she got to the Lafayette area. Context, next sentence: CNN made repeated attempts to contact administrators or representatives of Huntingdon Place.	
	- Interpretation 1: She was {some adjective} when she got to the Lafayette area, but not <i>alive</i> .	5
	- Interpretation 2: {Somebody} was alive when she got to the Lafayette area, but not <i>she</i> .	2
	- Interpretation 3: She was alive {at some point of time}, but not <i>when she got to the Lafayette area</i> .	5

Table 3: Annotation examples. We show the original sentence containing a negation (the negated token is either a noun or an adjective), its context, and all potential interpretations with their scores.

	Dependency	#	%	Score	
				Mean	SD
Nouns	nsubj	231	30.0	4.45	0.88
	root	169	21.7	2.96	1.41
	pobj	70	9.0	3.99	1.31
	amod	50	6.4	4.72	0.8
	ccomp	45	5.7	3.62	1.34
	other	212	27.3	3.73	1.49
	total	777	100.0	3.86	1.38
Adjectives	nsubj	57	28.5	4.12	0.80
	root	50	25.0	4.82	0.48
	ccomp	22	11.0	4.91	0.29
	pobj	21	10.5	4.19	1.05
	xcomp	12	6.0	4.42	1.32
	other	38	19.0	4.08	1.46
total	200	100.0	4.40	0.99	
All		977	100.0	3.97	1.33

Table 2: Corpus analysis. For each dependency, we show the total number and percentage of interpretations, mean score and standard deviation.

the negated token is a noun, and 200 when it is an adjective. On average, we generate 2.5 potential interpretation per negation when the negated token is a noun, and 2.7 when it is an adjective (we selected 309 and 75 negations respectively).

When the negated token is a noun, scores are overall lower (3.86 vs. 4.40), and scores are higher when the *dependency* is either *nsubj* (nominal subject, 4.45) or *amod* (adjectival modifier, 4.72). Regardless of *dependency*, mean scores are always over 4 when the negated token is an adjective.

**Annotation Quality.** The procedure to generate potential interpretations (Section 4.2) was tuned iteratively until we achieved considerable annotation agreement in pilot annotations. To ensure quality, we calculated Pearson correlations with 20% of annotations, and stopped the refinement process when we achieved 0.76 Pearson correlation. Note that Pearson is better suited than agree-

ment measures designed for categorical labels, as not all disagreements are equally bad, e.g., 4 vs. 1 is worse than 4 vs. 5.

## 5.1 Annotation Examples

Table 3 presents two complete annotation examples when the negated token is a noun and adjective. We show all potential interpretations generated and the manually assigned scores.

We generate three potential positive interpretations from the first example, *The victim in this case is not a young child*, and two of them received high scores (4 and 5). When reading the statement in context, it is clear that the judge implied that *Something (a younger human) would be a younger child* (Interpretation 2), and that *The victim of this case is an older (not young) child* (Interpretation 3). Interpretation (1), *The victim in this case is a young something*, receives a low score (2 out of 5). One could argue that this interpretations should receive a higher score because *The victim in this case is a young adult*, we simply provide real annotations drawn from our corpus.

The procedure to generate potential positive interpretations also generates three interpretations from the second example, *But she was alive when she got to the Lafayette area*, and two of them receive the highest score (5 out of 5). Interpretation (1) encodes the intuitive meaning that *She was dead when she got to the Lafayette area*, and Interpretation (3) captures that *She was alive before she got to the Lafayette area*. Interpretation (2) receives a low score (2 out of 5), as there is no evidence suggesting which individuals were alive when they got to the Lafayette area.

Type	Name	Description
Basic	neg_cue	word form of the negation cue
	neg_token	word form and part-of-speech tag of negated token
Path	syn_path_dep	path of dependencies from focus to negated token (or verb)
	syn_path_pos	path of POS tags from focus to negated token (or verb)
	last_syn_path_dep	last syntactic dependency in syn_path_dep
	last_syn_path_pos	last part-of-speech tag in syn_path_pos
Focus	focus_length	number of tokens in potential focus
	focus_first_word	word form and part-of-speech tag of first word in focus
	focus_last_word	word form and part-of-speech tag of last word in focus
	focus_direction	flag indicating whether focus occurs before or after neg_token
	focus_head_word	word form of the head of focus
	focus_head_pos	part-of-speech tag of the head of focus
	focus_head_rel	syntactic dependency of the head of focus

Table 4: Features used to assign scores to automatically generated potential interpretations.

Feature set	Gold			Predicted		
	Nouns	Adjectives	All	Nouns	Adjectives	All
neg_cue	-0.10	-0.24	0.06	0.02	-0.26	-0.02
basic	0.12	-0.10	0.11	0.05	-0.39	0.01
basic + path	0.36	0.59	0.40	0.17	0.58	0.24
basic + path + focus	0.36	0.52	0.42	0.33	0.39	0.34

Table 5: Pearson correlations obtained with the test split and several combination of features. We detail results by the part-of-speech tag of the negated token (noun or adjective).

## 6 Learning to Score Potential Interpretations

We solve the task of scoring potential positive interpretations using standard supervised machine learning. We divide negations and their corresponding interpretations into training (80%) and test (20%), and use SVM with RBF kernel as implemented in scikit-learn (Pedregosa et al., 2011). We tune parameters  $C$  and  $\gamma$  using 10-fold cross-validation using the training set.

### 6.1 Feature Selection

Table 4 lists the full feature set. We extract features from the negated token (noun or adjective), part-of-speech tags and dependency tree.

*Basic* features are straightforward. They include the negation cue, and the word form and part-of-speech tag of the negated token.

*Path* features are derived from the syntactic path between the subgraph selected as focus and the negated token or closest verb. If the negated token is a noun, we extract the path between the subgraph and the negated token in Scenario (1), and between the subgraph and the closest verb in Scenario (2) (Section 4.2). If the negated token is an adjective, we extract the path between the subgraph and the negated token. We include two paths (dependencies and part-of-speech tags), and the last dependency and part-of-speech tag.

*Focus* features characterize the dependency subgraph chosen as focus to generate the potential interpretation. We include the number of tokens, word form and part-of-speech tags of the first and last tokens, and whether the focus occurs before or after the negated token. Additionally, we extract the word form, part-of-speech-tag and dependency of the head of the focus, which we define as the token whose syntactic head is outside the focus.

## 7 Experimental Results

We perform two kinds of experiments. First, we score all potential positive interpretations automatically generated (Section 7.1). Second, we identify interpretations scored with the highest score, 5 out of 5 (Section 7.2). We always build separate models for nouns and adjectives, and train with gold linguistic information (POS tags and dependencies). We report results on the test set using both gold and predicted linguistic information. For gold, we use the annotations provided with the CoNLL-2011 release, and for auto, we use the output of SyntaxNet (Andor et al., 2016).

### 7.1 Scoring all Potential Interpretations

We score all potential interpretations using SVM for regression, and calculate Pearson correlation for evaluation purposes. Table 5 shows results obtained with several combinations of features.

When extracting features from gold linguistic

	Gold						Predicted					
	Nouns			Adjectives			Nouns			Adjectives		
	P	R	F	P	R	F	P	R	F	P	R	F
majority baseline	0.00	0.00	0.00	0.47	1.0	0.64	0.00	0.00	0.00	0.31	1.00	0.48
neg_mark	0.66	0.33	0.44	0.47	1.00	0.64	0.00	0.00	0.00	0.31	1.00	0.48
basic	0.66	0.37	0.47	0.47	1.00	0.64	0.62	0.12	0.21	0.31	1.00	0.48
basic + path	0.78	0.64	0.70	0.60	0.95	0.73	0.73	0.60	0.66	0.37	1.00	0.54
basic + path + focus	0.71	0.63	0.67	0.64	0.94	0.76	0.64	0.50	0.56	0.50	0.83	0.62

Table 6: Precision, Recall and F-measure obtained with the test split for instances with the highest score (5 out of 5). Predicting these interpretations correctly allows our models to identify which of the automatically generated potential interpretations are valid given the negation.

information (part-of-speech tags and syntactic dependencies), using only the negation cue as feature or *basic* features (negation cue and negated token) is rather useless (Pearson correlations range from -0.24 to -0.10). Using *basic + path* features yields 0.36 and 0.59 Pearson correlations for nouns and adjectives respectively, and including *focus* features is detrimental (0.36 and 0.52).

When extracting features from predicted linguistic information, we observe a similar trend in Pearson correlations. Results using predicted linguistic information are not directly comparable with those using gold linguistic information. Our methodology to generate potential interpretations relies heavily on syntactic dependencies, and using predicted interpretations implies that some interpretations present in our corpus cannot be automatically generated because of mistakes made by the parser. Out of the 196 potential interpretations in the original test set (20% of 977 annotated interpretations), we evaluate with the 94 interpretation generated with predicted dependencies (48%).

## 7.2 Identifying Valid Potential Interpretations

While scoring all potential positive interpretation generated is interesting, determining which of those interpretations are certain (scored 5 out of 5) is arguably more useful in a real system. Indeed, an inference tool would ideally extract certain interpretations from negation, and identify other potential interpretations as a byproduct of our generate-and-rank approach.

To estimate performance under this scenario, we approach the task as a standard binary classification task. Interpretations scored 5 receive the positive label, and other interpretations receive the negative label. Table 6 presents results in the test set (Precision, Recall and F-score) for the positive label using the majority baseline and several com-

binations of features, and gold and predicted linguistic information.

The majority baseline fails to detect any interpretation scored with 5 when the negated token is a noun (in this case, the majority of interpretations are not scored 5), and obtains a modest 0.64 F-score when the negated token is an adjective. Using gold linguistic information, *neg\_mark* as the only feature or *basic* features improve performance when the negated token is a noun (F-score: 0.44 and 0.47), but does not improve results when the negated token is an adjective. Adding *path* features brings performance up (nouns: 0.70, adjectives: 0.73), and adding *focus* features yields similar results (nouns: 0.67, adjectives: 0.76).

Using predicted linguistic information, we observe the same general trends, but adding *focus* features brings a substantial improvement over *basic + path* for adjectives: 0.54 vs. 0.62.

## 8 Conclusions

This paper presents a framework to extract positive meaning from negation when the negation cue modifies a noun or adjective. First, we generate potential positive interpretations deterministically. Second, we rank them according to their likelihood. On average, we generate 2.5 potential interpretations when the negated token is a noun, and 2.7 when the negated token is an adjective.

Experimental results show that scoring all potential positive interpretations is challenging, we obtain overall Pearson correlation of 0.42 using features extracted from gold linguistic information (0.36 for nouns and 0.52 for adjectives). But when identifying interpretations annotated with the highest score (5 out of 5), F-scores are relatively high: 0.67 for nouns and 0.76 for adjectives. The latter evaluation is more suitable, as the ultimate goal is to identify valid positive interpretations and discard other potential interpretations generated with our generate-and-rank approach.

## Abstract

In this paper, we propose using metaheuristics—in particular, simulated annealing and the new D-Bees algorithm—to solve word sense disambiguation as an optimization problem within a knowledge-based lexical substitution system. We are the first to perform such an extrinsic evaluation of metaheuristics, for which we use two standard lexical substitution datasets, one English and one German. We find that D-Bees has robust performance for both languages, and performs better than simulated annealing, though both achieve good results. Moreover, the D-Bees-based lexical substitution system outperforms state-of-the-art systems on several evaluation metrics. We also show that D-Bees achieves competitive performance in lexical simplification, a variant of lexical substitution.

## 1 Introduction

Lexical substitution is a special case of automatic paraphrasing in which the goal is to provide contextually appropriate replacements for a given word, such that the overall meaning of the context is maintained. The task has applications in question answering, text summarization, sentence compression, information extraction, machine translation, and natural language generation (Androustopoulos and Malakasiotis, 2010). It is also frequently employed as an *in vivo* evaluation of word sense disambiguation (WSD) systems (McCarthy and

Navigli, 2009; Toral, 2009; Miller et al., 2015), because while lexical substitution requires words to be sense-disambiguated, it does not impose use of a predefined sense inventory.

Past work in WSD, whether or not it forms part of a lexical substitution system, has employed a wide range of approaches (Agirre and Edmonds, 2007). Supervised methods usually achieve the best results, but at the tremendous cost of producing manually annotated training data specific to the language and domain. Knowledge-based and unsupervised methods rely only on pre-existing resources such as machine-readable dictionaries and raw corpora. Though generally less accurate, they have the advantage of being more flexible and more adaptable to new languages and domains. For knowledge-based methods, this has been especially true since the advent of large, multilingual, collaboratively constructed resources such as Wikipedia and Wiktionary (Zesch et al., 2008).

In this paper, we present two novel approaches to lexical substitution which are knowledge-based, generally language-independent, and use a combination of traditional wordnets and Wiktionary. The first approach uses simulated annealing (Kirkpatrick et al., 1983), which was first proposed for use in WSD by Cowie et al. (1992) but has attracted relatively little attention since then. The second approach uses D-Bees (Abualhaija and Zimmermann, 2016), a relatively new, biologically inspired disambiguation algorithm that models swarm intelligence. Both algorithms are *metaheuristic* (Talbi, 2009) in that they treat WSD as an optimization problem and modify heuristic (approximate) solu-

tions to avoid entrapment in local optima. Ours is the first extrinsic evaluation of any metaheuristic approaches to WSD in a lexical substitution setting.

We evaluate and compare both approaches on two lexical substitution datasets, one English and one German. We find that both approaches perform well, with D-Bees in particular exceeding state-of-the-art performance in many tasks. We also apply the systems to lexical simplification, a variant of lexical substitution in which the goal is to provide substitutes which are easier to understand. Here, too, we find that D-Bees performs near or above the state of the art.

## 2 Background

### 2.1 Lexical Substitution and Simplification

In lexical substitution, a system is given a word in context and tasked with producing a list of words that could be substituted for the word without altering the overall meaning. For example, given the word “bright” in the sentence “Einstein was a bright man,” valid substitutes would include “sharp” and “intelligent”, but not “shiny” or “luminous”, even though the latter two are synonymous with “bright” in other contexts. It is generally expected that the list of substitutes be ordered by acceptability. Most lexical substitution systems therefore comprise two distinct phases: *generation*, in which the system assembles a set of suitable substitutes for the target word, and *ranking*, in which the system orders them according to how well they fit the context.

There have been a number of organized evaluation campaigns for lexical substitution systems, including the English-language task at SemEval-2007 (McCarthy and Navigli, 2009) and the German task at GermEval 2015 (Miller et al., 2015). These campaigns provide standardized datasets where a large number of word–context combinations have been manually annotated with acceptable substitutes. Systems are evaluated by comparing their output to this gold standard, using any or all of three scoring methodologies:

- In the *best* methodology (McCarthy and Navigli, 2009), systems are allowed to suggest as many substitutes as they wish. However, the credit for each guess is normalized by the total number of guesses. The best guess should be placed first in the list. Across the entire dataset, four metrics are calculated: recall ( $R$ ), mode recall ( $R_m$ ), precision ( $P$ ), and mode

precision ( $P_m$ ).<sup>1</sup>

- In *out of ten (OOT)* (McCarthy and Navigli, 2009), systems suggest up to ten substitutes, though neither the exact number nor the order of these is important. This methodology uses minor variations of *best*’s  $R$ ,  $R_m$ ,  $P$ , and  $P_m$ .
- *Generalized average precision (GAP)* (Kishida, 2005) uses a single metric to score a fully ranked list of substitutes. Unlike *OOT*, *GAP* is sensitive to the relative positions of the correct and incorrect substitutes in the list.

For reasons of space, we do not provide detailed explanations and formulas for the nine metrics, but refer readers to the cited papers.

Lexical simplification is a variant of lexical substitution in which the correct ranking is determined not just by the substitutes’ contextual fitness but also by their simplicity. (For example, rare words are generally considered to be more complex, as readers are less likely to be familiar with their meanings.) As with other types of text simplification, lexical simplification can be used to make complex texts understandable by a wider range of readers, such as children or second language learners.

To date there has been one shared task in lexical simplification (Specia et al., 2012). Its main evaluation metric is based on Cohen’s (1960)  $\kappa$ . Two post-hoc evaluation metrics are also used. The first, *top-ranked (TRnk)*, evaluates the simplest set of substitutes that is ranked first by the system, compared with the top-ranked set of substitutes in the gold standard. This represents the intersection between the first substitute set found by the system with the first set in the gold standard. The intersection should include at least one substitute. The second metric, *recall at n (R@n)* is the ratio of candidates from the top  $n$  sets of substitutes to those in the gold standard, where  $1 \leq n \leq 3$ . For a given  $n$ , the contexts with at least  $n + 1$  substitutes in the gold standard are considered.

### 2.2 Word Sense Disambiguation, Optimization, and Metaheuristics

Word sense disambiguation, the task of determining which of a word’s meanings is the one intended in a given context, is a prerequisite for generating substitutes in knowledge-based lexical substitution.

<sup>1</sup>These metrics are inspired by, but distinct from, the traditional recall and precision metrics from information retrieval.

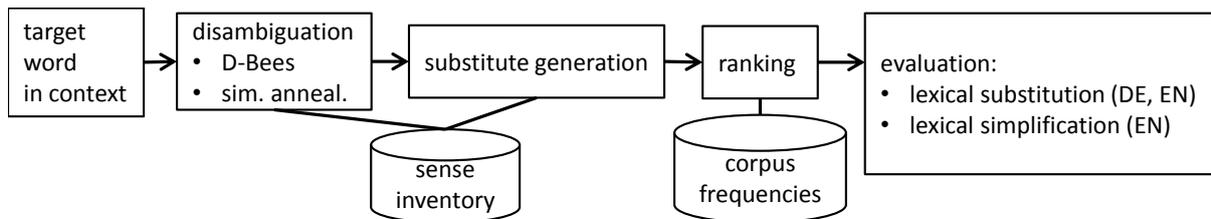

Figure 1: Our approach to lexical substitution and simplification of a target word in context.

There are many different approaches to WSD; for our purposes it is convenient to define it as an optimization problem where the aim is to disambiguate a sequence of words simultaneously (Abualhaija and Zimmermann, 2016): Let  $W = (w_1, w_2, \dots, w_n)$  be a sequence of  $n$  words to be disambiguated, and  $\sigma = (s_1, s_2, \dots, s_n)$  the corresponding sequence of senses for each word. Let  $\mathcal{S} = \{\sigma_1, \dots, \sigma_m\}$  be the set of all sequences of senses that represent sense combinations of the words in  $W$ . Then the objective function is  $\arg \max_{\sigma \in \mathcal{S}} \ell(\sigma)$ , where  $\ell$  is the score assigned to a sequence of senses according to some measure of semantic similarity, such as those surveyed by Zesch and Gurevych (2010).

WSD as an optimization problem is NP-hard. This can be worked around by using metaheuristics, which are approximate, tractable algorithms that find near-optimal solutions. Metaheuristics can be *single-solution* and *population-based* search methods. The former manipulate and transform a single solution, giving more focus to the promising regions. Population-based methods work on multiple solutions, distributing their focus and exploring several regions of the search space simultaneously.

### 3 Approach

We investigate two knowledge-based, language-independent approaches to lexical substitution, whose main difference lies in the metaheuristic WSD component preceding the generation phase. Both approaches use a top-down generation process, in which the target word is first disambiguated in context with respect to a particular sense inventory, and then used to suggest a list of substitutes.<sup>2</sup> In the following subsections, we describe the two disambiguation components and the common substitute generation and ranking components. (See overview in Figure 1.)

<sup>2</sup>This contrasts with a bottom-up approach, where a list of all possible substitutes for the target word is first generated and then filtered to suit the context.

#### 3.1 Disambiguation with Simulated Annealing

Simulated annealing (Kirkpatrick et al., 1983) is a single-solution algorithm in which a randomly created solution is iteratively modified until a “good-enough” solution is found. To apply it to WSD, we use essentially the same setup as Cowie et al. (1992). We start with a randomly initialized *sense combination*  $\sigma_0 = (s_1, s_2, \dots, s_n)$  from a given sense inventory, for each word in the context. We then retrieve the glosses for each sense, preprocess them via lemmatization and stop word removal, and give each remaining term a score of  $n - 1$  if it appears  $n$  times. We calculate the configuration’s *redundancy*,  $R_0$ , by summing up all the scores. In other words,  $R_0$  is the lexical overlap between sense definitions. The aim of simulated annealing is to maximize this overlap, or more precisely to minimize the *energy* function  $E_i = 1/(1 + R_i)$  in each iteration  $i$ .

In this iterative process, each iteration makes a random change on the configuration  $\sigma_i$  to produce  $\sigma_{i+1}$ , on which the corresponding  $E_i$  is computed. If  $E_{i+1} < E_i$  (i.e.,  $\Delta E < 0$ ), then the new configuration replaces the old configuration for the next iteration. Otherwise, the new configuration might still be accepted with probability  $\text{Pr} = \exp(-\Delta E/T)$ , where  $T$  is initially set to 1 but replaced with  $0.9T$  for each subsequent iteration. This way, the algorithm risks exploring poor-looking paths that might nonetheless yield better results in the long run, and the earlier the iterations are, the greater the probability that a poor path is followed. In our experiments we iterate up to 30 times.

#### 3.2 Disambiguation with D-Bees

D-Bees (Abualhaija and Zimmermann, 2016) is a population-based algorithm inspired by bee colony optimization (BCO) (Teodorović, 2009). BCO models the foraging behaviour of honey bees, where thousands of individuals with limited knowledge collaborate to maximize their collective bene-

fit. In nature, bees fly around their hive to look for nectar and pollen. When they find it, they return to the hive and perform a dance to advertise its location and quality to the others. The observers then decide whether to remain committed to their own path or to abandon it in favour of one of the advertised paths. BCO simulates this method through a multi-agent decentralized system.

D-Bees starts by choosing one of the target words as the hive, which spawns bee agents and sends them to other words in the context. The number of bee agents equals the number of candidate senses of the hive; each bee agent starts off with one of these senses in its memory. For each word it visits, the bee disambiguates it by randomly selecting a candidate sense, building up a path of senses and maintaining a running total similarity score. This *forward pass* continues until a set number of moves is reached.

The bee then makes a *backward pass* to the hive and exchanges its partial solution with the other agents on the virtual dancing floor. Each bee then determines whether it should stick to its path or adopt that of another bee; this is accomplished through *loyalty* and *recruiting probability* functions that depend mainly on the quality of the partial solutions. On the next forward pass, the bees resume their searches from the ends of their chosen paths. The forward and backward passes are alternated until there are no more words to be disambiguated. The bee agent with the best solution determines the final sense labelling of all words in the context.

In experiments on separate tuning datasets, we determined the number of moves in the forward pass to be one-third the number of context words. For the calculation of semantic similarity, we use a variant of the adapted Lesk algorithm (Banerjee and Pedersen, 2002). For each sense, we build a textual representation by concatenating its gloss with those of its hyper- and hyponyms. We then calculate the lexical overlap between the two texts.

### 3.3 Substitute Generation

Once the target word is disambiguated with respect to a particular sense inventory, we generate an unordered list of substitutes (to be subsequently ordered by the ranking module). The sense inventory we use for disambiguation is WordNet 3.1 (Fellbaum, 1998) for our English tasks, and GermaNet 10.0 (Hamp and Feldweg, 1997; Henrich and Hinrichs, 2010) for the German one. These are

expert-built resources in which words representing the same concept are grouped together into *synsets*; synsets are in turn linked into a network by semantic relations such as hypernymy and meronymy.

In preliminary experiments on generating substitutes, we varied two independent parameters: which lexical-semantic resources to use as the source of substitutes, and which semantic relations to follow from the disambiguated synset.

With respect to the first parameter, we tried drawing substitutes from the disambiguation inventory (WordNet or GermaNet) alone, and also drawing additional substitutes from Wiktionary. Our use of Wiktionary as a complementary resource is motivated by Meyer and Gurevych (2012), who found its coverage to be complementary to those of expert-built resources, and by Henrich and Hinrichs (2012), who found that using information from both GermaNet and Wiktionary improved WSD performance. We used a relatively simple, Lesk-like method for mapping senses from WordNet/GermaNet to Wiktionary.

For the second parameter, we tried one setup in which we took all synonyms found in the disambiguated synset and in its hypernyms, and one in which we additionally pulled in synonyms from the hyponyms and all other related synsets (except antonyms). The first setup was informed by the annotation guidelines of the lexical substitution datasets, which indicate that it is permissible to suggest substitute terms that are more generic but not more specific. The second setup was informed by the analyses of Kremer et al. (2014) and Miller et al. (2016), which found, contrarily, that other semantic relations, including hyponyms, were a fruitful source of substitutes.

We obtained the best overall results when using both WordNet/GermaNet and Wiktionary, and when following semantic relations of all types (other than antonymy), to build the substitute list. We therefore used this setup for all our lexical substitution and simplification experiments.

### 3.4 Ranking

The final step of lexical substitution is to rank the substitutes. Our method, like those employed in previous lexical substitution tasks, assumes that a substitute's suitability depends on the type of its semantic relation to the target word. We therefore order the substitutes as follows: synonyms, hypernyms, hyponyms, other relations. Within

each semantic relation type, we sort the substitutes first by source (first WordNet/GermaNet, then Wiktionary), and then secondarily by reverse frequency in a large corpus. In preliminary experiments, we found that this method was generally better than simply sorting the entire substitute list by reverse frequency. To determine lemma frequency, we use the same frequency lists used to construct the original datasets: WaCky (Baroni et al., 2009) for German, and BNC (Burnard, 2007) for English.

## 4 Lexical Substitution for German

### 4.1 Dataset and Baselines

In our experiments, we use the data from GermEval 2015 (Miller et al., 2015), a shared task for German-language lexical substitution. It is split into a training and a test set of 1040 and 1000 sentences from the German edition of Wikipedia. Each sentence in the dataset contains one of 75 unique target words (25 nouns, 25 verbs, and 25 adjectives); in the test set, ten sentences are provided for each of the nouns and adjectives, and twenty for each verb.

Miller et al. (2015) report results of several naïve baselines, the best-performing of which are *weighted sense* (Toral, 2009) and *top-ranked synonym* (McCarthy and Navigli, 2009). Neither baseline makes any attempt to disambiguate the target word; rather, they build a substitute list by gathering synonyms of all possible senses of the target, as well as synonyms of closely related senses such as hypernyms, and then ranking these words by their frequency (either within the list itself or in a large corpus). We consider these two naïve baselines as reasonable lower bounds.

The more challenging baseline performance comes from the best-performing participating systems at GermEval 2015, which represent the state of the art in German-language lexical substitution. One of these systems (Hintz and Biemann, 2015) is a supervised, bottom-up approach inspired by previous English-language work by Szarvas et al. (2013a). It first retrieves a list of substitutes from various lexicons, then applies a maxent classifier to determine whether each substitute fits the context. The second system (Jackov, 2015) is based on techniques from machine translation. It first disambiguates the input text by mapping German words to concepts represented by WordNet synsets. It then produces and scores various parsing hypotheses, and selects the synonyms and hypernyms of

the target in the best-scoring hypothesis.

### 4.2 Results and Analysis

Table 1 shows the results of the baselines described above, along with those of our basic D-Bees- and simulated annealing-based systems, and an enhanced version of the D-Bees system that we describe below.<sup>3</sup> Both our basic systems outperform the prior state of the art for the four *OOT* metrics, with the D-Bees-based system performing slightly better than the one using simulated annealing. However, neither system was able to beat Hintz and Biemann (2015) for the *GAP* and *best* metrics.

In light of this gap, we modified the D-Bees-based system to account for some idiosyncrasies of our German-language resources:

- Where GermaNet provided additional spellings of a synonym (e.g., “*wacklig*” for “*wackelig*”), we placed the variant spellings at the end of the substitute list. This prevented the top ranks of the list from being overloaded with nearly identical terms.
- Where our resources provided gender-specific variants of a synonym, we filtered out those that did not match the gender of the target. For example, when building the substitute list for “*Meisterin*” (female champion), we exclude “*Meister*” (male champion), even though GermaNet lists it as a synonym.
- To control for Wiktionary’s lack of consistency, we filtered out Wiktionary-derived synonyms where the synonymy relation was not symmetric. For example, the Wiktionary entry for “*Likör*” gives “*Crème*” as a synonym, but the entry for “*Crème*” does not give “*Likör*”, so when building a substitute list for “*Likör*”, we do not include “*Crème*”.

With these resource-specific enhancements, the D-Bees system achieves state-of-the-art performance not only for *OOT* but also for *GAP*, and performs only slightly worse than Hintz and Biemann (2015) for *best*. (This is an impressive result considering that Hintz and Biemann (2015) is a supervised system while ours is based solely on external knowledge bases and does not require any training data.) We also examined its performance by part of speech. We found that it remains the

<sup>3</sup>Here, as well as in §5, we report results on the test split and used the training split for tuning our algorithms.

Table 1: System performance on the GermEval 2015 lexical substitution dataset.

System	Best				OOT				GAP
	<i>P</i>	<i>R</i>	<i>P<sub>m</sub></i>	<i>R<sub>m</sub></i>	<i>P</i>	<i>R</i>	<i>P<sub>m</sub></i>	<i>R<sub>m</sub></i>	
D-Bees	7.66	7.66	14.85	14.85	20.68	20.68	37.73	37.73	12.94
D-Bees (enhanced)	10.39	10.39	22.39	22.39	<b>21.88</b>	<b>21.88</b>	<b>39.64</b>	<b>39.64</b>	<b>16.40</b>
simulated annealing	9.40	9.40	19.67	19.67	19.95	19.95	36.16	36.16	14.34
Hintz and Biemann (2015)	<b>11.20</b>	<b>11.10</b>	<b>24.28</b>	<b>24.21</b>	19.49	19.31	33.99	33.89	15.96
Jackov (2015)	6.73	6.45	13.36	12.86	20.14	19.32	33.18	31.92	11.26
top-ranked synonyms	10.04	10.04	19.82	19.82	15.21	15.21	27.99	27.99	12.25
weighted sense	7.50	7.50	13.46	13.46	20.54	20.54	35.55	35.55	14.28

best-performing system for *GAP* across all parts of speech, and for nouns and verbs is able to match or exceed Hintz and Biemann (2015) on some *best* metrics.

## 5 Lexical Substitution for English

### 5.1 Dataset and Baselines

Our English-language data is taken from the SemEval-2007 shared task (McCarthy and Navigli, 2009). That task uses a sample of 201 target words (nouns, verbs, adjectives and adverbs); for each word, ten context sentences are selected from the English Internet Corpus (Sharoff, 2006). Five human annotators provided up to three substitutes for each target. The dataset is split into a training set (300 sentences) and a test set (1710 sentences).

McCarthy and Navigli (2009) provide results for the aforementioned “top-ranked synonyms” algorithm as a lower bound on performance. State-of-the-art performance across the nine evaluation metrics is represented by the top-performing systems at SemEval-2007 (Giuliano et al., 2007; Hassan et al., 2007; Yuret, 2007; Zhao et al., 2007) and by several later systems (Biemann and Riedl, 2013; Melamud et al., 2015).<sup>4</sup> Of these systems, only Yuret (2007) is supervised.

### 5.2 Results and Analysis

Table 2 shows the results for the state-of-the-art and naïve baselines, along with results of our two basic systems and, as before, an enhanced version

<sup>4</sup>We are aware of several further lexical substitution systems (Moon and Erk (2013), Ó Séaghdha and Korhonen (2014), Roller and Erk (2016), Sinha and Mihalcea (2011), Szarvas et al. (2013b), and Thater et al. (2010) as reimplemented by Kremer et al. (2014)), though they do not report results on the full SemEval-2007 test set, or else do not report any of the same metrics we do, or else are concerned only with ranking but not generating substitutes.

of the D-Bees system. Our systems’ performance is generally much lower here than on the German-language data, with D-Bees failing to exceed the state of the art.

As with our German experiments, we tried modifying the D-Bees-based system to work around the language-specific problems we observed. The most significant of these adaptations are as follows:

- Our analysis suggested that WordNet’s notoriously fine sense granularity was adversely affecting the WSD process. We therefore modified D-Bees to perform “soft” WSD (Ramakrishnan et al., 2004), meaning that we allow it to select several different senses as the correct ones—in our case, up to five. To compensate for the larger number of substitution candidates, we limit the ranked list of substitutes to 20. (This harkens back to the bottom-up approaches defined in §3.) Substitutes generated from the best disambiguation solution are ranked highest.
- In contrast to German, English lexical substitutes are often drawn from indirect hypernyms (Kremer et al., 2014; Miller et al., 2016). (This too may be an artifact of WordNet’s fine granularity.) We therefore extended our substitute search to two levels of hypernyms.
- The glosses provided by WordNet sometimes consist of a list of equivalent terms which do not appear in the list of synonyms. For example, WordNet defines one sense of the adverb “right” as “precisely, exactly”, though it does not actually list those words as synonyms. We therefore include as the lowest-ranked substitutes those words from the target’s gloss that match its part of speech.

Table 2: System performance on the SemEval-2007 lexical substitution dataset.

System	Best				OOT				GAP
	$P$	$R$	$P_m$	$R_m$	$P$	$R$	$P_m$	$R_m$	
D-Bees	8.73	8.73	14.88	14.88	24.88	24.88	35.53	35.53	13.25
D-Bees (enhanced) simulated annealing	11.77	11.77	19.35	19.35	34.68	34.68	47.80	47.80	<b>17.93</b>
Zhao et al. (2007)	11.35	11.35	18.86	18.86	33.88	33.88	46.91	46.91	—
Giuliano et al. (2007)	6.95	6.94	20.33	20.33	<b>69.03</b>	<b>68.90</b>	58.54	58.54	—
Yuret (2007)	<b>12.90</b>	<b>12.90</b>	20.65	20.65	46.15	46.15	61.30	61.30	—
Hassan et al. (2007)	12.77	12.77	<b>20.73</b>	<b>20.73</b>	49.19	49.19	<b>66.26</b>	<b>66.26</b>	—
Melamud et al. (2015)	8.09	8.09	13.41	13.41	27.65	27.65	39.19	39.19	—
Biemann and Riedl (2013)	—	—	—	—	27.48	27.48	37.19	37.19	—
top-ranked synonyms	9.95	9.95	15.28	15.28	29.70	29.35	40.57	40.57	—

- As WordNet contains no hypernymy relations for adjectives, for our purposes we use its “similar-to” relation instead.
- For word frequency, we generally prefer the counts provided by WordNet, since they are sense-disambiguated. (This use of manually sense-annotated data makes our approach weakly supervised.) In other cases, such as when ranking substitutes from Wiktionary, we use Web 1T (Brants and Franz, 2006) instead of BNC. Web 1T is a much larger, more modern, Web-derived corpus that may better reflect the lemma distributions in the Web-derived SemEval-2007 dataset.

The enhanced D-Bees-based system performs significantly better than the base system, though in common with the two post-SemEval-2007 systems, it still fails to surpass the state of the art for *best* and *OOT*. The two knowledge-based systems that outperform our system by a large margin, Giuliano et al. (2007) and Hassan et al. (2007), employ particularly strong substitute generation components that use a combination of WordNet with a rich thesaurus resource—the *Oxford American Writer Thesaurus* and the *Microsoft Encarta* encyclopedia, respectively. Both resources outperform Wiktionary in terms of coverage of synonyms and semantically related words. However, as these resources are proprietary, they were not available to us.

Our system’s performance is roughly on par with Zhao et al. (2007), another bottom-up approach. Our enhanced system does achieve the highest known *GAP* score, though this is largely because most prior work does not use this metric, or else

applies it only to the ranking of gold-standard substitutes.

## 6 Lexical Simplification

### 6.1 Experimental Setup

Our experiments use the dataset from the SemEval-2012 English lexical simplification task (Specia et al., 2012). It uses the same contexts and target words as the SemEval-2007 dataset, but the gold-standard substitutes, which include the original target words, have been manually re-ranked according to their perceived simplicity. Unlike SemEval-2007, the SemEval-2012 task is concerned exclusively with ranking substitutes; all the original participating systems were given the gold-standard substitutes and simply asked to put them in the correct order. However, to score our own systems we use their own substitute lists, removing only those substitutes that do not also appear in the gold-standard list. This puts us at somewhat of a disadvantage, since our substitute lists often contain only a subset of the gold-standard substitutes. It also makes use of the  $\kappa$  metric problematic, since  $\kappa$  expects the system and gold-standard lists to contain the same set of substitutes. We therefore report only  $TRnk$  and  $R@n$  scores.

Specia et al. (2012) report scores for two lower-bound baselines: one puts the substitute lists in random order, and the other orders them by inverse frequency of occurrence in Web 1T.<sup>5</sup> The state of the art is represented by Jauhar and Specia (2012),

<sup>5</sup>A third baseline leaves the lists in their original order (i.e., by inverse number of annotators who chose them). We ignore it here as it relies entirely on manual labelling.

Table 3: System performance on the SemEval-2012 lexical simplification dataset.

System	TRnk	R@1	R@2	R@3
D-Bees (enhanced) (original ordering)	37.5	71.6	<b>75.5</b>	76.4
D-Bees (enhanced) (unigram ordering)	50.9	<b>72.8</b>	75.2	76.3
D-Bees (enhanced) ( $n$ -gram ordering)	47.1	71.3	74.5	75.7
Jauhar and Specia (2012)	<b>60.2</b>	57.5	68.9	76.9
unigram ordering baseline	58.5	55.9	68.1	76.0
random ordering baseline	34.0	32.1	61.2	<b>82.5</b>

a supervised system that classifies substitutes using a context-sensitive  $n$ -gram frequency model, a bag-of-words model, and psycholinguistic features. At SemEval-2012 it achieved the best performance for every metric except  $R@3$ , where it was beaten only by the random baseline.

We first calculated the proportion of instances for which our systems suggested at least one substitute appearing in the gold standard (other than the target word itself). For the simulated annealing system, the percentage was 45.7%, for the D-Bees system it was 58.7%, and for the enhanced D-Bees system, it was 81.6%. We tentatively conclude that the soft WSD of enhanced D-Bees is necessary to generate sufficient numbers of substitutes in common with the gold standard, and exclude our other two systems from further consideration.

Since the SemEval-2012 lexical simplification task is concerned only with ranking, we test three different rankings of the enhanced D-Bees substitute list. First, we preserve the original order of the system. Second, we order by unigram frequency in Web 1T, as in the SemEval-2012 baseline. Our third ranking is an  $n$ -gram ordering approach that we found to work well ( $\kappa = 0.461$ ) on the full gold-standard substitute lists. Here the substitutes are sorted according to the summation of the combined frequency of the substitute and context words. More formally, let  $W$  be the set of all unique words in the context window, excluding the target  $w_t$ , and let  $S$  be the set of substitutes for  $w_t$ . Then each substitute  $s \in S$  is given a score

$$F(s) = \sum_{w \in W} f(s, w),$$

where  $f(s, w)$  is the Web 1T co-occurrence frequency for  $s$  and  $w$ . The list of substitutes is then sorted by descending score.

## 6.2 Results and Analysis

Table 3 shows the published results for our baselines, along with the results from the enhanced D-Bees-based system from §5.2 using various ranking methods. While none of our configurations scored particularly well on  $TRnk$ , all of them surpassed the state of the art for  $R@1$  and  $R@2$ , and performed about as well as Jauhar and Specia (2012) for  $R@3$ . These results are particularly impressive in light of the fact that the SemEval-2012 systems had access to the gold-standard substitutes, whereas our systems did not.

The good  $R@n$  scores when using the original ordering indicate that the D-Bees-based system is (quite serendipitously) predisposed to selecting simple substitutes and ranking them relatively highly. We note that there is relatively little difference between our three system configurations, suggesting that all three ranking methods are doing more or less the same thing, at least for the first few substitutes. This result is somewhat surprising in light of Specia et al.’s (2012) assumption that the notion of simplicity is context-dependent. (It is this notion that our  $n$ -gram-based ranking model was attempting to capture.) It could be that, for our systems, the context (including text complexity) is already sufficiently accounted for during WSD.

## 7 Conclusion

In this paper, we have presented the first extrinsic evaluations of simulated annealing and D-Bees in a lexical substitution setting. We used each algorithm as the WSD component in the same knowledge-based, language-independent lexical substitution system. The systems were tested on German and English datasets, and surpassed state-of-the-art performance on the former. The D-Bees system generally had better results, so we applied some resource-specific adaptations based on our own observations of GermaNet and WordNet, as well as on previ-

ously published studies on German and English lexical substitution. These adaptations led to dramatic improvements in performance on both datasets. We also tested the adapted D-Bees system in a lexical simplification setting, where (in spite of some handicaps) it exceeded state-of-the-art performance on two evaluation metrics. Our findings would seem to validate the utility of metaheuristic approaches for lexical substitution and simplification, with the caveat that optimal performance is achieved only when the systems are adapted to the language or linguistic resources used. This adaptation effort may nonetheless be lower than that required to source annotated training data for supervised approaches.

Regarding future work, there are several issues of interest. The first concerns our use of collaboratively constructed language resources. While our WSD components used only expert-built resources, we found it beneficial to draw additional substitution candidates from Wiktionary. For this we used a very basic sense alignment technique, though a more profound sense mapping between WordNet/GermaNet and Wiktionary, such as those surveyed by Gurevych et al. (2016), might lead to better downstream results. The approach D-Bees uses for calculating sense similarity is also quite basic; though it seemed to work well in practice, we are keen to investigate other methods, such as taking the WordNet/GermaNet graph structure into account, or using other measures of text similarity to compare glosses.

## Acknowledgments

## Abstract

Recognizing and generating paraphrases is an important component in many natural language processing applications. A well-established technique for automatically extracting paraphrases leverages bilingual corpora to find meaning-equivalent phrases in a single language by “pivoting” over a shared translation in another language. In this paper we revisit bilingual pivoting in the context of neural machine translation and present a paraphrasing model based purely on neural networks. Our model represents paraphrases in a continuous space, estimates the degree of semantic relatedness between text segments of arbitrary length, or generates candidate paraphrases for any source input. Experimental results across tasks and datasets show that neural paraphrases outperform those obtained with conventional phrase-based pivoting approaches.

## 1 Introduction

Paraphrasing can be broadly described as the task of using an alternative surface form to express the same semantic content (Madnani and Dorr, 2010). Much of the appeal of paraphrasing stems from its potential application to a wider range of NLP problems. Examples include query and pattern expansion (Riezler et al., 2007), summarization (Barzilay, 2003), question answering (Lin and Pantel, 2001), semantic parsing (Berant and Liang, 2014), semantic role labeling (Woodsend and Lapata, 2014), and machine translation (Callison-Burch et al., 2006).

Most of the recent literature has focused on the automatic extraction of paraphrases from various different types of corpora consisting of parallel, non-parallel, and comparable texts. One of the most successful proposals uses bilingual parallel corpora to induce paraphrases based on techniques from phrase-based statistical machine translation (SMT, Koehn et al. (2003)). The intuition behind

Bannard and Callison-Burch’s (2005) bilingual pivoting method is that two English strings  $e_1$  and  $e_2$  that translate to the same foreign string  $f$  can be assumed to have the same meaning. The method then pivots over  $f$  to extract  $\langle e_1, e_2 \rangle$  as a pair of paraphrases. Drawing inspiration from syntax-based SMT, several subsequent efforts (Callison-Burch, 2008; Ganitkevitch et al., 2011) extended this technique to syntactic paraphrases leading to the creation of PPDB (Ganitkevitch et al., 2013; Ganitkevitch and Callison-Burch, 2014), a large-scale paraphrase database containing over a billion of paraphrase pairs in 23 different languages.

In this paper we revisit the bilingual pivoting approach from the perspective of neural machine translation, a new approach to machine translation based purely on neural networks (Kalchbrenner and Blunsom, 2013; Bahdanau et al., 2014; Sutskever et al., 2014; Luong et al., 2015). At its core, NMT uses a deep neural network trained end-to-end to maximize the conditional probability of a correct translation given a source sentence, using a bilingual corpus. NMT models have obtained state-of-the-art performance for several language pairs (Jean et al., 2015b; Luong et al., 2015), using only parallel data for training, and minimal linguistic information. In this paper we show how the bilingual pivoting method can be ported to NMT and argue that it offers at least three advantages over conventional methods. Firstly, our neural paraphrasing model learns continuous space representations for phrases and sentences (aka *embeddings*) that can be usefully incorporated in downstream tasks such as recognizing textual similarity and entailment. Secondly, the proposed model is able to either score a pair of paraphrase candidates (of arbitrary length) and generate target paraphrases for a given source input. Due to the architecture of NMT, generation takes advantage of wider context compared to phrase-based approaches: target paraphrases are predicted based on the meaning of the source input and all previously generated target words.

In the remainder of the paper, we introduce our

paraphrase model and experimentally compare it to the phrase-based pivoting approach. We evaluate the model’s paraphrasing capability both *intrinsically* in a paraphrase detection task (i.e., decide the degree of semantic similarity between two sentences) and *extrinsically* in a generation task. Across tasks and datasets our results show that neural paraphrases yield superior performance when assessed automatically and by humans.

## 2 Related Work

The literature on paraphrasing is vast with methods varying according to the type of paraphrase being induced (lexical or structural), the type of data used (e.g., monolingual or parallel corpus), the underlying representation (surface form or syntax trees), and the acquisition method itself. For an overview of these issues we refer the interested reader to Madnani and Dorr (2010). We focus on bilingual pivoting methods and aspects of neural machine translation pertaining to our model. We also discuss related work on paraphrastic embeddings.

**Bilingual Pivoting** Paraphrase extraction using bilingual parallel corpora was proposed by Barnard and Callison-Burch (2005). Their method first extracts a bilingual phrase table and then obtains English paraphrases by pivoting through foreign language phrases. Paraphrases for a given phrase are ranked using a paraphrase probability defined in terms of the translation model probabilities  $P(f|e)$  and  $P(e|f)$  where  $f$  and  $e$  are the foreign and English strings, respectively.

Motivated by the wish to model sentential paraphrases, follow-up work focused on syntax-driven techniques again within the bilingual pivoting framework. Extensions include representing paraphrases via rules obtained from a synchronous context free grammar (Ganitkevitch et al., 2011; Madnani et al., 2007) as well as labeling paraphrases with linguistic annotations such as CCG categories (Callison-Burch, 2008) and part-of-speech tags (Zhao et al., 2008).

In contrast, our model is syntax-agnostic, paraphrases are represented on the surface level without knowledge of any underlying grammar. We capture paraphrases at varying levels of granularity, words, phrases or sentences without having to *explicitly* create a phrase table.

**Neural Machine Translation** There has been a surge of interest recently in repurposing sequence transduction neural network models for machine

translation (Sutskever et al., 2014). Central to this approach is an encoder-decoder architecture implemented by recurrent neural networks. The encoder reads the source sequence into a list of continuous-space representations from which the decoder generates the target sequence. An attention mechanism (Bahdanau et al., 2014) is used to generate the region of focus during decoding.

We employ NMT as the backbone of our paraphrasing model. In its simplest form our model exploits a one-to-one NMT architecture: the source English sentence is translated into  $k$  candidate foreign sentences and then back-translated into English. Inspired by multi-way machine translation which has shown performance gains over single-pair models (Zoph and Knight, 2016; Dong et al., 2015; Firat et al., 2016a), we also explore an alternative pivoting technique which uses multiple languages rather than a single one. Our model inherits advantages from NMT such as a small memory footprint and conceptually easy decoding (implemented as beam search). Beyond paraphrase generation, we experimentally show that the representations learned by our model are useful in semantic relatedness tasks.

**Paraphrastic Embeddings** The successful use of word embeddings in various NLP tasks has provided further impetus to use paraphrases. Wieting et al. (2015) take the paraphrases contained in PPDB and embed them into a low-dimensional space using a recursive neural network similar to Socher et al. (2013). In follow-up work (Wieting et al., 2016), they learn sentence embeddings based on supervision provided by PPDB. In our approach, embeddings are learned as part of the model and are available for any-length segments making use of no additional machinery beyond NMT itself.

## 3 Neural Paraphrasing

In this section we present PARANET, our **Paraphrasing** model based on **Neural Machine Translation**. PARANET uses neural machine translation to first translate from English to a foreign pivot, which is then back-translated to English, producing a paraphrase. In the following, we briefly overview the basic encoder-decoder NMT framework and then discuss how it can be extended to paraphrasing.

### 3.1 NMT Background

In the neural encoder-decoder framework for MT (Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015), the encoder, a recurrent neural network (RNN), is used to compress the meaning of the source sentence into a sequence of vectors. The decoder, a conditional RNN language model, generates a target sentence word-by-word. For the language pair, an encoder takes in a source sentence  $X = \{x_1, \dots, x_{T_X}\}$ , as a sequence of linguistic symbols and produces a sequence of context vectors  $C = \{h_1, \dots, h_{T_X}\}$ . PARANET uses a bi-directional RNN, where each context vector  $h_t$  is the concatenation of the forward and the backward RNN’s hidden states at time  $t$ .

The decoder is a conditional RNN language model that produces, given the source sentence, a probability distribution over the translation. At each time step  $t'$ , the decoder’s hidden state is updated:

$$z_{t'} = \text{RNN}(z_{t'-1}, y_{t'-1}, c_{t'}) \quad (1)$$

The update uses the previous hidden state  $z_{t'-1}$ , the previous target symbol  $y_{t'-1}$  and the time dependent context  $c_{t'}$ , which is computed by an attention mechanism  $\alpha_{t',t}$  over the source sentences’ context vectors:

$$c_{t'} = \sum_{t=1}^{T_X} \alpha_{t',t} h_t \quad (2)$$

$$\alpha_{t',t} \propto e^{f(z_{t'-1}, h_t)} \quad (3)$$

$g$  is a feedforward neural network with a softmax activation function in the output layer which returns the probability of the next target symbol. The probability of the target sentence  $Y = \{y_1, \dots, y_{T_Y}\}$ , is the product of the probabilities of the symbols within the sentence:

$$P(Y|X) = \prod_{t'=1}^{T_Y} P(y_{t'} | y_{<t'}, X) \quad (4)$$

### 3.2 Pivoting

Pivoting is often used in machine translation to overcome the shortage of parallel data, i.e., when there is not a translation path from the source language to the target. Instead, pivoting takes advantage of paths through an intermediate language. The idea dates back at least to Kay (1997), who observed that ambiguities in translating from one language onto another may be resolved if a translation into some third language is available, and has met with success in traditional phrase-based SMT (Wu and Wang, 2007; Utiyama and Isahara, 2007)

and more recently in neural MT systems (Firat et al., 2016b).

In the case of paraphrasing, there is not a path from English to English. Instead, a path from English to French to English can be used. In other words, we translate a source sentence into a pivot language and then translate the pivot back into the source language. Pivoting using NMT ensures that the entire sentence is considered when choosing a pivot. The fact that contextual information is considered when translating, allows for a more accurate pivoted sentence. It also places greater emphasis on capturing the meaning of the sentence, which is a key part of paraphrasing.

A naive approach to pivoting is one-to-one back-translation. The source English sentence  $E_1$ , is translated into a single French sentence  $F$ . Next,  $F$  is translated back into English, giving a probability distribution over English sentences,  $E_2$ . This translation distribution acts as the paraphrase distribution  $P(E_2|E_1, F)$ :

$$P(E_2|E_1, F) = P(E_2|F) \quad (5)$$

One-to-one back-translating offers an easy way to paraphrase, because existing NMT systems can be used with no additional training or changes. However, there are several disadvantages; for example the French sentence  $F$  must fully capture the exact meaning of  $E_1$ , as  $E_1$  and  $E_2$  are conditionally independent given  $F$ . Since there is rarely a clear one-to-one mapping between sentences in different languages, information about the source sentence can be lost, leading to inaccuracies in the paraphrase probabilities. To avoid this, we propose back-translating through multiple sentences within one and multiple foreign languages.

**Multi-pivoting** PARANET pivots through the set of  $K$ -best translations  $\mathcal{F} = \{F_1, \dots, F_K\}$  of  $E_1$ . This ensures that multiple aspects (semantic and syntactic) of the source sentence are captured. Moreover, multiple pivots provide resilience against a single bad translation, which would prevent one-to-one back-translation from producing accurate paraphrase probabilities.

Translating from multiple pivot sentences into one target sentence requires that the decoder be re-defined. Firat et al. (2016b) propose several ways in which multiple pivot sentences can be incorporated into a NMT decoder. We extended their late averaging approach to incorporate weights. Consider the case of two pivot sentences from the same language,  $F_1$  and  $F_2$ . Each translation path individ-

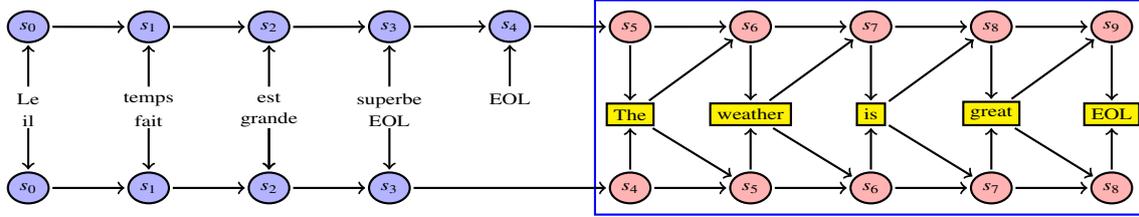

Figure 1: Late-weighted combination: two pivot sentences are simultaneously translated to one target sentence. Blue circles indicate the encoders, which individually encode the two source sentences. After the EOL token is seen, decoding starts (red circles). At each time step the two decoders produce a probability distribution over all words, which are then combined (in the yellow square) using Equation (6). From this combined distribution a word is chosen, which is then given as input to each decoder.

ually computes the distribution over the target vocabulary  $P(y_{t'} = w|y_{<t'}, F_1)$  and  $P(y_{t'} = w|y_{<t'}, F_2)$ . Our *late-weighted combination* approach defines the path with respect to both translations as:

$$P(y_{t'} = w|y_{<t'}, F_1, F_2) = \lambda_1 P(y_{t'} = w|y_{<t'}, F_1) + \lambda_2 P(y_{t'} = w|y_{<t'}, F_2)$$

While Firat et al. (2016b) train a new model to capture these joint translations, we leave the model unchanged, instead treating PARANET as a *meta* encoder-decoder model (see Figure 1).

Unlike late averaging, PARANET assigns weights  $\lambda$  to each pivot sentence. These weights are set to the initial translation probabilities  $P(F_i|E_1)$ , thus capturing the model’s confidence in the accuracy of the translation:

$$P(y_{t'}=w|y_{<t'}, F_1, F_2) = P(F_1|E_1)P(y_{t'}=w|y_{<t'}, F_1) + P(F_2|E_1)P(y_{t'}=w|y_{<t'}, F_2)$$

Which can be trivially extended to include all translations from the  $K$ -best list:

$$P(y_{t'} = w|y_{<t'}, \mathcal{F}) = \frac{1}{\sum_{i=1}^K P(F_i|E_1)} \cdot P(y_{t'} = w|y_{<t'}, F_i) \quad (6)$$

To ensure a probability distribution, we normalize the  $K$ -best list  $\mathcal{F}$ , such that the translation probabilities sum to one.

**Multi-lingual Pivoting** PARANET further expands on the multi pivot approach by pivoting not only over multiple sentences from one language, but also over multiple sentences from multiple languages. Multi-lingual pivoting has been recently shown to improve translation quality (Firat et al., 2016b), especially for low-resource language pairs. Here, we hypothesize that it will also lead to more accurate paraphrases.

Multi-lingual pivoting requires a small extension to late-weighted combination. We illustrate with German as a second language. First,

the source sentence is translated into a  $K$ -best list of French  $\mathcal{F}^{Fr}$ , and a  $K$ -best list of German  $\mathcal{F}^{De}$ . Late-weighted combination is then applied, producing  $P(y_{t'} = w|y_{<t'}, \mathcal{F}^{Fr})$  and  $P(y_{t'} = w|y_{<t'}, \mathcal{F}^{De})$ . These two output distributions are averaged, producing a multi-sentence, multi-lingual paraphrase probability:

$$P(y_{t'} = w|y_{<t'}, \mathcal{F}^{Fr}, \mathcal{F}^{De}) = \frac{1}{2} (P(y_{t'} = w|y_{<t'}, \mathcal{F}^{Fr}) + P(y_{t'} = w|y_{<t'}, \mathcal{F}^{De}))$$

which is used to obtain probability distributions over sentences:

$$P(E_2|E_1) = \prod_{t'=1}^{T_{E_2}} P(y_{t'}|y_{<t'}, \mathcal{F}^{Fr}, \mathcal{F}^{De}) \quad (7)$$

This can be trivially generalized to multiple languages. In this paper we use up to three.

### 3.3 PARANET Applications

The applications of PARANET are many and varied. We discuss some of these here and present detailed experimental evidence in Section 4. PARANET can be readily used for paraphrase detection (the task of analyzing two text segments and determining if they have the same meaning), by computing Equation (7). In addition, it can identify which linguistic units are considered paraphrases and to what extent. PARANET’s explanatory power stems from the attention mechanism inherent in the NMT systems.

In encoder-decoder models, attention is used during each step of decoding to indicate which are the relevant source words. In our case, each word of the paraphrase attends to words within the pivot sentence and each word in the pivot sentence attends to words within the source sentence. By summing out the weighted pivot sentence, it is possible to see the attention from paraphrase to

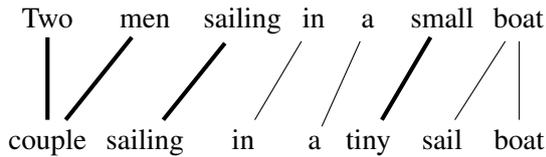

Figure 2: Attention between two sentences. Line thickness indicates the strength of the attention.

source:

$$\alpha(E_2^i, E_1^j, \mathcal{F}) = \sum_F P(E_2|E_1, F) \cdot \sum_m^{T_F} (\alpha_{i,m}^{E_2,F} \cdot \alpha_{m,j}^{F,E_1}) \quad (8)$$

An example shown in Figure 2 where attention has successfully identified the semantically equivalent parts of two sentences. Beyond providing interpretable paraphrasing, attention scores can be used as features in both generation and classification tasks.

Furthermore, PARANET can be readily used to perform text generation (via the NMT decoder) without additional resources or parameter estimation. It also learns phrase and sentence embeddings for free without any model adjustments or recourse to resources like PPDB.

## 4 Experiments

We evaluated PARANET in several ways: (a) we examined whether the paraphrases learned by our model correlate with human judgments of paraphrase quality; (b) we assessed PARANET in paraphrase and similarity detection tasks; and (c) in a sentence-level paraphrase generation task. We first present details on how PARANET and comparison models were trained and then discuss our results.

### 4.1 Neural Machine Translation Training

We used Groundhog<sup>1</sup> as the implementation of the NMT system for all experiments. We generally followed the settings and training procedure from previous work (Bahdanau et al., 2014; Sennrich et al., 2016a). As such, all networks have a hidden layer size of 1000, and an embedding layer size of 620. During training, we used Adadelta (Zeiler, 2012), a minibatch size of 80, and the training set was reshuffled between epochs. We trained a network for approximately 7 days on a single GPU, then the embedding layer was fixed and training continued, as suggested in Jean et al. (2015a), for 12 hours. Additionally, the softmax was calculated over a filtered list of candidate translations. Following Jean et al. (2015a), we set the common

<sup>1</sup>[github.com/sebastien-j/LV\\_groundhog](https://github.com/sebastien-j/LV_groundhog)

vocabulary size as 10000 and 25 uni-gram translations, using a bilingual dictionary based on fast-align (Dyer et al., 2013).

In our experiments, we used up to six encoder-decoder NMT models (three pairs); English→French, French→English, English→Czech, Czech→English, English→German, German→English. All systems were trained on the available training data from the WMT15 shared translation task (4.2 million, 15.7 million, and 39 million sentence pairs for EN↔DE, EN↔CS, and EN↔FR, respectively). For EN↔DE and EN→CS, we also had access to back-translated monolingual training data (Sennrich et al., 2016a), which we also used in training. The data was pre-processed using standard pre-processing scripts found in MOSES (Koehn et al., 2007). Rare words were split into sub-word units, following Sennrich et al. (2016b). BLEU scores for each NMT system can be seen in Table 1.

### 4.2 Statistical Machine Translation Training

Throughout our experiments we compare PARANET against a paraphrase model trained with a commonly used Statistical Machine Translation system (SMT), which we henceforth refer to as PARASTAT. Specifically, for each language pair used, an equivalent IBM Model 4 phrase-based translation model was trained. Additionally, an Operation Sequence Model (OSM) was included, which has been shown to improve the performance of SMT systems (Durrani et al., 2011). SMT translation models were implemented using both GIZA++ (Och and Ney, 2003) and MOSES (Koehn et al., 2007) and were trained using the same pre-processed bilingual data provided to the NMT systems. The SMT systems used a KenLM 5-gram language model (Heafield, 2011), trained on the mono-lingual data from WMT 2015. For all languages pairs, both KenLM and MOSES were trained using the standard settings. BLEU scores for the SMT systems are given in Table 1.

Under the SMT models, paraphrase probabilities were calculated analogously to Equation (7):

$$P(E_2|E_1, \mathcal{F}) = \sum_F^{\mathcal{F}} P(E_2|F)P(F|E_1) \quad (9)$$

where  $P(E_2|F)$  and  $(F|E_1)$ , are defined by the phrase based translation model, and  $\mathcal{F}$  denotes the  $K$ -best translations of  $E_1$ , whose probabilities are normalized. Unlike PARANET these pivot sentences have to be combined outside of the decoder.

Direction	F→E		E→F	
System	SMT	NMT	SMT	NMT
French	0.241	0.201	0.233	0.271
German	0.207	0.282	0.208	0.248
Czech	0.216	0.197	0.145	0.176

Table 1: BLEU scores (WMT 2015 test set) for SMT and NMT models (foreign to English (F→E) and English to foreign (E→F) directions).

### 4.3 Correlation with Human Judgments

The PPDB 2.0 Human Evaluation data set is a sample of paraphrase pairs taken from PPDB which have been human annotated for semantic similarity (Pavlick et al., 2015). 26,455 samples were taken from range of syntactic categories, resulting in paraphrase candidates varying from single words to multi-word expressions. Each paraphrase pair was judged by five people on a 5-point scale. Ratings were then averaged giving each paraphrase pair a score between 1 and 5.

Using this dataset we measure the correlation (Spearman  $\rho$ ) between (length normalized) PARANET probabilities (Equation (7)) assigned to paraphrase pairs and human judgments. Figure 3 shows correlation coefficients for all language pairs using a single foreign pivot and 200 pivots. Across all language combinations multiple pivots<sup>2</sup> achieve better correlations, with the German, Czech pair performing best with  $\rho = 0.53$ . For comparison, Pavlick et al. (2015) report a correlation of  $\rho = 0.41$  using Equation (9) and PPDB (Ganitkevitch et al., 2013). The latter contains over 100 million paraphrases and was constructed over several English-to-foreign parallel corpora including Europarl v7 (Koehn, 2005) which contains bitexts for the 19 European languages.

Following Pavlick et al. (2015), we next developed a supervised scoring model. Specifically, we fit a decision tree regressor on the PPDB 2.0 dataset using the implementation provided in scikit-learn (Pedregosa et al., 2011). To improve accuracy and control over-fitting we built an ensemble of regression trees using the Extra-Trees algorithm (Geurts et al., 2006) which fits a number of randomized decision trees (a.k.a. extra-trees) on various sub-samples of the dataset. In our experiments 1,000 trees were trained to minimize mean square error. The regressor was trained with the following basic features: sentence length,

<sup>2</sup>Across tasks and datasets we find that multiple pivots outperform single pivots. We omit these comparisons from subsequent experiments for the sake of brevity.

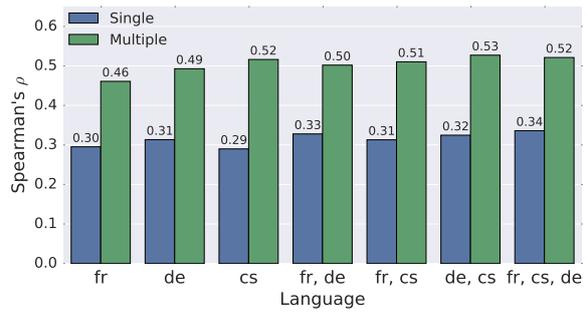

Figure 3: Correlation of PARANET predictions against human ratings for paraphrase pairs. Comparison using single and multiple pivots, across language combinations.

1-4 gram string similarity, the paraphrase probability  $P(E_2|E_1)$ , the language model score  $P(E_1)$ , cosine distance of the sentence vectors, as calculated by the encoder. To address the problem of rare sentences receiving low probabilities regardless of the source sentence, we create an inverse weighting by  $P(E_2|E_2)$ , which approximates how difficult it is to recover  $E_2$ :

$$pscore(E_2, E_1) = \frac{P(E_2|E_1)}{P(E_2|E_1) + P(E_2|E_2)} \quad (10)$$

Two features reflect the alignment between candidate paraphrases. We built an alignment matrix according to Equation (8), and used the mean of the diagonal as feature. This acts as a proxy of how much movement there is between two paraphrases. The second feature is the number of unaligned words which we compute by calculating hard alignments between the two paraphrases.

Regressors varied with respect to how  $P(E_2|E_1)$  was computed, keeping the string based features the same. Equations (7) and (9) were used to calculate paraphrase probability for PARANET and PARASTAT, respectively. For both models beam search (with width set to 100) was used to generate the  $K$ -best list. For each language, the  $K$ -best list is the union of the 100-best list of  $E_1$  and the 100-best list of  $E_2$ , giving a maximum of 200 pivot sentences. As set out in Pavlick et al. (2015) evaluation is done using cross validation: in each fold, we hold out 200 phrases. Table 2 presents results for PARANET and PARASTAT using different languages as pivots. PARANET outperforms PARASTAT across the board. Furthermore, despite using fewer features and pivot languages, it obtains a closer correspondence to human data compared to PPDB 2.0 (Pavlick et al., 2015).

#### 4.4 Paraphrase Identification and Similarity

The SemEval-2015 shared task on Paraphrase and Semantic Similarity In Twitter (PIT) uses a training and development set of 17,790 sentence pairs and a test set of 972 sentence pairs. By design, the dataset contains colloquial sentences representing informal language usage and sentence pairs which are lexically similar but semantically dissimilar. Sentence pairs were crawled from Twitter’s trending topics and associated tweets (see Xu et al. (2014) for details). The shared task consists of a (binary) paraphrase identification subtask (i.e., determine whether two sentences are paraphrases) and an optional semantic similarity task (i.e., determine the similarity between two sentences on a scale of 1–5, where 5 means completely equivalent and 1 not equivalent).

We trained a decision tree regressor on the PIT-2015 similarity dataset using the features described above. Once trained, the decision tree regressor can be readily applied to the semantic similarity subtask. For the paraphrase detection subtask, we use the same model and apply a threshold (optimized on the validation set) such that those pairs that are over this threshold are deemed paraphrases.

Tables 3 and 4 present our results on the two subtasks together with previously published results. We evaluate system performance on the detection task using F1 (the harmonic mean of precision and recall). For semantic similarity, system outputs are compared by Pearson correlation against human scores. The first block in the tables summarize results for PARANET and PARASTAT using different languages as pivots. The second block includes three baselines provided by the organizers of the shared task: a random baseline, a logistic regression baseline with minimal

n-gram word overlap features; and a model which uses weighted matrix factorization (WTMF) and has access to dictionary definitions provided in WordNet, OntoNotes, and Wiktionary (Guo and Diab, 2012). The last two rows show the highest scoring systems: ASOBK (Eyecioglu and Keller, 2015) ranked 1st in the identification subtask and MITRE (Zarrella et al., 2015) in the similarity subtask. Whereas ASOBK uses knowledge-lean features based on word and character n-gram overlap, MITRE is a combination of multiple systems including mixtures of string matching metrics, alignments using tweet-specific word representations, and recurrent neural networks.

As can be seen, PARANET achieves better similarity and detection score than all baselines and PARASTAT, for any combinations of lan-

Table 5: Results on the Semeval-2015 semantic similarity dataset. Boldface indicates the best performing paraphrasing model.

guages. This is particularly impressive as the translation models were trained on very dissimilar data. Compared to the state of the art, PARANET fares worse, however our model was not particularly optimized on the PIT-2015 dataset which was merely used as a testbed for a fair comparison. It is thus reasonable to assume that taking into account more elaborate features (e.g., based on character embeddings) would improve performance. The highest semantic similarity score is obtained with PARANET trained using German data. The highest scoring paraphrase detection model was PARANET trained on French and Czech data. Interestingly, using multiple pivot languages seems to offer small improvements in most cases. The languages selected as pivots in our experiments were somewhat ad-hoc. We expect to get more mileage if these are selected from the same language family or with more linguistic insight (e.g., morphologically rich vs. poor).

#### 4.5 Semantic Textual Similarity

In semantic textual similarity (STS), systems rate the degree of semantic equivalence between two text snippets. We present results on the Semeval-2015 English subtask which contains sentences from a wide range of domains, including newswire headlines, image descriptions, and answers from Q&A websites. The training/test sets consist of 11,250 and 3,000 sentence pairs, respectively. Sentence pairs are rated on a 1–5 scale, with 5 indicating they are completely equivalent.

We used the decision tree regressor with the same features described in the previous section. Again, we experimented with one, two, and three languages as pivots, and compared PARANET and PARASTAT directly. Our results are summarized in Table 5. The third block in the table presents a

simple cosine-based baseline provided by the organizers (Tokencos) and the top-performing system (DLS@CU) which uses PPDB paraphrases to identify semantically similar words and word2vec embeddings trained on approximately 2.8 billion tokens (Sultan et al., 2014).

PARANET outperforms PARASTAT on all languages and language combinations. Both systems outperform the Semeval baseline but are worse compared to the top scoring system. We see for PARANET Czech achieves the highest scores, this could be in part due to Czech non-strict word order, which allows paraphrases that are simple rearrangements not be penalized.

#### 4.6 Paraphrase Generation

Finally, we evaluated PARANET (and PARASTAT) in a paraphrase generation task. We created sentential paraphrases for three (parallel monolingual) datasets representative of different domains and genres: (a) the Multiple-Translation Chinese (MTC) corpus (Huang et al., 2002) contains news stories from three sources of journalistic Mandarin Chinese text translated into English by 4 translation agencies; we sampled 1,000 sentences for training and testing, respectively (each source sentence had an average of 4 paraphrases); (b) the Jules Verne Twenty Thousand Leagues Under the Sea novel (Leagues) corpus (Pang et al., 2003) contains two English translations of the French novel; we sampled 500 sentences for training/testing (each source sentence had one paraphrase); and (c) the Wikianswers corpus (Fader et al., 2013) which contains questions taken from the website<sup>3</sup> wiki answers; we sampled 1,000 questions for training/testing (each question has on average 21 paraphrases).

In order to select the best paraphrase candidate for a given input sentence, PARASTAT was optimized on the training set using Minimum Error Training (MERT, Och and Ney (2003)). MERT integrates automatic evaluation metrics such as BLEU into the training process to achieve optimal end-to-end performance. Naively optimizing for BLEU, however, will result in a trivial paraphrasing system heavily biased towards producing identity “paraphrases”. Sun and Zhou (2012) introduce iBLEU which we also adopt. iBLEU penalizes paraphrases which are similar to the source

<sup>3</sup><http://wiki.answers.com/>

Model	PARASTAT	PARANET
<i>fr</i>	0.280	0.299
<i>de</i>	0.282	0.295
<i>cz</i>	0.280	0.291
Gold	0.599	

Table 6: Mean iBLEU across three datasets.

sentence and rewards those close to the target:

$$iBLEU(s, r_s, c) = \alpha BLEU(c, r_s) - (1 - \alpha) BLEU(c, s)$$

where  $s$ , is the source sentence,  $r_s$ , is the target and  $c$  is the candidate paraphrase.  $(1 - \alpha)BLEU(c, s)$ , measures the originality of the candidate paraphrase,  $BLEU(c, r_s)$  measures semantic adequacy, and  $\alpha$  is a tuning parameter which balances the two. Sentence level BLEU is calculated using plus one smoothing (Lin and Och, 2004).

PARANET relies on a relatively simple architecture which is trained end-to-end with the objective of maximizing the likelihood of the training data. Since evaluation metrics cannot be straightforwardly integrated into this training procedure, we reranked the  $k$ -best paraphrases obtained from PARANET using a simple classifier which favors sentences which are dissimilar to the source. Specifically, we trained a decision tree regression model with iBLEU as the target variable using the same features described in Section 4.4. Examples of paraphrases generated by PARANET are shown in the Appendix.

System output was assessed automatically using iBLEU with human-written paraphrases as reference. In addition, we evaluated the generated text by eliciting human judgments via Amazon Mechanical Turk. We randomly selected 100 source sentences from each data set and generated output with PARANET and PARASTAT (using German as a pivot). We also included a randomly selected human paraphrase as a goldstandard. Workers (self-reported native English speakers) were asked to rank the three paraphrases from best to worst (ties were allowed) in order of semantic equivalence (does the paraphrase convey the same meaning as the source?) and fluency (is the description written in well-formed English?). Participants were explicitly told to give high ranks to output demonstrating a fair amount of paraphrasing and low ranks to trivial paraphrases (e.g., deletion of articles or punctuation). We collected 5 responses per input sentence.

Table 6 summarizes our results across the three

Model	Wikianswers	Leagues	MTC	All
PARASTAT	2.09	2.38	2.23	2.26
PARANET	<b>1.86</b>	1.94	<b>1.70</b>	<b>1.83</b>
Humans	2.17	<b>1.81</b>	2.0	2.0

Table 7: Mean Rankings given to paraphrases by human participants (a lower score is better).

datasets. For the sake of brevity, we only show results with one pivot language since combinations performed slightly worse for both models. We set  $\alpha = 0.8$  for iBLEU as we experimentally found it offers the best trade-off between semantic equivalence and dissimilarity. As an upper-bound we also measure iBLEU amongst the gold paraphrases provided by humans. Again, we observe that PARANET has a slight advantage over PARASTAT in terms of iBLEU, however both systems tend to paraphrase less compared to the gold-standard. Table 7 shows the mean ranks given to these systems by human subjects. An Analysis of Variance (ANOVA) revealed a reliable effect of system type. Post-hoc Tukey tests showed that PARANET is significantly ( $p < 0.01$ ) better than PARASTAT across datasets; PARANET is also significantly ( $p < 0.01$ ) better than the the gold standard on both MTC and the Wikianswers dataset. We attribute this to the noisy nature of these two datasets which contain a wealth of paraphrases, a few of which are ungrammatical, contain typos or abbreviations leading to low scores among humans.

## 5 Conclusions

In this work we presented PARANET, a neural paraphrasing model based on bilingual pivoting. Experimental results across several tasks (similarity prediction, paraphrase identification, and paraphrase generation) show that PARANET outperforms conventional paraphrasing methods. In the future, we plan to exploit the attention scores more directly for extracting paraphrase pairs (in analogy to PPDB) and as features for classification tasks (e.g., textual entailment). We would also like to investigate how PARANET can be adapted using reinforcement learning (Ranzato et al., 2016) to text generation tasks such as simplification and sentence compression.

## Abstract

Crosslingual word embeddings represent lexical items from different languages using the same vector space, enabling crosslingual transfer. Most prior work constructs embeddings for a pair of languages, with English on one side. We investigate methods for building high quality crosslingual word embeddings for many languages in a unified vector space. In this way, we can exploit and combine information from many languages. We report competitive performance on bilingual lexicon induction, monolingual similarity and crosslingual document classification tasks.

## 1 Introduction

Monolingual word embeddings have facilitated advances in many natural language processing tasks, such as natural language understanding (Collobert and Weston, 2008), sentiment analysis (Socher et al., 2013), and dependency parsing (Dyer et al., 2015). Crosslingual word embeddings represent words from several languages in the same low dimensional space. They are helpful for multilingual tasks such as machine translation (Brown et al., 1993) and bilingual named entity recognition (Wang et al., 2013). Crosslingual word embeddings can also be used in transfer learning, where the source model is trained on one language and applied directly to another language; this is suitable for the low-resource scenario (Yarowsky and Ngai, 2001; Duong et al., 2015b; Das and Petrov, 2011; Täckström et al., 2012).

Most prior work on building crosslingual word embeddings focuses on a pair of languages. English is usually on one side, thanks to the wealth

of available English resources. However, it is highly desirable to have a crosslingual word embeddings for many languages so that different relations can be exploited.<sup>1</sup> For example, since Italian and Spanish are similar, they are excellent candidates for transfer learning. However, few parallel resources exist between Italian and Spanish for directly building bilingual word embeddings. Our multilingual word embeddings, on the other hand, map both Italian and Spanish to the same space without using any direct bilingual signal between them. In addition, multilingual word embeddings allow multiple source language transfer learning, producing a more general model and overcoming data sparseness (McDonald et al., 2011; Guo et al., 2016; Agić et al., 2016). Moreover, multilingual word embeddings are also crucial for multilingual applications such as multi-source machine translation (Zoph and Knight, 2016), and multi-source transfer dependency parsing (McDonald et al., 2011; Duong et al., 2015a).

We propose several algorithms to map bilingual word embeddings to the same vector space, either during training or during post-processing. We apply a linear transformation to map the English side of each pretrained crosslingual word embedding to the same space. We also extend Duong et al. (2016), which used a lexicon to learn bilingual word embeddings. We modify the objective function to jointly build multilingual word embeddings during training. Unlike most prior work which focuses on downstream applications, we measure the quality of our multilingual word embeddings in three ways: bilingual lexicon induction, monolingual word similarity, and crosslingual document classification tasks. Relative to a benchmark of

---

<sup>1</sup>From here on we refer to crosslingual word embeddings for a pair of languages and multiple languages as *bilingual word embeddings* and *multilingual word embeddings* respectively.

training on each language pair separately and to various published multilingual word embeddings, we achieved high performance for all the tasks.

In this paper we make the following contributions: (a) novel algorithms for post hoc combination of multiple bilingual word embeddings, applicable to any pretrained bilingual model; (b) a method for jointly learning multilingual word embeddings, extending Duong et al. (2016), to jointly train over monolingual corpora in several languages; (c) achieving competitive results in bilingual, monolingual and crosslingual transfer settings.

## 2 Related work

Crosslingual word embeddings are typically based on co-occurrence statistics from parallel text (Luong et al., 2015; Gouws et al., 2015; Chandar A P et al., 2014; Klementiev et al., 2012; Kočiský et al., 2014; Huang et al., 2015). Other work uses more widely available resources such as comparable data (Vulić and Moens, 2015) and shared Wikipedia entries (Søgaard et al., 2015). However, those approaches rely on data from Wikipedia, and it is non-trivial to extend them to languages that are not covered by Wikipedia. Lexicons are another source of bilingual signal, with the advantage of high coverage. Multilingual lexical resources such as PanLex (Kamholz et al., 2014) and Wiktionary<sup>2</sup> cover thousands of languages, and have been used to construct high performance crosslingual word embeddings (Mikolov et al., 2013a; Xiao and Guo, 2014; Faruqui and Dyer, 2014).

Previous work mainly focuses on building word embeddings for a pair of languages, typically with English on one side, with the exception of Coulmance et al. (2015), Søgaard et al. (2015) and Ammar et al. (2016). Coulmance et al. (2015) extend the bilingual skipgram model from Luong et al. (2015), training jointly over many languages using the Europarl corpora. We also compare our models with an extension of Huang et al. (2015) adapted for multiple languages also using bilingual corpora. However, parallel data is an expensive resource and using parallel data seems to under-perform on the bilingual lexicon induction task (Vulić and Moens, 2015). While Coulmance et al. (2015) use English as the pivot language, Søgaard et al. (2015) learn multilingual word em-

<sup>2</sup>wiktionary.org

beddings for many languages using Wikipedia entries which are the same for many languages. However, their approach is limited to languages covered in Wikipedia and seems to under-perform other methods. Ammar et al. (2016) propose two algorithms, MultiCluster and MultiCCA, for multilingual word embeddings using set of bilingual lexicons. MultiCluster first builds the graph where nodes are lexical items and edges are translations. Each cluster in this graph is an anchor point for building multilingual word embeddings. MultiCCA is an extension of Faruqui and Dyer (2014), performing canonical correlation analysis (CCA) for multiple languages using English as the pivot. A shortcoming of MultiCCA is that it ignores polysemous translations by retaining only one-to-one dictionary pairs (Gouws et al., 2015), disregarding much information. As a simple solution, we propose a simple post hoc method by mapping the English parts of each bilingual word embedding to each other. In this way, the mapping is always exact and one-to-one.

Duong et al. (2016) constructed bilingual word embeddings based on monolingual data and PanLex. In this way, their approach can be applied to more languages as PanLex covers more than a thousand languages. They solve the polysemy problem by integrating an EM algorithm for selecting a lexicon. Relative to many previous crosslingual word embeddings, their joint training algorithm achieved state-of-the-art performance for the bilingual lexicon induction task, performing significantly better on monolingual similarity and achieving a competitive result on cross lingual document classification. Here we also adopt their approach, and extend it to multilingual embeddings.

### 2.1 Base model for bilingual embeddings

We briefly describe the base model (Duong et al., 2016), an extension of the continuous bag-of-word (CBOW) model (Mikolov et al., 2013a) with negative sampling. The original objective function is

$$\sum_{i \in D} \left( \log \sigma(\mathbf{u}_{w_i}^\top \mathbf{h}_i) + \sum_{j=1}^p \log \sigma(-\mathbf{u}_{w_{i_j}}^\top \mathbf{h}_i) \right), \quad (1)$$

where  $D$  is the training data,  $\mathbf{h}_i = \frac{1}{2k} \sum_{j=-k; j \neq 0}^k \mathbf{v}_{w_{i+j}}$  is a vector encoding the context over a window of size  $k$  centred around position  $i$ ,  $\mathbf{V}$  and  $\mathbf{U} \in \mathbb{R}^{|V_e| \times d}$  are learned matrices referred to as the context and centre word

embeddings, where  $V_e$  is the vocabulary and  $p$  is the number of negative examples randomly drawn from a noise distribution,  $w_{ij} \sim P_n(w)$ .

Duong et al. (2016) extend the CBOW model for application to two languages, using monolingual text in both languages and a bilingual lexicon. Their approach augments CBOW by generating not only the middle word, but also its translation in the other language. This is done by first selecting a translation  $\bar{w}_i$  from the lexicon for the middle word  $w_i$ , based on the cosine distance between the context  $h_i$  and the context embeddings  $\mathbf{V}$  for each candidate foreign translation. In this way source monolingual training contexts must generate both source and target words, and similarly target monolingual training contexts also generate source and target words. Overall this results in compatible word embeddings across the two languages, and highly informative nearest neighbours across the two languages. This leads to the new objective function

$$\sum_{i \in D_s \cup D_t} \left( \log \sigma(\mathbf{u}_{w_i}^\top \mathbf{h}_i) + \log \sigma(\mathbf{u}_{\bar{w}_i}^\top \mathbf{h}_i) \right) + \sum_{j=1}^p \log \sigma(-\mathbf{u}_{w_{ij}}^\top \mathbf{h}_i) + \delta \sum_{w \in V_s \cup V_t} \|\mathbf{u}_w - \mathbf{v}_w\|_2^2, \quad (2)$$

where  $D_s$  and  $D_t$  are source and target monolingual data,  $V_s$  and  $V_t$  are source and target vocabulary. Comparing with the CBOW objective function in Equation (1), this represents two additions: the translation cross entropy  $\log \sigma(\mathbf{u}_{\bar{w}_i}^\top \mathbf{h}_i)$ , and a regularisation term  $\sum_{w \in V_s \cup V_t} \|\mathbf{u}_w - \mathbf{v}_w\|_2^2$  which penalises divergence between context and center word embedding vectors for each word type, which was shown to improve the embedding quality (Duong et al., 2016).

### 3 Post hoc Unification of Embeddings

Our goal is to learn multilingual word embeddings over more than two languages. One simple way to do this is to take several learned bilingual word embeddings which share a common target language (here, English), and map these into a shared space (Mikolov et al., 2013a; Faruqui and Dyer, 2014). In this section we propose post hoc methods, however in §4 we develop an integrated multilingual method using joint inference.

Formally, the input to the post hoc combination methods are a set of  $n$  pre-trained bilingual word

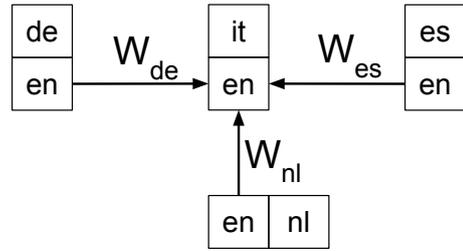

Figure 1: Examples of unifying four bilingual word embeddings between en and it, de, es, nl to the same space using post hoc linear transformation.

embedding matrices, i.e.,  $C_i = \{(E_i, F_i)\}$  with  $i \in \mathbf{F}$  is the set of foreign languages (not English),  $E_i \in \mathbb{R}^{|V_{e_i}| \times d}$  are the English word embeddings and  $F_i \in \mathbb{R}^{|V_{f_i}| \times d}$  are foreign language word embeddings for language  $i$ , with  $V_{e_i}$  and  $V_{f_i}$  being the English and foreign language vocabularies and  $d$  is the embedding dimension. These bilingual embeddings can be produced by any method, e.g., those discussed in §2.

**Linear Transformation.** The simplest method is to learn a linear transformation which maps the English part of each bilingual word embedding into the same space (inspired by Mikolov et al. (2013a)), as illustrated in Figure 1. One language pair is chosen as the pivot, en-it in this example, and the English side of the other language pairs, en-de, en-es, en-nl, are mapped to closely match the English side of the pivot, en-it. This is achieved through learning linear transformation matrices for each language,  $W_{de}, W_{es}$  and  $W_{nl}$ , respectively, where each  $W_i \in \mathbb{R}^{d \times d}$  is learned to minimize the objective function  $\|E_i \times W_i - E_{pivot}\|_2^2$  where  $E_{pivot}$  is the English embedding of the pivot pair, en-it.

Each foreign language  $f_i$  is then mapped to the same space using the learned matrix  $W_i$ , i.e.,  $F'_i = F_i \times W_i$ . These projected foreign embeddings are then used in evaluation, along with the English side of the language pair with largest English vocabulary coverage, i.e., biggest  $|V_{e_i}|$ . Together these embeddings allow for querying of monolingual and cross-lingual word similarity, and multilingual transfer of trained models.

The advantage of this approach is that it is very fast and simple to train, since the objective function is strictly convex and has a closed form solution. Moreover, unlike Mikolov et al. (2013a) who learn the projection from a source to a target

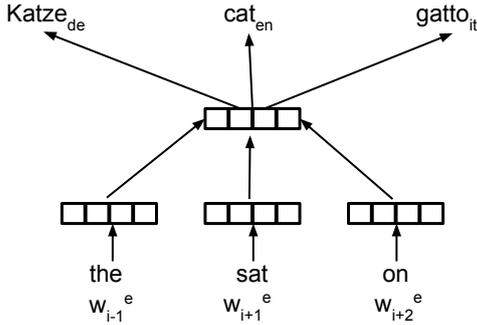

Figure 2: Examples of our multilingual joint training model without mapping for learning multilingual embeddings for three languages  $en$ ,  $it$ ,  $de$  using joint inference.

language, we learn the projection from English to English, thus do not require a lexicon, sidestepping the polysemy problem.<sup>3</sup>

#### 4 Multilingual Joint Training

Instead of combining bilingual word embeddings in the post-processing step, it might be more beneficial to do it during training, so that languages can interact with each other more freely. We extend the method in §2.1 to jointly learn the multilingual word embeddings during training. The input to the model is the combined monolingual data for each language and the set of lexicons between any language pair.

We modify the base model (Duong et al., 2016) to accommodate more languages. For the first step, instead of just predicting the translation for a single target language, we predict the translation for all languages in the lexicon. That is, we compute  $w_i^f = \operatorname{argmax}_{w \in \operatorname{dict}_e^f(w_i^e)} \cos(\mathbf{v}_w, \text{context})$ , which is the best translation in language  $f$  of source word  $w_i^e$  in language  $e$ , given the bilingual lexicon  $\operatorname{dict}_e^f$  and the context. For the second step, we jointly predict word  $w_i^e$  and all translations  $w_i^f$  in all foreign languages  $f \in \mathbf{T}$  that we have dictionary  $\operatorname{dict}_e^f$  as illustrated in Figure 2.

<sup>3</sup>A possible criticism of this approach is that a linear transformation is not powerful enough for the required mapping. We experimented with non-linear transformations but did not observe any improvements. Faruqui and Dyer (2014) extended Mikolov et al. (2013a) as they projected both source and target languages to the same space using canonical correlation analysis (CCA). We also adopted this approach for multilingual environment by applying multi-view CCA to map the English part of each pre-trained bilingual word embedding to the same space. However, we only observe minor improvements.

The English word *cat* might have several translations in German  $\{Katze, Raupe, Typ\}$  and Italian  $\{gatto, gatta\}$ . In the first step, we select the closest translation given the context for each language, i.e. *Katze* and *gatto* for German and Italian respectively. In the second step, we jointly predict the English word *cat* together with selected translations *Katze* and *gatto* using the following modified objective function:

$$\mathcal{O} = \sum_{i \in D_{all}} \left( \log \sigma(\mathbf{u}_{w_i^e}^\top \mathbf{h}_i) + \sum_{f \in \mathbf{T}} \log \sigma(\mathbf{u}_{w_i^f}^\top \mathbf{h}_i) + \sum_{j=1}^p \log \sigma(-\mathbf{u}_{w_{ij}}^\top \mathbf{h}_i) \right) + \delta \sum_{w \in V_{all}} \|\mathbf{u}_w - \mathbf{v}_w\|_2^2, \quad (3)$$

where  $D_{all}$  and  $V_{all}$  are the combined monolingual data and vocabulary for all languages. Each of the  $p$  negative samples,  $w_{ij}$ , are sampled from a unigram model over the combined vocabulary  $V_{all}$ .

**Explicit mapping.** As we keep adding more languages to the model, the hidden layer in our model – shared between all languages – might not be enough to accommodate all languages. However, we can combine the strength of the linear transformation proposed in §3 to our joint model as described in Equation (3). We explicitly learn the linear transformation jointly during training by adding the following regularization term to the objective function:

$$\mathcal{O}' = \mathcal{O} + \alpha \sum_{i \in D_e} \sum_{f \in \mathbf{F}} \|\mathbf{u}_{w_i^f} W_f - \mathbf{u}_{w_i^e}\|_2^2, \quad (4)$$

where  $D_e$  is the English monolingual data (since we use English as the pivot language),  $\mathbf{F}$  is the set of foreign languages (not English),  $W_f \in \mathbb{R}^{d \times d}$  is the linear transformation matrix, and  $\alpha$  controls the contribution of the regularization term and will be tuned in §6.<sup>4</sup> Thus, the set of learned parameters for the model are the word and context embeddings  $\mathbf{U}, \mathbf{V}$  and  $|\mathbf{F}|$  linear transformation matrices,  $\{W_f\}_{f \in \mathbf{F}}$ . After training is finished, we linearly transform the foreign language embeddings with the corresponding learned matrix  $W_f$ , such that all embeddings are in the same space.

#### 5 Experiment Setup

Our experimental setup is based on that of Duong et al. (2016). We use the first 5 million sen-

<sup>4</sup>For an efficient implementation, we apply this constraint to only 10% of English monolingual data.

Model		it-en		es-en		nl-en		nl-es		Average

Table 1: Bilingual lexicon induction performance for four pairs. Bilingual word embeddings (BiWE) is the state-of-the-art result from Duong et al. (2016) where each pair is trained separately. Our proposed methods including linear transformation (Linear), joint prediction as in Equation (3) (Joint) and joint prediction with explicit mapping as in Equation (4) (+mapping). We report recall at 1 and 5 with respect to four baseline multilingual word embeddings. The best scores for are shown in bold.

tences from the tokenized monolingual data from the Wikipedia dump from Al-Rfou et al. (2013).<sup>5</sup> The dictionary is from PanLex which covers more than 1,000 language varieties. We build multilingual word embeddings for 5 languages (*en*, *it*, *es*, *nl*, *de*) jointly using the same parameters as Duong et al. (2016).<sup>6</sup> During training, for a fairer comparison, we only use lexicons between English and each target language. However, it is straightforward to incorporate a lexicon between any pair of languages into our model. The pre-trained bilingual word embeddings for the post-processing experiment in §3 are also from Duong et al. (2016).

In the following sections, we evaluate the performance of our multilingual word embeddings in comparison with bilingual word embeddings and previous published multilingual word embeddings (MultiCluster, MultiCCA, MultiSkip and MultiTrans) for three tasks: bilingual lexicon induction (§6), monolingual similarity (§7) and crosslingual document classification (§8). MultiCluster and MultiCCA are the models proposed from Ammar et al. (2016) trained on monolingual data using bilingual lexicons extracted from aligning Europarl corpus. MultiSkip is the reimplementation of the multilingual skipgram model from Coul-

mance et al. (2015). MultiTrans is the multilingual version of the translation invariance model from Huang et al. (2015). Both MultiSkip and MultiTrans are trained directly on parallel data from Europarl. All the previous work is trained with 512 dimensions on 12 languages acquired directly from Ammar et al. (2016).

## 6 Bilingual Lexicon Induction

In this section we evaluate our multilingual models on the bilingual lexicon induction (BLI) task, which tests the bilingual quality of the model. Given a word in the source language, the model must predict the translation in the target language. We report recall at 1 and 5 for the various models listed in Table 1. The evaluation data for *it-en*, *es-en*, and *nl-en* pairs was manually constructed (Vulić and Moens, 2015). We extend the evaluation for *nl-es* pair which do not involve English.<sup>7</sup>

The BiWE results for pairs involving English in Table 1 are from Duong et al. (2016), the current state of the art in this task. For the *nl-es* pair, we cannot build bilingual word embeddings, since we do not have a corresponding bilingual lexicon. Instead, we use English as the pivot language. To get the *nl-es* translation, we use two bilingual embeddings of *nl-en* and *es-en* from Duong et al. (2016). We get the best English translation for the Dutch word, and get the top 5 Spanish

<sup>5</sup>We will use the whole data if there are less than 5 million sentences.

<sup>6</sup>Default learning rate of 0.025, negative sampling with 25 samples, subsampling rate of value  $1e^{-4}$ , embedding dimension  $d = 200$ , window size 48, run for 15 epochs and  $\delta = 0.01$  for combining word and context embeddings.

<sup>7</sup>We build 1,000 translation pairs for *nl-es* pair with the source word from Vulić and Moens (2015) and ground truth candidates from Google Translate but manually verified.

translations with respect to the English word. This simple trick performs surprisingly well, probably because bilingual word embeddings involving English such as `nl-en` and `es-en` from Duong et al. (2016) are very accurate.

For the linear transformation, we use the first pair `it-en` as the pivot and learn to project `es-en`, `de-en`, `nl-en` pairs to this space as illustrated in Figure 1. We use English part ( $E'_{biggest}$ ) from transformed `de-en` pair as the English output. Despite simplicity, linear transformation performs surprisingly well.

Our joint model to predict all target languages simultaneously, as described in Equation (3), performs consistently better in contrast with linear transformation at all language pairs. The joint model with explicit mapping as described in Equation (4) can be understood as the combination of joint model and linear transformation. For this model, we need to tune  $\alpha$  in Equation (4). We tested  $\alpha$  with value in range  $\{10^{-i}\}_{i=0}^5$  using `es-en` pair on BLI task.  $\alpha = 0.1$  gives the best performance. To avoid over-fitting, we use the same value of  $\alpha$  for all experiments and all other pairs. With this tuned value  $\alpha$ , our joint model with mapping clearly outperforms other proposed methods on all pairs. More importantly, this result is substantially better than all the baselines across four language pairs and two evaluation metrics. Comparing with the state of the art (BiWE), our final model (joint + mapping) are more general and more widely applicable, however achieves relatively better result, especially for recall at 5.

## 7 Monolingual similarity

The multilingual word embeddings should preserve the monolingual property of the languages. We evaluate using the monolingual similarity task proposed in Luong et al. (2015). In this task, the model is asked to give the similarity score for a pair of words in the same language. This score is then measured against human judgment. Following Duong et al. (2016), we evaluate on three datasets, WordSim353 (WS-en), RareWord (RW-en), and the German version of WordSim353 (WS-de) (Finkelstein et al., 2001; Luong et al., 2013; Luong et al., 2015).

Table 2 shows the result of our multilingual word embeddings with respect to several baselines. The trend is similar to the bilingual lexicon induction task. Linear transformation per-

	Model	WS-de	WS-en	RW-en
Baselines	MultiCluster	51.0 [98.3]	53.9 [100]	38.1 [57.6]
	MultiCCA	60.2 [99.7]	66.3 [100]	43.1 [71.1]
	MultiSkip	48.4 [96.6]	51.2 [99.7]	33.9 [55.4]
	MultiTrans	56.4 [92.6]	61.1 [97.2]	<b>51.1</b> [23.1]
Ours	Linear	67.5 [99.4]	<b>74.7</b> [100]	45.4 [75.5]
	Joint	68.5 [99.4]	74.6 [100]	43.8 [75.5]
	Joint + Mapping	<b>70.4</b> [99.4]	74.4 [100]	45.1 [75.5]
	BiWE	71.1 [99.4]	76.2 [100]	44.0 [75.5]

Table 2: Spearman’s rank correlation for monolingual similarity measurement for various models on 3 datasets WS-de (353 pairs), WS-en (353 pairs) and RW-en (2034 pairs). We compare against 4 baseline multilingual word embeddings. BiWE is the result from Duong et al. (2016) where each pair is trained separately which serves as the reference for the best bilingual word embeddings. The best results for multilingual word embeddings are shown in bold. Numbers in square brackets are the coverage percentage.

forms surprisingly well. Our joint model achieves a similar result, with linear transformation (better on WS-de but worse on WS-en and RW-en). Our joint model with explicit mapping regains the drop and performs slightly better than linear transformation. More importantly, this model is substantially better than all baselines, except for MultiTrans on RW-en dataset. This can probably be explained by the low coverage of MultiTrans on this dataset. Our final model (Joint + Mapping) is also close to the best bilingual word embeddings (BiWE) performance reported by Duong et al. (2016).

## 8 Crosslingual Document Classification

In the previous sections, we have shown that our methods for building multilingual word embeddings, either in the post-processing step or during training, preserved high quality bilingual and monolingual relations. In this section, we demonstrate the usefulness of multi-language crosslingual word embeddings through the crosslingual document classification (CLDC) task.

This task exploits transfer learning, where the document classifier is trained on the source language and tested on the target language. The source language classifier is transferred to the target language using crosslingual word embeddings as the document is represented as the sum of bag-

		en→de	de→en	it→de	it→es	en→es	Avg
Baselines	MultiCluster	<b>92.9</b>	69.1	79.1	<b>81.0</b>	<b>63.1</b>	<b>77.0</b>
	MultiCCA	69.2	50.7	83.1	79.0	45.3	65.5
	MultiSkip	79.9	63.5	71.8	76.3	60.4	70.4
	MultiTrans	87.7	75.2	70.4	64.4	56.1	70.8
Ours	Linear	83.8	75.7	74.8	67.3	57.4	71.8
	Joint	86.2	75.7	82.3	70.7	56.0	74.2
	Joint + Mapping	89.5	<b>81.6</b>	<b>84.3</b>	74.1	53.9	76.7
Bilingual	Luong et al. (2015)	88.4	<b>80.3</b>	-	-	-	-
	Chandar A P et al. (2014)	<b>91.8</b>	74.2	-	-	-	-
	Duong et al. (2016)	86.3	76.8	-	-	<b>53.8</b>	-

Table 3: Crosslingual document classification accuracy for various model. Chandar A P et al. (2014) and Luong et al. (2015) achieved a state-of-the-art result for  $en \rightarrow de$  and  $de \rightarrow en$  respectively, served as the reference. The best results for bilingual and multilingual word embeddings are bold.

of-word embeddings weighted by *tf.idf*. This setting is useful for target low-resource languages where the annotated data is insufficient.

The train and test data are from multilingual RCV1/RCV2 corpus (Lewis et al., 2004) where each document is annotated with labels from 4 categories: CCAT (Corporate/Industrial), ECAT (Economics), GCAT (Government/Social) and MCAT (Markets). We extend the evaluation from Klementiev et al. (2012) to cover more language pairs. We use the same data split for  $en \rightarrow de$  and  $de \rightarrow en$  pairs but additionally construct the train and test data for  $it \rightarrow de$ ,  $it \rightarrow es$  and  $en \rightarrow es$ . For each pair, we use 1,000 documents in the source language as the training data and 5,000 documents in the target language as the test data. The training data is randomly sampled, but the test data (for *es*) is evenly balanced among labels.

Table 3 shows the accuracy for the CLDC task for many pairs and models with respect to the baselines. For all bilingual models (Duong et al., 2016; Luong et al., 2015; Chandar A P et al., 2014), the bilingual word embeddings are constructed for each pair separately. In this way, they can only get the pairs involving English since there are many bilingual resources involving English on one side. For all our models, including Linear, Joint and Joint + Mapping, the embedding space is available for multiple languages; this is why we can exploit different relations, such as  $it \rightarrow es$ . This is the motivation for the work reported in this paper. Suppose we want to build a document clas-

sifier for *es* but lack any annotations. It is common to build  $en-es$  crosslingual word embeddings for transfer learning, but this only achieves 53.8 % accuracy. Yet when we use *it* as the source, we get 81.0% accuracy. This is motivated by the fact that *it* and *es* are very similar.

The trend observed in Table 3 is consistent with previous observations. Linear transformation performs well. Joint training performs better especially for the  $it \rightarrow de$  pair. The joint model with explicit mapping is generally our best model, even better than the base bilingual model from Duong et al. (2016). The  $de \rightarrow en$  result improves on the existing state of the art reported in Luong et al. (2015). Our final model (Joint + Mapping) achieved competitive results compared with four strong baseline multilingual word embeddings, achieving best results for two out of five pairs. Moreover, the best scores for each language pairs are all from multilingual training, emphasizing the advantages over bilingual training.

## 9 Analysis

Mikolov et al. (2013b) showed that monolingual word embeddings capture some analogy relations such as  $\vec{\text{Paris}} - \vec{\text{France}} + \vec{\text{Italy}} \approx \vec{\text{Rome}}$ . It seems that in our multilingual embeddings, these relations still hold. Table 4 shows some examples of such relations where each word in the analogy query is in different languages.

All our baselines (MultiCluster, MultiCCA, MultiSkip, MultiTrans) are trained using different datasets. While MultiSkip and MultiTrans

chico <sub>es</sub> - bruder <sub>de</sub> + sorella <sub>it</sub> (boy - brother + sister)	ehemann <sub>de</sub> - padre <sub>es</sub> + madre <sub>it</sub> (husband - father + mother)	principe <sub>it</sub> - junge <sub>de</sub> + meisje <sub>nl</sub> (prince - boy + girl)
<b>chica</b> <sub>es</sub> (girl)	<b>echtgenote</b> <sub>nl</sub> (wife)	<b>principessa</b> <sub>it</sub> (princess)
<b>ragazza</b> <sub>it</sub> (girl)	<b>moglie</b> <sub>it</sub> (wife)	<b>princess</b> <sub>en</sub>
<b>meisje</b> <sub>nl</sub> (girl)	her <sub>en</sub>	<b>princesa</b> <sub>es</sub> (princess)
<b>girl</b> <sub>en</sub>	marito <sub>it</sub> (husband)	príncipe <sub>es</sub> (prince)
<b>mädchen</b> <sub>de</sub> (girl)	haar <sub>nl</sub> (her)	<b>prinzessin</b> <sub>de</sub> (princess)

are trained on parallel corpora, MultiCluster and MultiCCA use monolingual corpora and bilingual lexicons which are similar to our proposed methods. Therefore, for a strict comparison<sup>8</sup>, we train our best model (Joint + Mapping) using the same monolingual data and set of bilingual lexicons on the same 12 languages with MultiCluster and MultiCCA. Table 5 shows the performance on intrinsic and extrinsic tasks proposed in Ammar et al. (2016). Multilingual dependency parsing and document classification are trained on a set of source languages and test on a target language in the transfer learning setting. Monolingual word similarity task is similar with our monolingual similarity task described in §7, multilingual word similarity is an extension of monolingual word similarity task but tested for pair of words in different languages. Monolingual QVEC, multilingual QVEC test the linguistic content of word embeddings in monolingual and multilingual setting. Monolingual QVEC-CCA and multilingual QVEC-CCA are the

<sup>8</sup>also with respect to the word coverage since MultiSkip and MultiTrans usually have much lower word coverage, biasing the intrinsic evaluations.

extended versions of monolingual QVEC and multilingual QVEC also proposed in Ammar et al. (2016). Table 5 shows that our model achieved competitive results, best at 4 out of 9 evaluation tasks.

## 10 Conclusion

In this paper, we introduced several methods for building unified multilingual word embeddings. These represent an improvement because they exploit more relations and combine information from many languages. The input to our model is just a set of monolingual data and a set of bilingual lexicons between any language pairs. We induce the bilingual relationship for all language pairs while keeping high quality monolingual relations. Our multilingual joint training model with explicit mapping consistently achieves better performance compared with linear transformation. We achieve new state-of-the-art performance on bilingual lexicon induction task for recall at 5, similar excellent results with the state-of-the-art bilingual word embeddings on monolingual similarity task (Duong

et al., 2016). Moreover, our model is competitive at the crosslingual document classification task, achieving a new state of the art for  $de \rightarrow en$  and  $it \rightarrow de$  pair.

## Acknowledgments

This work was conducted during Duong’s internship at IBM Research Tokyo and partially supported by the University of Melbourne and National ICT Australia (NICTA). We are grateful for support from NSF Award 1464553 and the DARPA/I2O, Contract Nos. HR0011-15-C-0114 and HR0011-15-C-0115. We thank Yuta Tsuboi and Alvin Grissom II for helpful discussions, and Doris Hoogeveen for helping with the `nl-es` evaluation.

# Building Lexical Vector Representations from Concept Definitions

Danilo S. Carvalho and Minh Le Nguyen

Japan Advanced Institute of Science and Technology

1-1 Asahidai, Nomi City, Ishikawa, Japan

{danilo, nguyenml}@jaist.ac.jp

## Abstract

The use of distributional language representations have opened new paths in solving a variety of NLP problems. However, alternative approaches can take advantage of information unavailable through pure statistical means. This paper presents a method for building vector representations from meaning unit blocks called concept definitions, which are obtained by extracting information from a curated linguistic resource (Wiktionary). The representations obtained in this way can be compared through conventional cosine similarity and are also interpretable by humans. Evaluation was conducted in semantic similarity and relatedness test sets, with results indicating a performance comparable to other methods based on single linguistic resource extraction. The results also indicate noticeable performance gains when combining distributional similarity scores with the ones obtained using this approach. Additionally, a discussion on the proposed method's shortcomings is provided in the analysis of error cases.

## 1 Introduction

Vector-based language representation schemes have gained large popularity in Natural Language Processing (NLP) research in the recent years. Their success comes from both the asserted benefits in several NLP tasks and from the ability to build them from unannotated textual data, widely available in the World Wide Web. The tasks benefiting from vector representations include Part-of-Speech (POS) tagging (dos Santos and Zadrozny, 2014), dependency parsing (Bansal et al., 2014), Named Entity Recognition (NER) (Seok et al.,

2016), Machine Translation (Sutskever et al., 2014), among others.

Such representation schemes are, however, not an all-in-one solution for the many NLP application scenarios. Thus, different representation methods were developed, each one focusing in a limited set of concerns, e.g., semantic relatedness measurement (Mikolov et al., 2013; Pennington et al., 2014) and grammatical dependencies (Levy and Goldberg, 2014). Most of the popular methods are based on a *distributional* approach: the meaning of a word is defined by the context of its use, i.e., the neighboring words. However, distributional representations carry no explicit linguistic information and cannot easily represent some important semantic relationships, such as synonymy and antonymy (Nguyen et al., 2016). Further problems include the difficulty in obtaining representations for out-of-vocabulary (OOV) words and complex constructs (collocations, idiomatic expressions), the lack of interpretable representations (Faruqui and Dyer, 2015), and the necessity of specific model construction for cross-language representation.

This paper presents a linguistically motivated language representation method, aimed at capturing and providing information unavailable on distributional approaches. Our contributions are: (i) a technique for building conceptual representations of linguistic elements (morphemes, words, collocations, idiomatic expressions) from a single collaborative language resource (*Wiktionary*<sup>1</sup>); (ii) a method of combining said representations and comparing them to obtain a semantic similarity measurement. The conceptual representations, called *Term Definition Vectors*, address more specifically the issues of semantic relationship analysis, out-of-vocabulary word interpreta-

<sup>1</sup>[www.wiktionary.org](http://www.wiktionary.org)

tion and cross-language conceptual mapping. Additionally, they have the advantages of being interpretable by humans and easy to operate, due to their sparsity. Experiments were conducted with the *SimLex-999* (Hill et al., 2015) test collection for word similarity, indicating a good performance in this task and exceeding the performance of other single information source studies, when combined with a distributional representation and Machine Learning. Error analysis was also conducted to understand the strengths and weaknesses of the proposed method.

The remainder of this paper is organized as follows: Section 2 presents relevant related works and highlights their similarities and differences to this research. Section 3 explains our approach in detail, covering its linguistic motivation and the characteristics of both representation model and comparison method. Section 4 describes the experimental evaluation and discusses the evaluation results and error analysis. Finally, Section 5 offers a summary of the findings and some concluding remarks.

## 2 Related Work

In order to address the limitations of the most popular representation schemes, approaches for all-in-one representation models were also developed (Pilehvar and Navigli, 2015; Derrac and Schockaert, 2015). They comprise a combination of techniques applied over different data sources for different tasks. Pilehvar and Navigli (2015) presented a method for combining Wiktionary and Wordnet (Fellbaum and others, 1998) sense information into a semantic network and a corresponding relatedness similarity measurement. The method is called ADW (Align, Disambiguate, Walk), and works by first using a Personalized PageRank (PPR) (Haveliwala, 2002) algorithm for performing a random walk on the semantic network and compute a *semantic signature* of a linguistic item (sense, word or text): a probability distribution over all entities in the network where the weights are estimated on the basis of the network's structural properties. Two linguistic items are then aligned and disambiguated by finding their two closest senses, comparing their semantic signatures under a set of vector and rank-based similarity measures (JensenShannon divergence, cosine, Rank-Biased Overlap, and Weighted Overlap). ADW achieved state-of-the-art performance

in several semantic relatedness test sets, covering words, senses and entire texts.

Recski et al. (2016) presented a hybrid system for measuring the semantic similarity of word pairs, using a combination of four distributional representations (*SENNa* (Collobert and Weston, 2008), (Huang et al., 2012), *word2vec* (Mikolov et al., 2013), and *GloVe* (Pennington et al., 2014)), *WordNet*-based features and *Alang* (Kornai, 2010) graph-based features to train a RBF kernel Support Vector Regression on the *SimLex-999* (Hill et al., 2015) data set. This system achieved state-of-the-art performance in *SimLex-999*.

The work presented in this paper takes a similar approach to Pilehvar and Navigli (2015), but stops short on obtaining a far reaching concept graph. Instead, it focuses on exploring the details of each sense definition. This includes term etymologies, morphological decomposition and translation links, available in Wiktionary. Another difference is that the translation links are used to map senses between languages in this work, whereas they are used for bridging gaps between sense sets on monolingual text in Pilehvar and Navigli (2015).

Another concern regarding distributional representations is their lack of interpretability from a linguistic standpoint. Faruqui and Dyer (2015) addresses this point, relying on linguistic information from Wordnet, Framenet (F. Baker et al., 1998), among other sources (excluding Wiktionary), to build interpretable word vectors. Such vectors accommodate several types of information, ranging from Part-of-Speech (POS) tags to sentiment classification and polarity. The obtained linguistic vectors achieved very good performance in a semantic similarity test. Those vectors, however, do not include morphological and translation information, offering discrete, binary features.

Regarding the extraction of definition data from Wiktionary, an effective approach is presented by Zesch et al. (2008a), which is also used for building a semantic representation (Zesch et al., 2008b). However, the level of detail and structure format obtained by such method was not deemed adequate for this work and an alternative extraction method was developed (Sections 3.2 and 3.3).

## 3 Term Definition Vectors

The basic motivation for the representation model here described is both linguistic and epistemic:

trying to represent knowledge as a set of individual concepts that relate to one another and are related to a set of terms. This idea is closely related to the Ogden/Richards *triangle of reference* (Ogden et al., 1923) (Figure 1), which describes a relationship between linguistic symbols and the objects they represent. The following notions are then defined:

- *Concept*: The unit of knowledge. Represents an individual meaning, e.g., rain (as in the natural phenomenon), and can be encoded into a term (symbol). It corresponds to the “thought or reference” from the triangle of reference.
- *Term*: A unit of perception. In text, it can be mapped to fragments ranging from morphemes to phrases. Each one can be decoded into one or more *concepts*. Stands for the “symbol” in the triangle of reference.
- *Definition*: A minimal, but complete explicitation of a concept. It comprises the textual explanation of the concept (sense) and its links to other concepts in a knowledge base, corresponding to the “symbolizes” relationship in the triangle of reference. The simplest case is a dictionary definition, consisting solely of a short explanation (typically a single sentence), with optional term highlights, linking to other dictionary entries. The information used for building definitions in this work is described in Section 3.3.

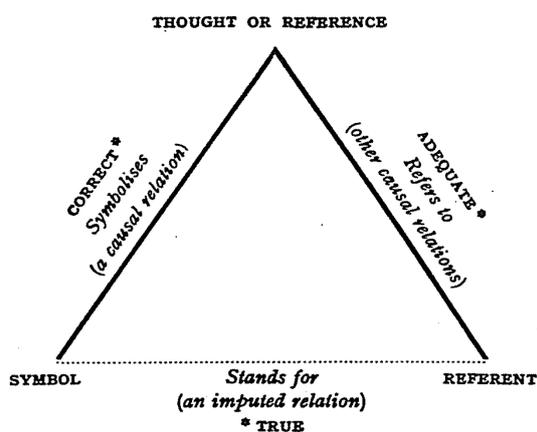

Figure 1: Ogden/Richards triangle of reference, also known as *semiotic triangle*. Describes a relationship between linguistic symbols and the objects they represent. (Ogden et al., 1923)

### 3.1 Distributional & Definitional Semantics

Distributional approaches for language representation, also known as *latent* or *statistical semantics*, are rooted in what is called the *distributional hypothesis* (Sahlgren, 2008). This concept stems from the notion that words are always used in a context, and it is the context that defines their meaning. Thus, the meaning of a term is concealed, i.e. latent, and can be revealed by looking at its context. In this sense, it is possible to define the meaning of a term to be a function of its neighboring term frequencies (co-occurrence). Using different definitions for “neighbor”, e.g., adjacent words in *word2vec* (Mikolov et al., 2013) and “modifiers in a dependency tree” (Levy and Goldberg, 2014), it is possible to produce a variety of vector spaces, called *embeddings*. Good embeddings enable the use of vector operations on words, such as comparison by cosine similarity. They also solve the data sparsity problem of large vocabularies, working as a dimensionality reduction method. There are, however, semantic elements that are not directly related to context, and thus are not well represented by distributional methods, e.g., the antonymy and hypernymy relations. Furthermore, polysemy can bring potential ambiguity problems in cases where the vectors are only indexed by surface form (word  $\rightarrow$  embedding).

An alternative line of thinking is to define the meanings first and then associate the corresponding terms (reference  $\rightarrow$  symbol). In this notion, meanings are *explicit* and need only to be resolved, i.e., disambiguated, for any given term. Concepts are thus represented by prior definitions instead of distributions over corpora, hence the name “*definitional semantics*” is used in this work to generalize such approaches.

To illustrate the difference between both approaches, a simple analogy can be made, where a person reads a book with difficult or new vocabulary. The distributional approach would be akin to reading the book while trying to guess the meaning of the unknown words by context. If the book is long, as the reading progresses, the guesses tend to become more accurate, as a human will try to piece together the information patterns surrounding the new words. On the other hand, the definitional approach would be equivalent to reading the entire contents of a dictionary before reading the book. The main advantage of the former is in-

dependence from any previously compiled knowledge base, e.g. a dictionary, which are subject to completeness and correctness concerns. The latter offers answers for the rarer words that are difficult to guess and the possibility to explain exactly how a certain meaning was inferred (interpretability).

The proposed definitional representation is then obtained through the following strategy:

1. Formalization of the basic unit of knowledge: the concept.
2. Information extraction from a linguistic resource into a set of concepts.
3. Lexical association: term  $\leftrightarrow$  concept.
4. Definition of a term as a composition (mixture) of concepts, allowing partial or complete disambiguation.

Figure 2 illustrates the process. A term is said ambiguous if it is composed by more than one concept. Therefore in this context, disambiguation is the action of reducing the number of concepts in a term's composition. This can be done by collecting additional information about the term, such as Part-of-Speech. A complete disambiguation reduces the composition to a single concept.

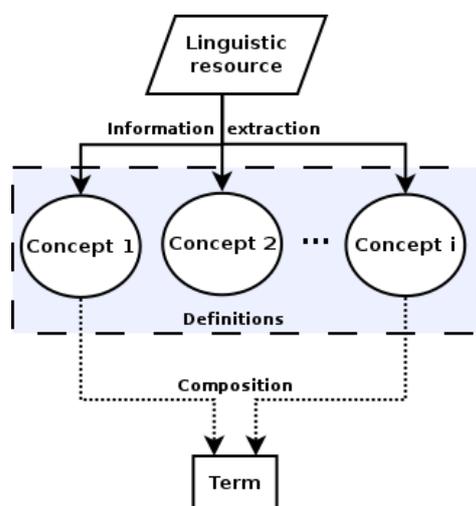

Figure 2: Process of definitional representation. Given a set of concepts obtained from a linguistic resource, a term can be defined as a composition of concepts. A term is said ambiguous if it is composed by more than one concept.

### 3.2 Linguistic Information Extraction

*Wiktionary*<sup>2</sup> was used as the single linguistic resource. Wiktionary is a collaborative lexical resource, comprising millions of vocabulary entries from several languages. It includes contextual information, etymology, semantic relations, translations, inflections, among other types of information for each entry. Its contents are actively curated by a large, global community. This choice was motivated by a several reasons, more importantly:

- It is the largest lexical resource openly available for the public, covering more than 10 million lexical entries from 172 languages.
- It is constantly updated. Daily changes are consolidated in monthly releases.
- Entries are organized in a way that separates each meaning of a term, simplifying definition extraction.
- Entries include range from morphemes, e.g., “pre-”, to idiomatic expressions, e.g., “take matters into one’s own hands”.

The data available from Wiktionary is semi-structured, composed of a set of markup documents, one for each entry, following a reasonably consistent standard of annotations for each language covered. In order to extract the linguistic information, an application was developed to convert the markup into a structured (JSON + schema) representation. The structured data was optimized for the retrieval of Wiktionary senses and link types were categorized to produce concept definitions.

### 3.3 Concept Definitions

Formalization of the knowledge unit used in this work was done by firstly mapping each concept to a single Wiktionary sense. The concept is represented as a lexical/semantic graph, where a main addressing term, the root node, is connected to other terms through a set of edges. Each edge denotes a different type of lexical/semantic relationship, e.g. prefixation, synonymy/antonymy. The edges are also weighted, denoting the intensity of a relationship. Figure 3 shows a simplified visualization of a pair of different concept graphs for

<sup>2</sup>[www.wiktionary.org](http://www.wiktionary.org)

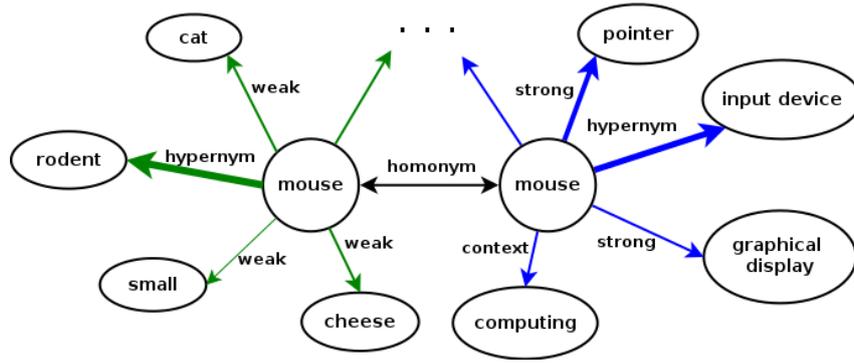

Figure 3: A simplified visualization of two concept graphs for the term “mouse”. The leftmost one denotes the concept of the small rodent and the other denotes the computer input device. The edge labels represent the relationship type and the thickness represent the its intensity.

Table 1: Link types used for the construction of concept graphs. They comprise both lexical (morphology, etymology) and semantic relationships between the root term, i.e., the Wiktionary entry title, and the terms used to describe the meaning.

Type	Description
weak	A term included in the description of the meaning on the Wiktionary entry.
strong	A term linked to another entry, i.e. a {highlight}, included in the description of the meaning.
context	A Wiktionary context link, explaining a specific situation in which the meaning described occurs.
synonym	A synonym relation. If it is an antonym, the sign of the link is reversed.
hypernym	A hypernym relation.
homonym	A homonym relation.
abbreviation	If the meaning described is given by interpreting the root term as an abbreviation.
etymology	Used to describe the origin of the root term of this meaning.
prefix	Denotes a prefixation (morphological) relationship of the root term.
suffix	Denotes a suffixation relationship. Same as above.
confix	Denotes a confixing relationship. Same as above.
affix	Denotes an affixation relationship. Same as above.
stem	Denotes a morphological stem relationship of the root term.
inflection	Denotes an inflectional relationship of the root term.

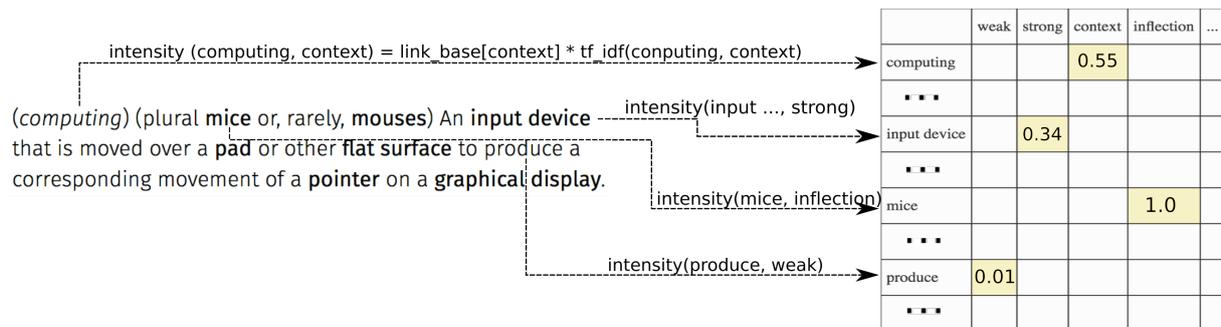

Figure 4: Representation of one Wiktionary sense definition for ”mouse” as an encoded matrix: the *concept definition*. Each Wiktionary link is categorized and mapped to a vector space.

a single lexical entry of Wiktionary. The different link types are used to create a vector space, in which the edges of the definition graph are represented. Table 1 describes the link types used in this work.

Each concept graph is represented by a  $M \times T$  matrix called *concept definition*, where  $L$  is the

number of link types and  $T$  is the vocabulary size. The link intensities are defined for each type, by multiplying a manually defined constant *link\_base* (a model parameter) by the TF-IDF score calculated for the vocabulary with respect to the type. Figure 4 illustrates the process.

Wiktionary entries also cover foreign terms,

listing senses in the source language, e.g., English meanings of the French word “avec” in the English language section. Definitions for these terms are also included into the concept definition set. Additionally, translation links are provided for many sense definitions. Such links, as well as term redirections, i.e., distinct terms pointing to the same Wiktionary entry, are mapped to a single concept. This allows foreign terms to take advantage of the same concept graphs as the source language equivalents.

### 3.4 Definition Vectors

Finally, association between the concept definitions and terms is established by composition. This is done by simple element-wise sum and average of all concept definition matrices mapped to a Wiktionary entry. The resulting matrix is flattened in its row axis, i.e, rows are concatenated in order, producing a  $L \times T$ -dimensional sparse vector called *term definition vector*. If the term is not a Wiktionary entry, i.e., is out-of-vocabulary (OOV), a character n-gram-based attempt of morphological decomposition is done and if a complete morpheme match is found in the concept definition set, the matched concepts are composed for the OOV term. This decomposition attempt is done as follows:

1. For each character  $c_i, i \in [0, n]$  in a OOV term of length  $n$ :
  - i Create empty list *morph\_cand* of morpheme candidates.
  - ii Set index  $j = i$ .
  - iii Find Wiktionary entries that match  $c$  and add them to *morph\_cand*. For the first and last characters, include prefixes and suffixes in the search, respectively.
  - iv Concatenate  $c_{j+1}$  to  $c$ .
  - v Increment  $j$ .
  - vi Repeat from iii.

This will produce a sequence of  $n$  morpheme candidate lists. If a sequence produced by taking a single morpheme candidate from each list matches the entire OOV term, it is considered a candidate decomposition. If there are multiple candidate decompositions, the one with the shortest stem is selected.

Figure 5 illustrates an OOV composition for the nonexistent term “unlockability”, which has

a complete morpheme match in the concept definition set. If a complete morpheme match is not found, the term is considered a proper noun (if no POS is provided), and given a null (zero) vector.

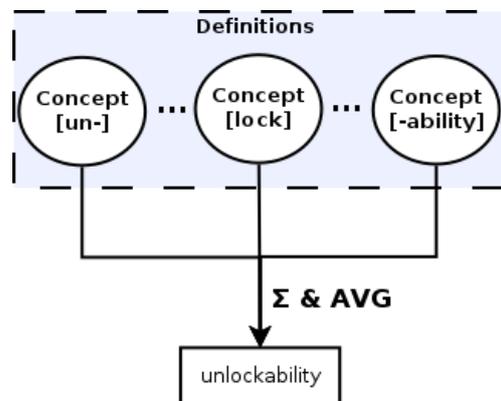

Figure 5: Morpheme match in concept definitions for the OOV term “unlockability”.

Similarity comparison between two terms is done by measuring the cosine similarity between their definition vectors. A value closer to 1 indicates high similarity, a value closer to  $-1$  indicates opposition and a value closer to 0 indicates unrelatedness. Table 2 shows a comparison table between semantic matches obtained using this method, *word2vec* (Mikolov et al., 2013) and *GloVe* (Pennington et al., 2014).

Table 2: Top closest and farthest to the term “happy” by Term Definition Vector, and closest Word2Vec (GoogleNews corpus), and GloVe (Wikipedia2014 + Gigaword) cosine similarities.

Def.Vec	Def.Vec (-)	Word2Vec	GloVe
joyous	sad	glad	glad
dexterous	unhappy	pleased	good
content	joyless	ecstatic	sure
felicitous	somber	overjoyed	proud
lucky	depressed	thrilled	excited

The definition vectors obtained in this way are also human interpretable to a certain extent. Each dimension corresponds to a link from the concept graphs used to compose a term definition. The values correspond to the strengths of such links. A human readable representation of the definition vector for the word “sunny”, containing a maximum of two values per link type, can be written in the form: *weak@(a:0.0006, lot:0.003); strong@(cheerful:0.032, radiant:0.032); synonym@(bright:1.11, sunlit:1.11); suffix@(-y:1);*

*stem@(sun:1); pos@(adjective:0.11, noun:0.11)*. In this example, *strong@radiant* is a single vector dimension and the term is not disambiguated (multiple POS).

## 4 Experiments

### 4.1 Experimental setup

The definition vector representations obtained in this work were evaluated in the *SimLex-999* test collection for semantic similarity benchmark (Hill et al., 2015). This test collection contains a set of 999 English word pairs, associated to a similarity score given by a group of human annotators. The set is divided in 666 nouns pairs, 222 verb pairs and 111 adjective pairs. The Part-of-Speech (POS) information allows partial or complete disambiguation of the definition vectors. The choice of *SimLex-999* was due to the type of similarity measured by this set, which excludes relatedness and is closer to the type of information captured by the concept definitions. Additionally, the *WordSim-353* (Finkelstein et al., 2001), *RG-65* (Rubenstein and Goodenough, 1965) and *MEN* (Bruni et al., 2014) test collections for semantic relatedness were also included in the evaluation, to verify the representation performance in measuring relatedness. While the *MEN* test collection also includes POS information, *WordSim-353* and *RG-65* do not include it, so sense distinction was not applied for the latter. Unfortunately, the test collections used in this work did not contain foreign words, so the translation-link features presented in Section 3.3 are solely presented as part of the method’s description, and are not evaluated. This is due to the method being developed without focus on a specific test. The semantic similarity measurement was consequence of the method’s design, but not its main target.

Evaluation is done by computing the Spearman’s rank correlation coefficient ( $\rho$ ) between the human annotators’ similarity or relatedness scores and the scores given by the automated methods. A coefficient of value 1 means a perfect match between the relative positions of the pairs, when ranked by their similarity scores.

For the *SimLex-999* test, the cosine similarity between the term definition vectors was set as the similarity score. For the *WordSim-353*, *RG-65* and *MEN* tests, the absolute value of the cosine similarity was used instead, since opposite words are related. An additional test was performed to

explore the possibility of combining distributional and definitional approaches. In this test, a small set of features was created to train a Learning-to-Rank model, in order to improve the similarity scores. The features were as follows:

- Presence of synonym, hypernym, strong and weak links<sup>3</sup> between the pair of words. Each link type is a separate feature.
- Term definition vector similarity.
- Word2vec similarity.

The features were computed for each pair and passed to  $SVM^{rank}$  (Joachims, 2006) for training and validation. A 10-fold cross-validation test using random pairs without replacement was run for the entire sets (5-fold for *RG-65*), except *MEN*. The *MEN* test collection is separated into training and testing sets, with 2K and 1K word pairs respectively, so these were used in place of the cross-validation. For each fold, the ranking scores provided by the trained ranker were used as similarity scores for calculating  $\rho$ . The average of all folds was considered the final result.

Experimental data and model parameters were set as follows:

- Linguistic information source: Wiktionary English database dump (XML + Wiki markup), 2015-12-26, containing more than 4 million entries. A reduced set, with only English, French, Greek, Japanese, Latin and Vietnamese language entries was used in the experiments. This set had about 734K entries, from which approx. 1 million concepts were extracted.
- *link\_base* constants were set as: *weak* = 0.2, *strong* = 2.0, *context* = 0.5, *synonym* = 10.0, *hypernym* = 5.0, *homonym* = 7.0, *etymology* = 1.0 (also applied to morphological links) and *pos* = 1.0. The constants were adjusted by increasing or decreasing their values individually in intervals of 0.2, and observing the effect in  $\rho$  for *SimLex-999* in the first fold of the cross-validation. The optimal values were selected and kept constant for the remaining folds and for the other tests. This was done because

<sup>3</sup>See Table 1

Table 3: Performance of different methods for the SimLex-999, WordSim-353, RG-65, and MEN test sets, reported as Spearman’s rank correlation coefficient  $\rho$ . The methods marked with  $\diamond$  use a single information source. Fields marked with “-” indicate that the results were not available for assessment.

Method	$\rho$ @SimLex-999	$\rho$ @WordSim-353	$\rho$ @RG-65	$\rho$ @MEN-1K
Word2Vec (W2V) $\diamond$	0.38	<b>0.78</b>	0.84	0.73
GloVe $\diamond$	0.40	0.76	0.83	-
Term Def. Vectors (TDV) $\diamond$	0.56	0.36	0.68	0.42
Ling Dense	0.58	0.45	0.67	-
dLCE $\diamond$	0.59	-	-	-
TDV + W2V + SVM <sup>rank</sup>	<b>0.62</b>	0.75	0.72	0.78
Recski et al. (2016)	<b>0.76</b>	-	-	-
ADW	-	0.75	<b>0.92</b>	-

changing *link\_base* for each fold would create an unrealistic use scenario for our system, which cannot change *link\_base* online. The cross-validation was repeated two times, with very minor differences between both test runs. The constant values reported here are from the last run.

- SVM<sup>rank</sup> was set with a default linear kernel and  $C$  parameter (training error trade-off) was set to 8 for MEN and 5 for the other test collections. The value was increased in unit intervals, until convergence was longer than a time threshold (10 minutes). This parameter was adjusted using the training set for MEN, or inside each CV fold for the rest.
- Both *Word2Vec* and *GloVe* were used with pre-trained, 300-dimensional models: 100 billion words GoogleNews corpus and Common Crawl 42 billion token corpus respectively.

dLCE (Nguyen et al., 2016) was chosen as baseline, for being the best single information source method in the SimLex-999 test collection. Further results include Recski et al. (2016) (state-of-the-art), Ling Dense (Faruqui and Dyer, 2015), Word2Vec (Mikolov et al., 2013), and GloVe (Pennington et al., 2014). For WordSim-353, GloVe, Word2Vec, Ling Dense, and ADW (Pilehvar and Navigli, 2015) were included. For RG-65, Ling Dense, GloVe, and ADW (state-of-the-art), were included.

## 4.2 Results

The experimental results are presented in Table 3, where they are compared to other methods.

The results indicate that in the semantic similarity test, the term definition vectors perform closely to other representation models taking advantage of curated data, such as WordNet. It also outperforms the most popular distributional representations. However, they are clearly outclassed in the semantic relatedness test, for which the distributional approaches show superior performance.

An interesting observation can be made when combining word2vec similarity with term definition features through the use of Machine Learning. A performance trade-off seems to exist at the semantic relatedness tests, but the same is not true for the similarity test. This allowed the combined model to improve considerably at little cost. Further analysis helped in understanding the reason for this particularity (Section 4.3).

Lastly, the experiments have also shown that the method for extracting concept definitions is not computationally expensive. The developed implementation took about 6 minutes to extract all concept definitions from the structured Wiktionary data used in the tests, using a modern desktop computer (3GHz processor and at least 8GB RAM). Structuring Wiktionary data took less than 20 minutes with the same equipment, and was done a single time.

## 4.3 Error analysis

Identifying the flaws in a method is a fundamental step in improving it and also in understanding the problem it tries to solve. With this in mind, the error cases identified in measuring similarity from the SimLex-999 set were observed in detail. In

this analysis we considered as error any word pair that was put among the top 15% similarity scores by the human annotators, but was ranked in the lower 50% using the definition vectors. The same applies for the bottom 15% scored by humans, that are ranked in the upper half by our approach.

The errors found were classified in four categories:

- **Insufficient links in Wiktionary:** this type of error occurs when the wiktionary sense corresponding to a concept lacks annotations. Typical cases contain only a short description, with no links. The concept graph is then left with only weak links, which have little impact on similarity calculation. The pair *drizzle–rain* (noun) is one example of this.
- **Undeclared hypernymy:** certain cases of hypernymy are not solved in the concept extraction, since they require multiple hops in the definition links to be found. The pairs *cop–sheriff* and *alcohol–gin* (noun) are instances of such problem.
- **Casual vs. formal language semantics:** not a flaw in the method per se, but an error caused by the differences in formal description of a language (in a dictionary), when compared to casual use. The pair *noticeable–obvious* (adjective) illustrates this.
- **Other:** flaws in the extraction process or annotation problems in Wiktionary.

Those errors affect the pairs in the top 15% human similarity scores 7 times more than the lower 15%. They are distributed as shown in Table 4.

Table 4: Distribution of definition vector error types in SimLex-999.

Type of error	Proportion
Insufficient links	21.4%
Undeclared hypernymy	38.1%
Casual semantics	14.3%
Other	26.2%

Having about one quarter of the errors in the “other” category shows that there is some space for improvement in the concept extraction process. The insufficient links and undeclared hypernymy categories are cases in which distributional approaches may do better if similarity is high, due to the words intrinsic relatedness.

Analysis of SVM<sup>rank</sup> scores showed that the insufficient links category benefited the most from the combination with word2vec. The reason is that the features chosen for use with the ranker made such cases distinguishable and more likely to receive a larger weight from the word2vec similarity score after training. The undeclared hypernymy cases, on the other hand, are not so evident and would require a more complex approach on the concept extraction process.

## 5 Conclusion

Alternative approaches to distributional language representations can take advantage of information unavailable through pure statistical means. Taking advantage of large curated linguistic resources is a popular way of obtaining such information and offers large room for exploration. With this in mind, we propose a novel method for obtaining vector representations of lexical items using Wiktionary sense definitions. The lexical item representations are composed from basic meaning units called concept definitions, which are extracted from the linguistic resource. Results obtained from a semantic similarity evaluation test indicate performance comparable to other methods based on linguistic resource extraction. Furthermore, a noticeable performance gain was obtained by applying a Machine Learning approach to combine word2vec similarity scores with the ones obtained using this approach, exceeding both methods’ results.

Planned improvements include the use of a graph traversal approach to capture deeper semantic links and also the inclusion of translation links as separate dimensions in the concept vector space, in order to facilitate the use of obtained representations as a machine translation resource. The inclusion of distributional similarity measures as separate dimensions is also under study and provides an alternative way of combining the distributional and definitional approaches.

## Abstract

In this paper, we present a novel unsupervised algorithm for word sense disambiguation (WSD) at the document level. Our algorithm is inspired by a widely-used approach in the field of genetics for whole genome sequencing, known as the Shotgun sequencing technique. The proposed WSD algorithm is based on three main steps. First, a brute-force WSD algorithm is applied to short context windows (up to 10 words) selected from the document in order to generate a short list of likely sense configurations for each window. In the second step, these local sense configurations are assembled into longer composite configurations based on suffix and prefix matching. The resulted configurations are ranked by their length, and the sense of each word is chosen based on a voting scheme that considers only the top  $k$  configurations in which the word appears. We compare our algorithm with other state-of-the-art unsupervised WSD algorithms and demonstrate better performance, sometimes by a very large margin. We also show that our algorithm can yield better performance than the Most Common Sense (MCS) baseline on one data set. Moreover, our algorithm has a very small number of parameters, is robust to parameter tuning, and, unlike other bio-inspired methods, it gives a deterministic solution (it does not involve random choices).

## 1 Introduction

Word Sense Disambiguation (WSD), the task of identifying which sense of a word is used in a

given context, is a core NLP problem, having the potential to improve many applications such as machine translation (Carpuat and Wu, 2007), text summarization (Plaza et al., 2011), information retrieval (Chifu and Ionescu, 2012; Chifu et al., 2014) or sentiment analysis (Sumanth and Inkpen, 2015). Most of the existing WSD algorithms (Agirre and Edmonds, 2006; Navigli, 2009) are commonly classified into supervised, unsupervised, and knowledge-based techniques, but hybrid approaches have also been proposed in the literature (Hristea et al., 2008). The main disadvantage of supervised methods (that have led to the best disambiguation results) is that they require a large amount of annotated data which is difficult to obtain. Hence, over the last few years, many researchers have concentrated on developing unsupervised learning approaches (Schwab et al., 2012; Schwab et al., 2013a; Schwab et al., 2013b; Chen et al., 2014; Bhingardive et al., 2015). In this paper, we introduce a novel WSD algorithm, termed ShotgunWSD<sup>1</sup>, that stems from the Shotgun genome sequencing technique (Anderson, 1981; Istrail et al., 2004). Our WSD algorithm is also unsupervised, but it requires knowledge in the form of WordNet (Miller, 1995; Fellbaum, 1998) synsets and relations as well. Thus, our algorithm can be regarded as a hybrid approach.

WSD algorithms can perform WSD at the local or at the global level. A local WSD algorithm, such as the extended Lesk measure (Lesk, 1986; Banerjee and Pedersen, 2002; Banerjee and Pedersen, 2003), is designed to assign the appropriate sense, from an existing sense inventory, for a target word in a given context window of a few words. For instance, for the word “sense” in the context “You have a good sense of humor.”, the

<sup>1</sup>Our open source Java implementation of ShotgunWSD is freely available at <http://ai.fmi.unibuc.ro/Home/Software>.

sense that corresponds to the *natural ability* rather than the *meaning of a word* or the *sensation* should be chosen by a WSD algorithm. Rather more generally, a global WSD approach aims to choose the appropriate sense for each ambiguous word in a text document. The straightforward solution is the exhaustive evaluation of all sense combinations (configurations) (Patwardhan et al., 2003), but the time complexity is exponential with respect to the number of words in the text, as also noted by Schwab et al. (2012), Schwab et al. (2013a). Indeed, the brute-force (BF) solution quickly becomes impractical for windows of more than a few words. Hence, several approximation methods have been proposed for the global WSD task in order to overcome the exponential growth of the search space (Schwab et al., 2012; Schwab et al., 2013a). Our algorithm is designed to perform global WSD by combining multiple local sense configurations that are obtained using BF search, thus avoiding BF search on the whole text. A local WSD algorithm is employed to build the local sense configurations. We alternatively use two methods at this step, namely the extended Lesk measure (Banerjee and Pedersen, 2002; Banerjee and Pedersen, 2003) and an approach based on deriving sense embeddings from word embeddings (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013). Both local WSD approaches are based on WordNet synsets and relations.

Our global WSD algorithm can be briefly described in a few steps. In the first step, context windows of a fixed length  $n$  are selected from the document, and for each context window the top scoring sense configurations constructed by BF search are kept for the second step. The retained sense configurations are merged based on suffix and prefix matching. The configurations obtained so far are ranked by their length (the longer, the better), and the sense of each word is given by a majority vote on the top  $k$  configurations that cover the respective word. Compared to other state-of-the-art bio-inspired methods (Schwab et al., 2012; Schwab et al., 2013a), our algorithm has less parameters. Different from the other methods, these parameters ( $n$  and  $k$ ) can be intuitively tuned with respect to the WSD task. As we select a single context window at every possible location in a text, our algorithm becomes deterministic, obtaining the same global configuration for a given set

of parameters and input document. Thus, our algorithm is not affected by random chance, unlike stochastic algorithms such as Ant Colony Optimization (Lafourcade and Guinand, 2010; Schwab et al., 2012; Schwab et al., 2013a).

We have conducted experiments on SemEval 2007 (Navigli et al., 2007), Senseval-2 (Edmonds and Cotton, 2001) and Senseval-3 (Mihalcea et al., 2004) data sets in order to compare ShotgunWSD with three state-of-the-art approaches (Schwab et al., 2013a; Chen et al., 2014; Bhingardive et al., 2015) along with the Most Common Sense (MCS) baseline<sup>2</sup>, which is considered as the strongest baseline in WSD (Agirre and Edmonds, 2006). The empirical results show that our algorithm compares favorably to these approaches.

The rest of this paper is organized as follows. Related work on unsupervised WSD algorithms is presented in Section 2. The ShotgunWSD algorithm is described in Section 3. The experiments are given in Section 4. Finally, we draw our conclusions in Section 5.

## 2 Related Work

There is a broad range of methods designed to perform WSD (Agirre and Edmonds, 2006; Navigli, 2009; Vidhu Bhala and Abirami, 2014). The most accurate techniques are supervised (Iacobacci et al., 2016), but they require annotated training data which is not always available. In order to overcome this limitation, some researchers have proposed various unsupervised or knowledge-based WSD methods (Banerjee and Pedersen, 2002; Banerjee and Pedersen, 2003; Schwab et al., 2012; Nguyen and Ock, 2013; Schwab et al., 2013a; Schwab et al., 2013b; Chen et al., 2014; Agirre et al., 2014; Bhingardive et al., 2015). Since our approach is unsupervised and based on WordNet (Miller, 1995; Fellbaum, 1998), our focus is to present related work in the same direction. Banerjee and Pedersen (2002) extend the gloss overlap algorithm of Lesk (1986) by using WordNet relations. Patwardhan et al. (2003) proposed a brute-force algorithm for global WSD by employing the extended Lesk measure (Banerjee and Pedersen, 2002; Banerjee and Pedersen, 2003) to compute the semantic relatedness among senses in a given text. However, their BF approach is not suitable for whole text documents, because of the high computational time. More recently, Schwab

<sup>2</sup>Also known as the Most Frequent Sense baseline.

et al. (2012) have proposed and compared three stochastic algorithms for global WSD as alternatives to BF search, namely a Genetic Algorithm, Simulated Annealing, and Ant Colony Optimization. Among these, the authors (Schwab et al., 2012; Schwab et al., 2013a) have found that the Ant Colony Algorithm yields better results than the other two.

Recently, word embeddings have been used for WSD (Chen et al., 2014; Bhingardive et al., 2015; Iacobacci et al., 2016). Word embeddings are well known in the NLP community (Bengio et al., 2003; Collobert and Weston, 2008), but they have recently become more popular due to the work of Mikolov et al. (2013) which introduced the *word2vec* framework that allows to efficiently build vector representations from words. Chen et al. (2014) present a unified model for joint word sense representation and disambiguation. They use the Skip-gram model to learn word vectors. On the other hand, Bhingardive et al. (2015) use pre-trained word vectors to build sense embeddings by averaging the word vectors produced for each sense of a target word. As their goal is to find an approximation for the MCS baseline, they try to find the sense embedding that is closest to the embedding of the target word. Iacobacci et al. (2016) propose different methods through which word embeddings can be leveraged in a *supervised* WSD system architecture. Remarkably, they find that a WSD approach based on word embeddings alone can provide significant performance improvements over a state-of-the-art WSD system that uses standard WSD features.

### 3 ShotgunWSD

As also noted by Schwab et al. (2012), brute-force WSD algorithms based on semantic relatedness (Patwardhan et al., 2003) are not practical for whole text disambiguation due to their exponential time complexity. In this section, we describe a novel WSD algorithm that aims to avoid this computational issue. Our algorithm is inspired by the Shotgun genome sequencing technique (Anderson, 1981) which is used in genetics research to obtain long DNA strands. For example, Istrail et al. (2004) have used this technique to assemble the human genome. Before a long DNA strand can be read, Shotgun sequencing needs to create multiple copies of the respective strand. Next, DNA is randomly broken

down into many small segments called *reads* (usually between 30 and 400 nucleotides long), by adding a restriction enzyme into the chemical solution containing the DNA. The reads can then be sequenced using Next-Generation Sequencing technology (Voelkerding et al., 2009), for example by using an Illumina (Solexa) machine (Bennett, 2004). In genome assembly, the low quality reads are usually eliminated (Patel and Jain, 2012) and the whole genome is reconstructed by assembling the remaining reads. One strategy is to merge two or more reads in order to obtain longer DNA segments, if they have a significant overlap of matching nucleotides. Because of reading errors or mutations, the overlap is usually measured using a distance measure, e.g. edit distance (Levenshtein, 1966). If a backbone DNA sequence is available, the reads are aligned to the backbone DNA before assembly, in order to find their approximate position in the DNA that needs to be reconstructed.

We next present how we adapt the Shotgun sequencing technique for the task of global WSD. We will make a few observations along the way that will lead to a simplified method, namely *ShotgunWSD*, which is formally presented in Algorithm 1. We use the following notations in Algorithm 1. An array (or an ordered set of elements) is denoted by  $X = (x_1, x_2, \dots, x_m)$  and the length of  $X$  is denoted by  $|X| = m$ . Arrays are considered to be indexed starting from position 1, thus  $X[i] = x_i, \forall i \in \{1, 2, \dots, m\}$ .

Our goal is to find a configuration of senses  $G$  for the whole document  $D$ , that matches the ground-truth configuration produced by human annotators. A *configuration of senses* is simply obtained by assigning a sense to each word in a text. In this work, the senses are selected from WordNet (Miller, 1995; Fellbaum, 1998), according to steps 7-8 of Algorithm 1. Naturally, we will consider that the sense configuration of the whole document corresponds to the long DNA strand that needs to be sequenced. In this context, sense configurations of short context windows (less than 10 words) will correspond to the short DNA reads. A crucial difference here is that we know the location of the context windows in the whole document from the very beginning, so our task will be much easier compared to Shotgun sequencing (we do not need to use a backbone solution for the alignment of short sense configurations). At every possible location in the text document (step

```
1 Input:
2  $D = (w_1, w_2, \dots, w_m)$  – a document of  $m$  words denoted by  $w_i, i \in \{1, 2, \dots, m\}$ ;
3  $n$  – the length of the context windows ( $1 < n < m$ );
4  $k$  – the number of sense configurations considered for the voting scheme ( $k > 0$ );

5 Initialization:
6  $c \leftarrow 20$ ;
7 for  $i \in \{1, 2, \dots, m\}$  do
8    $S_{w_i} \leftarrow$  the set of WordNet synsets of  $w_i$ ;
9  $S \leftarrow \emptyset$ ;
10  $G \leftarrow (0, 0, \dots, 0)$ , such that  $|G| = m$ ;

11 Computation:
12 for  $i \in \{1, 2, \dots, m - n + 1\}$  do
13    $C_i \leftarrow \emptyset$ ;
14   while did not generate all sense configurations do
15      $C \leftarrow$  a new configuration  $(s_{w_i}, s_{w_{i+1}}, \dots, s_{w_{i+n-1}}), s_{w_j} \in S_{w_j}, \forall j \in \{i, \dots, i + n - 1\}$ , such that  $C \notin C_i$ ;
16      $r \leftarrow 0$ ;
17     for  $p \in \{1, 2, \dots, n - 1\}$  do
18       for  $q \in \{p + 1, 2, \dots, n\}$  do
19          $r \leftarrow r + \text{relatedness}(C[p], C[q])$ ;
20      $C_i \leftarrow C_i \cup \{(C, i, n, r)\}$ ;
21    $C_i \leftarrow$  the top  $c$  configurations obtained by sorting the configurations in  $C_i$  by their relatedness score (descending);
22    $S \leftarrow S \cup C_i$ ;

23 for  $l \in \{\min\{4, n - 1\}, \dots, 1\}$  do
24   for  $p \in \{1, 2, \dots, |S|\}$  do
25      $(C_p, i_p, n_p, r_p) \leftarrow$  the  $p$ -th component of  $S$ ;
26     for  $q \in \{1, 2, \dots, |S|\}$  do
27        $(C_q, i_q, n_q, r_q) \leftarrow$  the  $q$ -th component of  $S$ ;
28       if  $i_q - i_p < n_p$  and  $i_p \neq i_q$  then
29          $t \leftarrow \text{true}$ ;
30         for  $x \in \{1, \dots, l\}$  do
31           if  $C_p[n_p - l + x] \neq C_q[x]$  then
32              $t \leftarrow \text{false}$ ;
33         if  $t = \text{true}$  then
34            $C_{p \oplus q} \leftarrow (C_p[1], C_p[2], \dots, C_p[n_p], C_q[l + 1], C_q[l + 2], \dots, C_q[n_q])$ ;
35            $r_{p \oplus q} \leftarrow r_p$ ;
36           for  $i \in \{1, 2, \dots, n_p + n_q - l\}$  do
37             for  $j \in \{l + 1, l + 2, \dots, n_q\}$  do
38                $r_{p \oplus q} \leftarrow r_{p \oplus q} + \text{relatedness}(C_{p \oplus q}[i], C_q[j])$ ;
39            $S \leftarrow S \cup \{(C_{p \oplus q}, i_p, n_p + n_q - l, r_{p \oplus q})\}$ ;

40 for  $j \in \{1, 2, \dots, m\}$  do
41    $Q_j \leftarrow \{(C, i, d, r) \mid (C, i, d, r) \in S, j \in \{i, i + 1, \dots, i + d - 1\}\}$ ;
42    $Q_j \leftarrow$  the top  $k$  configurations obtained by sorting the configurations in  $Q_j$  by their length (descending);
43    $ps_{w_j} \leftarrow$  the predominant sense obtained by using a majority voting scheme on  $Q_j$ ;
44    $G[j] \leftarrow ps_{w_j}$ ;

45 Output:
46  $G = (ps_{w_1}, ps_{w_2}, \dots, ps_{w_m}), ps_{w_i} \in S_{w_i}, \forall i \in \{1, 2, \dots, m\}$  – the global configuration of senses returned by the algorithm.
```

---

12), we select a window of  $n$  words. The window length  $n$  is an external parameter of our algorithm that can be tuned for optimal results. For each context window we will compute all possible sense configurations (steps 14-15). A score is assigned to each sense configuration by using the semantic relatedness between word senses (steps 16-19), as described by Patwardhan et al. (2003).

We alternatively employ two measures to compute the semantic relatedness, one is the extended Lesk measure (Banerjee and Pedersen, 2002; Banerjee and Pedersen, 2003) and the other is a simple approach based on deriving sense embeddings from word embeddings (Mikolov et al., 2013). Both methods are described in Section 3.1. We will keep the top scoring sense configurations (step 21)

for the assembly phase (steps 23-39). In step 21, we use an internal parameter  $c$  in order to determine exactly how many sense configurations are kept per context window. Another important remark is that we assume that the BF algorithm used to obtain sense configurations for short windows does not produce output errors, so it is not necessary to use a distance measure in order to find overlaps for merging configurations. We simply check if the suffix of a former configuration coincides with the prefix of a latter configuration in order to join them together (steps 29-33). The length  $l$  of the suffix and the prefix that get overlapped needs to be greater than zero, so at least one sense choice needs to coincide. We gradually consider shorter and shorter suffix and prefix lengths starting with  $l = \min\{4, n - 1\}$  (step 23). Sense configurations are assembled in order to obtain longer configurations (step 34), until none of the resulted configurations can be further merged together. When merging, the relatedness score of the resulting configuration needs to be recomputed (steps 36-38), but we can take advantage of some of the previously computed scores (step 35). Longer configurations indicate that there is an agreement (regarding the chosen senses) that spans across a longer piece of text. In other words, longer configurations are more likely to provide correct sense choices, since they inherently embed a higher degree of agreement among senses. After the configuration assembly phase, we start assigning the sense to each word in the document (step 40). Based on the assumption that longer configurations provide better information, we build a ranked list of sense configurations for each word in the document (step 42). Naturally, for a given word, we only consider the configurations that contain the respective word (step 41). Finally, the sense of each word is given by a majority vote on the top  $k$  configurations from its ranked list (steps 43-44). The number of sense configurations  $k$  is an external parameter of our approach, and it can be tuned for optimal results.

### 3.1 Semantic Relatedness

For a sense configuration of  $n$  words, we compute the semantic relatedness between each pair of selected senses. We use two different approaches for computing the relatedness score and both of them are based on WordNet semantic relations. In this context, we essentially need to compute the se-

mantic relatedness of two WordNet synsets. For each synset we build a disambiguation vocabulary by extracting words from the WordNet lexical knowledge base, as follows. Starting from the synset itself, we first include all the synonyms that form the respective synset along with the content words of the gloss (examples included). We also include into the disambiguation vocabulary words indicated by specific WordNet semantic relations that depend on the part-of-speech of the word. More precisely, we have considered hyponyms and meronyms for nouns. For adjectives, we have considered similar synsets, antonyms, attributes, pertainyms and related (see also) synsets. For verbs, we have considered troponyms, hypernyms, entailments and outcomes. Finally, for adverbs, we have considered antonyms, pertainyms and topics. These choices have been made because previous studies (Banerjee and Pedersen, 2003; Hristea et al., 2008) have come to the conclusion that using these specific relations for each part-of-speech seems to provide useful information in the WSD process. The disambiguation vocabulary generated by the WordNet feature selection described so far needs to be further processed in order to obtain the final vocabulary. The first processing step is to eliminate the stopwords. The remaining words are stemmed using the Porter stemmer algorithm (Porter, 1980). The resulted stems represent the final set of features that we use to compute the relatedness score between two synsets. The two measures that we employ for computing the relatedness score are described next.

#### 3.1.1 Extended Lesk Measure

The original Lesk algorithm (Lesk, 1986) only considers one word overlaps among the glosses of a target word and those that surround it in a given context. Banerjee and Pedersen (2002) note that this is a significant limitation because dictionary glosses tend to be fairly short and they fail to provide sufficient information to make fine grained distinctions required for WSD. Therefore, Banerjee and Pedersen (2003) introduce a measure that takes as input two WordNet synsets and returns a numeric value that quantifies their degree of semantic relatedness by taking into consideration the glosses of related WordNet synsets as well. Moreover, when comparing two glosses, the extended Lesk measure considers overlaps of multiple consecutive words, based on the assumption that the

longer the phrase, the more representative it is for the relatedness of the two synsets. Given two input glosses, the longest overlap between them is detected and then replaced with a unique marker in each of the two glosses. The resulted glosses are then again checked for overlaps, and this process continues until there are no more overlaps. The lengths of the detected overlaps are squared and added together to obtain the score for the given pair of glosses. Depending on the WordNet relations used for each part-of-speech, several pairs of glosses are compared and summed up together to obtain the final relatedness score. However, if the two words do not belong to the same part-of-speech, we only use their WordNet glosses and examples. Further details regarding this approach are provided by Banerjee and Pedersen (2003).

### 3.1.2 Sense Embeddings

A simple approach based on word embeddings is employed to measure the semantic relatedness of two synsets. *Word embeddings* (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013) represent each word as a low-dimensional real valued vector, such that related words reside in close vicinity in the generated space. We have used the pre-trained word embeddings computed by the *word2vec* toolkit (Mikolov et al., 2013) on the Google News data set using the Skip-gram model. The pre-trained model contains 300-dimensional vectors for 3 million words and phrases.

The relatedness score between two synsets is computed as follows. For each word in the disambiguation vocabulary that represents a synset, we compute its word embedding vector. Thus, we obtain a cluster of word embedding vectors for each given synset. Sense embeddings are then obtained by computing the centroid of each cluster as the median of all the word embeddings in the respective cluster. We can naturally assume that some of the words in the cluster may actually be outliers. Thus, we believe that using the (geometric) median instead of the mean is more appropriate, as the mean is largely influenced by outliers. Finally, the semantic relatedness of two synsets is simply given by the cosine similarity between their cluster centroids.

It is important to note that an approach based on the mean of word vectors to construct sense embeddings is used by Bhingardive et al. (2015), but with a slightly different purpose than ours, namely

to determine which synset better fits a target word, assuming that this synset should correspond to the most common sense of the respective word. As such, they completely disregard the context of the target word. Different from their approach, we are trying to find how related two synsets of distinct words that appear in the same context window are. Furthermore, the empirical results presented in Section 4 show that our approach yields better performance than the MCS estimation method of Bhingardive et al. (2015), thus putting a greater gap between the two methods.

## 4 Experiments and Results

### 4.1 Data Sets

We compare our global WSD algorithm with several state-of-the-art unsupervised WSD methods using the same test data as in the works presenting them.

We first compare ShotgunWSD with two state-of-the-art approaches (Schwab et al., 2013a; Chen et al., 2014) and the MCS baseline, on the SemEval 2007 coarse-grained English all-words task (Navigli et al., 2007). The SemEval 2007 coarse-grained English all-words data set<sup>3</sup> is composed of 5 documents that contain 2269 ambiguous words (1108 nouns, 591 verbs, 362 adjectives, 208 adverbs) altogether. We also compare our approach with the MCS estimation method of Bhingardive et al. (2015), the MCS baseline and the extended Lesk algorithm (Torres and Gelbukh, 2009) on the Senseval-2 English all-words (Edmonds and Cotton, 2001) and the Senseval-3 English all-words (Mihalcea et al., 2004) data sets. The Senseval-2 data set<sup>4</sup> is composed of 3 documents that contain 2473 ambiguous words (1136 nouns, 581 verbs, 457 adjectives, 299 adverbs), while the Senseval-3 data set<sup>4</sup> is composed of 3 documents that contain 2081 ambiguous words (951 nouns, 751 verbs, 364 adjectives, 15 adverbs).

### 4.2 Parameter Tuning

As Schwab et al. (2013a), we tune our parameters on the first document of SemEval 2007. We first set the value of the internal parameter  $c$  to 20 without specifically tuning it. Using this value for  $c$  gives us a reasonable amount of configuration choices for the subsequent steps, without using too

<sup>3</sup><http://nlp.cs.swarthmore.edu/semeval/tasks/index.php>

<sup>4</sup><http://web.eecs.umich.edu/~mihalcea/downloads.html>

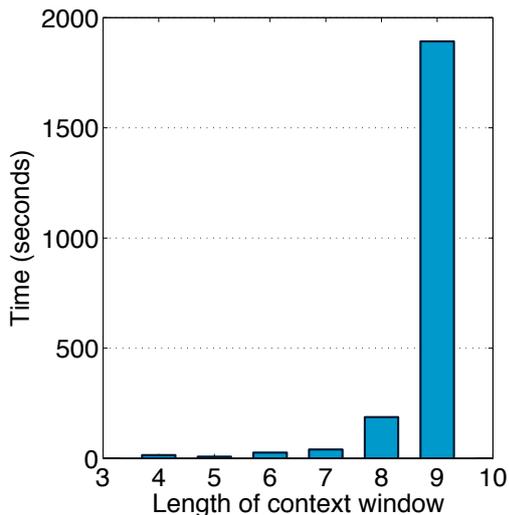

Figure 1: The running times (in seconds) of ShotgunWSD based on sense embeddings, on the first document of SemEval 2007, using various context window lengths  $n \in \{4, 5, 6, 7, 8, 9\}$ . The reported times were measured on a computer with Intel Core i7 3.4 GHz processor and 16 GB of RAM using a single Core.

much space and time. For tuning the parameters  $n$  and  $k$ , we employ sense embeddings for computing the semantic relatedness score. We begin by tuning the length of the context windows  $n$ . It is important to note that the upper bound accuracy of ShotgunWSD is given by the brute-force algorithm that explores every possible configuration of senses. Intuitively, we will get closer and closer to this upper bound as we use longer and longer context windows. However, the main decision factor is the time, which grows exponentially with respect to the length of the windows. Figure 1 illustrates the time required by our algorithm to disambiguate the first document in SemEval 2007, for increasing window lengths in the range 4-9. The algorithm runs in about 15 seconds for  $n = 4$  and in about 1892 seconds for  $n = 9$ , so it becomes nearly 120 times slower from using context windows of length 4 to context windows of length 9. As the algorithm runs in a reasonable amount of time for  $n = 8$  (187 seconds), we choose to use context windows of 8 words throughout the rest of the experiments.

The parameter  $k$  has almost no influence on the running time of the algorithm, so we tune this parameter with respect to the  $F_1$  score obtained on the first document of SemEval 2007. We try out several values of  $k$  in the set  $\{1, 3, 5, 10, 15, 20\}$

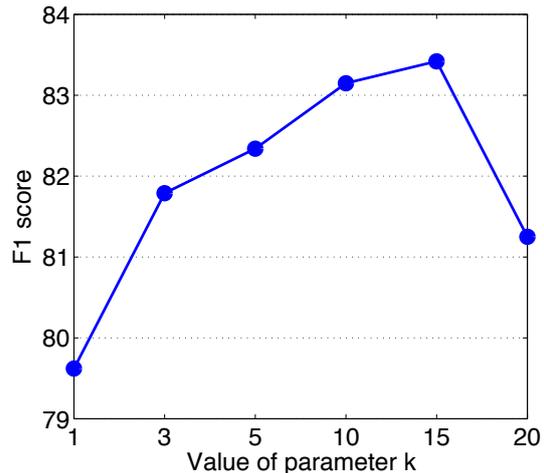

Figure 2: The  $F_1$  scores of ShotgunWSD based on sense embeddings on the first document of SemEval 2007, using different values for the parameter  $k \in \{1, 3, 5, 10, 15, 20\}$ .

and the results are shown in Figure 2. The best  $F_1$  score (83.42%) is obtained for  $k = 15$ . Hence, we choose to assign the final sense for each word using a majority vote based on the top 15 configurations.

To summarize, all the results of ShotgunWSD on SemEval 2007, Senseval-2 and Senseval-3 are reported using  $n = 8$  and  $k = 15$ . We hereby note that better results in terms of accuracy can probably be obtained by trying out other values for these parameters on each data set. However, tuning the parameters on a single document from SemEval 2007 ensures that we avoid overfitting to a particular data set.

### 4.3 Results on SemEval 2007

We first conduct a comparative study on the SemEval 2007 coarse-grained English all-words task in order to evaluate our ShotgunWSD algorithm. As described in Section 3.1, we use two different approaches for computing the semantic relatedness scores, namely extended Lesk and sense embeddings. We compare our two variants of ShotgunWSD with several algorithms presented in (Schwab et al., 2012; Schwab et al., 2013a), namely a Genetic Algorithm, Simulated Annealing, and Ant Colony Optimization. We also include in the comparison an approach based on sense embeddings (Chen et al., 2014). All the approaches comprised in the evaluation are unsupervised. We compare them with the MCS baseline which is based on human annotations. The  $F_1$

Method	$F_1$ Score
Most Common Sense	78.89%
Genetic Algorithms (Schwab et al., 2013a)	74.53%
Simulated Annealing (Schwab et al., 2013a)	75.18%
Ant Colony (Schwab et al., 2013a)	79.03%
S2C Unsupervised (Chen et al., 2014)	75.80%
ShotgunWSD + Extended Lesk	79.15%
ShotgunWSD + Sense Embeddings	79.68%

Table 1: The  $F_1$  scores of various unsupervised state-of-the-art WSD approaches, compared to the  $F_1$  scores of ShotgunWSD based on the extended Lesk measure and ShotgunWSD based on sense embeddings, on the SemEval 2007 coarse-grained English all-words task. The results reported for both ShotgunWSD variants are obtained for windows of  $n = 8$  words and a majority vote on the top  $k = 15$  configurations.

scores on SemEval 2007 are presented in Table 1. Among the state-of-the-art methods, it seems that the Ant Colony Optimization algorithm, based on a weighted voting scheme (Schwab et al., 2013a), is the only method able to surpass the MCS baseline. The unsupervised S2C approach gives lower results than the MCS baseline, but Chen et al. (2014) report better results in a semi-supervised setting. Both variants of ShotgunWSD yield better results than the MCS baseline (78.89%) and the Ant Colony Optimization algorithm (79.03%). Indeed, we obtain an  $F_1$  score of 79.15% when using the extended Lesk measure and an  $F_1$  score of 79.68% when using sense embeddings. We can also point out that ShotgunWSD gives slightly better results when sense embeddings are used instead of the extended Lesk method.

An important remark is that we have tuned the parameter  $k$  on the first document included in the test set, following the same evaluation procedure as Schwab et al. (2013a). Although this brings us to a fair comparison with Schwab et al. (2013a), it might also raise suspicions of overfitting the parameter  $k$  to the test set. Hence, we have tested all values of  $k$  in  $\{1, 3, 5, 10, 15, 20\}$  for ShotgunWSD based on word embeddings, and we have always obtained results above 79%, with the top score of 79.77% for  $k = 10$ .

#### 4.4 Results on Senseval-2

We compare the two alternative forms of ShotgunWSD with the MCS baseline, the MCS estimation method of Bhingardive et al. (2015) and the extended Lesk measure (Torres and Gelbukh,

Method	$F_1$ Score
Most Common Sense	60.10%
MCS Estimation (Bhingardive et al., 2015)	52.34%
Extended Lesk (Torres and Gelbukh, 2009)	54.60%
ShotgunWSD + Extended Lesk	55.78%
ShotgunWSD + Sense Embeddings	57.55%

Table 2: The  $F_1$  scores of an unsupervised WSD approach and the extended Lesk measure, compared to the  $F_1$  scores of ShotgunWSD based on the extended Lesk measure and ShotgunWSD based on sense embeddings, on the Senseval-2 English all-words data set. The results reported for both ShotgunWSD approaches are obtained for windows of  $n = 8$  words and a majority vote on the top  $k = 15$  configurations.

2009) on the Senseval-2 English all-words data set. As shown in Table 2, the ShotgunWSD based on sense embeddings obtains an  $F_1$  score that is almost 5% better than the  $F_1$  score of Bhingardive et al. (2015), while the ShotgunWSD based on extended Lesk gives an  $F_1$  score that is around 1% better than the  $F_1$  score reported by Torres and Gelbukh (2009). It is important to note that Torres and Gelbukh (2009) apply the extended Lesk measure by performing the brute-force search at the sentence level, hence it is not surprising that we are able to obtain better results. However, our best ShotgunWSD approach (57.55%) is still under the MCS baseline (60.10%).

#### 4.5 Results on Senseval-3

Method	$F_1$ Score
Most Common Sense	62.30%
MCS Estimation (Bhingardive et al., 2015)	43.28%
Extended Lesk (Torres and Gelbukh, 2009)	49.60%
ShotgunWSD + Extended Lesk	57.89%
ShotgunWSD + Sense Embeddings	59.82%

Table 3: The  $F_1$  scores of an unsupervised WSD approach and the extended Lesk measure, compared to the  $F_1$  scores of ShotgunWSD based on the extended Lesk measure and ShotgunWSD based on sense embeddings, on the Senseval-3 English all-words data set. The results reported for both ShotgunWSD approaches are obtained for windows of  $n = 8$  words and a majority vote on the top  $k = 15$  configurations.

We also compare the two variants of ShotgunWSD with the MCS baseline, the MCS estimation method of Bhingardive et al. (2015) and the extended Lesk measure (Torres and Gelbukh, 2009)

on the Senseval-3 English all-words data set. The  $F_1$  scores are presented in Table 3. The empirical results show that both ShotgunWSD variants give considerably better results compared to the MCS estimation method of Bhingardive et al. (2015). By using sense embeddings in a completely different way than Bhingardive et al. (2015), we are able to report an  $F_1$  score of 59.82%, which is much closer to the MCS baseline (62.30%). With an  $F_1$  score of 57.89%, the ShotgunWSD based on the extend Lesk measure brings an improvement of 8% over the extended Lesk algorithm applied at the sentence level (Torres and Gelbukh, 2009).

#### 4.6 Discussion

Considering all the experiments, we can conclude that ShotgunWSD gives better results (around 1%) when sense embeddings are used instead of the extended Lesk method. On one of the data sets, ShotgunWSD yields better performance than the MCS baseline. It is important to underline that the strong MCS baseline cannot be used in practice, since human input is required to indicate which sense of a word is the most frequent in a given text (a word's dominant sense will vary across domains and text genres). Corpora used for the evaluation of WSD methods usually contain this kind of annotations, but the MCS baseline will not work outside the annotated data. Therefore, we consider important even slightly outperforming the MCS baseline. Overall, our algorithm compares favorably to other state-of-the-art unsupervised WSD methods (Schwab et al., 2013a; Chen et al., 2014; Bhingardive et al., 2015) and to the extended Lesk measure (Banerjee and Pedersen, 2002; Torres and Gelbukh, 2009).

Regarding the performance of our algorithm, an interesting question that arises is how much does the assembly phase help. We look to investigate this further in future work, but we can carry out a small experiment to provide a quick answer to this question. We consider the ShotgunWSD variant based on sense embeddings without changing its parameters, and we remove the assembly phase completely. Therefore, the algorithm will no longer produce configurations of length greater than 8, as the parameter  $n$  is set to 8. We have evaluated this stub algorithm on SemEval 2007 and we have obtained a lower  $F_1$  score (77.61%). This indicates that the assembly phase in Algorithm 1 boosts the performance by nearly 2%. More ex-

periments are required to make sure that the performance boost is consistent across data sets.

## 5 Conclusions and Future Work

In this paper, we have introduced a novel unsupervised global WSD algorithm inspired by the Shotgun genome sequencing technique (Anderson, 1981). Compared to other bio-inspired WSD methods (Schwab et al., 2012; Schwab et al., 2013a), our algorithm has only two parameters. Furthermore, our algorithm is deterministic, obtaining the same result for a given set of parameters and input document. The empirical results indicate that our algorithm can obtain better performance than other state-of-the-art unsupervised WSD methods (Schwab et al., 2013a; Chen et al., 2014; Bhingardive et al., 2015). Although the fact that ShotgunWSD is deterministic brings several advantages, it is also a key difference from our source of inspiration, Shotgun sequencing, which is a non-deterministic technique.

In future work, we aim to investigate if training sense embeddings instead of deriving them from pre-trained word embeddings could yield better accuracy. Another promising direction is to compute the semantic relatedness of sense configurations based on the sum of sense tuples instead of sense pairs. An approach to combine the two semantic relatedness approaches independently used by ShotgunWSD, namely the extended Lesk measure and sense embeddings, is also worth exploring in the future.

## Acknowledgments

We thank the reviewers for their helpful suggestions. We also thank Alexandru I. Tomescu from the University of Helsinki for insightful comments about the Shotgun sequencing technique.

# LanideNN: Multilingual Language Identification on Character Window

Tom Kocmi and Ondřej Bojar

Charles University, Faculty of Mathematics and Physics

Institute of Formal and Applied Linguistics

{kocmi,bojar}@ufal.mff.cuni.cz

## Abstract

In language identification, a common first step in natural language processing, we want to automatically determine the language of some input text. Monolingual language identification assumes that the given document is written in one language. In multilingual language identification, the document is usually in two or three languages and we just want their names. We aim one step further and propose a method for textual language identification where languages can change arbitrarily and the goal is to identify the spans of each of the languages.

Our method is based on Bidirectional Recurrent Neural Networks and it performs well in monolingual and multilingual language identification tasks on six datasets covering 131 languages. The method keeps the accuracy also for short documents and across domains, so it is ideal for off-the-shelf use without preparation of training data.

## 1 Introduction

The World Wide Web is an ever growing source of textual data, especially data generated by web users. As more people get access to the web, more languages and dialects start to appear and need to be processed. In order to be able to use such data for further natural language processing (NLP) tasks, we need to know in which languages they were written. Language identification is thus a key component for both building various NLP resources from the web and also for running many web services.

Techniques of language identification can rely on handcrafted rules, usually of high precision but

low coverage, or data-driven methods that learn to identify languages based on sample texts of sufficient quantity.

In this paper, we present a data-driven method for language identification based on bidirectional recurrent neural networks called *LanideNN* (language identification by neural networks, NN). The model is trained on character sliding window of input texts with the goal of assigning a language to each character. We show that the method is applicable for a large number of languages and across text domains without any adaptation and that it performs well in monolingual (one language per document) as well as multilingual (a few languages per document) language identification tasks. Also, the performance does not drop with shorter texts.

The paper is structured as follows. In Section 2, we briefly review current approaches to language identification. Section 3 introduces our method, including the technical details of the neural network architecture. For the training of our model, we collect and manually clean a new dataset, as described in Section 4. The model is evaluated on standard test sets for monolingual (Section 5) as well as multilingual (Section 6) language identification. Section 7 illustrates the behavior of our method in the motivating setting: identifying languages in short texts. We conclude and summarize our plans in Section 8.

## 2 Related Work

Of the many possible approaches to language identification Hughes et al. (2006), character  $n$ -gram statistics are among the most popular ones. Cavnar et al. (1994) were probably the first; they used the 300 most frequent character  $n$ -grams (with  $n$  ranging from 1 to 5, as is also typically used in other works). All the  $n$ -gram-based ap-

proaches differ primarily in the calculation of the distance between the  $n$ -gram profile of the training and test text (Selamat, 2011; Yang and Liang, 2010), or by using additional features on top of the  $n$ -gram profiles (Padma et al., 2009; Carter et al., 2013). One of the fairly robust definitions of the distance (or similarity) was proposed by Choong et al. (2009) who simply check the proportion of  $n$ -gram types seen in the tested document of the most frequent  $n$ -gram types extracted from training documents for each language. The highest-scoring language is then returned.

Hughes et al. (2006) mention a number of freely available tools at that time. Since then, one aspect of the tools became also important: the number of languages covered.

The language identification tool CLD2<sup>1</sup> by Google detects 80 languages and uses a Naive Bayes classifier, treating specifically unambiguous scripts such as Greek and using either character unigrams (Han and similar scripts) or fourgrams.

Another popular tool is Langid.py by Lui and Baldwin (2012), covering 97 languages out of the box. Langid.py relies on Naive Bayes classifier with a multinomial event model and mixture of byte  $n$ -grams for training. The tool includes tokenization and fast feature extraction using Aho-Corasick string matching.

To our knowledge, and also according to the survey by Garg et al. (2014), neural networks have not been used often for language identification so far. One exception is Al-Dubaei et al. (2010), who combine a feed-forward network classifier with wavelet transforms of feature vectors to identify English and Arabic from the Unicode representation of words, sentences or whole documents. The benefit of NN in this setting is not very clear to us because English and Arabic can be distinguished by the script. During writing of this paper, we have found a new pre-print paper (Jaech et al., 2016) which handles language identification with NN. Specifically, they employ Convolutional Neural Networks followed by Recurrent Neural Networks. Their approach labels text on the word level, which is problematic in languages without clear word delimiters. In comparison with our model, they need to pre-process the data and break long words into smaller chunks, whereas we simply use text without any preprocessing.

In practice, several tools are often used at once,

<sup>1</sup><https://github.com/CLD2Owners/cld2>

with some form of majority voting. For example, Twitter internal language detector uses their in-house tool along with CLD2 and Langid.py, and this triple agreement is reported to make less than 1% of errors.<sup>2</sup>

Multilingual language identification, i.e. identification of the set of languages used in a document, is a less common task, explored e.g. by Lui et al. (2014) who use a generative mixture model on multilingual documents and establish the relative proportion of languages used. Character  $n$ -grams again serve as features, selected by information gain.

Solorio et al. (2014) organized a shared task in language identification at the word level. This matches our aim, but the task included only four language pairs and more importantly, the dataset was collected from Twitter and for copyright reasons it is not available any more.

### 3 Proposed Method

The method we propose is designed for short text without relying on document boundaries. Obviously, if documents are known and if they can be assumed to be monolingual, this additional knowledge should not be neglected. For the long term, we however aim at a streamlined processing of noisy data genuinely appearing in multilingual environments. For instance, our method could support the study of switching of languages (“code switching”) in e-mails or other forms of conversation, or to analyse various online media such as Twitter, see e.g. Montes-Alcalá (2007) or Solorio et al. (2014).

Our model takes source letters as input and provides a language label for each of them. Whenever we need to recognize the language of a document, we take the language assigned by our model to the majority of letters.

The goal of attributing a language tag to the smallest text units is one of the reasons why we decided to use neural networks and designed the model to provide a prediction at every time step without much overhead.

In the rest of this section, we explain the architecture and training methods of the model.

<sup>2</sup><https://blog.twitter.com/2015/evaluating-language-identification-performance>

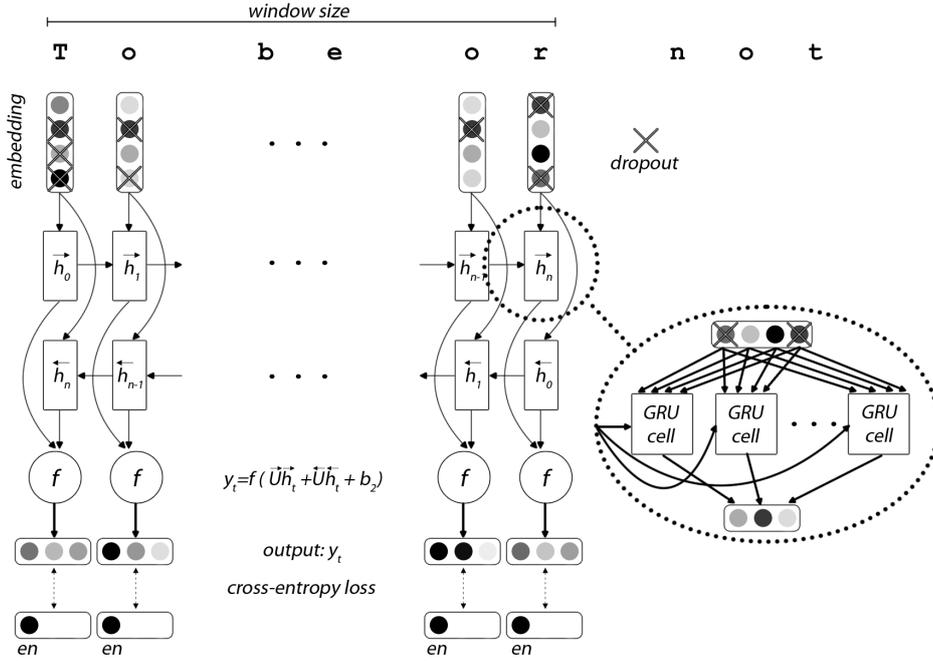

Figure 1: Illustration of our model LanideNN.

### 3.1 Bidirectional Recurrent Neural Networks

A recurrent neural network *RNN* (Elman, 1990) is a variant of neural networks with recurrent connections in time. In principle, the history information available to an RNN is not limited (subject to a processing window, if used), so the network can condition its output on features from a long distance. The LSTM, one of the variants of RNN, makes it particularly suitable for sequential prediction tasks with arbitrary time dependencies, as shown by Hochreiter and Schmidhuber (1997).

In this work, we use the Elman-type network, where the hidden layer  $h_t$  at a time step  $t$  is computed based on the current input layer  $x_t$  and the previous state of the hidden layer  $h_{t-1}$ . The output  $y_t$  is then derived from the  $h_t$  by applying the softmax function  $f$ . More formally:

$$h_t = \tanh(Wx_t + Vh_{t-1} + b_1) \quad (1)$$

$$y_t = f(Uh_t + b_2) \quad (2)$$

where  $U$ ,  $V$  and  $W$  are connection weights to be computed in training time and bias vectors  $b_1$  and  $b_2$ .

With the above definition, the RNN has access only to information preceding the current position in the text. In our setting, the rest of the text (in a fixed-size window) is available, so we want to allow the model to use also future information, i.e.

letters following the currently examined one. We therefore define a second RNN which reads the input from the end to the beginning, changing the definition to:

$$\vec{h}_t = \tanh(\vec{W}x_t + \vec{V}\vec{h}_{t-1} + \vec{b}_1) \quad (3)$$

$$\overleftarrow{h}_t = \tanh(\overleftarrow{W}x_t + \overleftarrow{V}\overleftarrow{h}_{t+1} + \overleftarrow{b}_1) \quad (4)$$

$$y_t = f(\overrightarrow{U}\vec{h}_t + \overleftarrow{U}\overleftarrow{h}_t + b_2) \quad (5)$$

where the left and right arrows indicate the direction of network.

The simple unit with only tanh non-linearity is difficult to train and therefore we have selected the Gated Recurrent Unit (GRU), recently proposed by Cho et al. (2014), as a replacement. We also considered Long Short-Term Memory cells (LSTM) but they achieved slightly worse results in our setting. This changes equations (1), (3) and (4). The proper equations for the GRU can be found in Cho et al. (2014).

The model outputs a probability distribution over all language tags. In order to determine the language of a character, we take the tag with the maximum value.

The complete model is sketched in Figure 1.

### 3.2 Training, Embeddings and Dropout

We train the model using the first-order stochastic gradient descent method Adam (Kingma and Ba, 2015). Our training criterion is the cross-entropy loss function<sup>3</sup>.

We represent each Unicode character using an  $e$ -dimensional real valued vector, analogously to word embeddings of Collobert et al. (2011). The character embeddings are initialized randomly and are trained together with the rest of the network.

To prevent overfitting, we use dropout (Srivastava et al., 2014) during model training on the character embedding layer<sup>4</sup>. The key idea is to randomly drop (avoid updating of) connections. This prevents neurons from co-adapting too much, i.e. starting to depend on outputs of other neurons too much, which is a typical symptom of overfitting to training data.

### 3.3 Model Design

Our model operates on a window of 200 characters of input text, i.e. individual letters, encoded in Unicode. Each character corresponds to one time step of the BiRNN in the respective direction, see Figure 1. The model classifies each character separately, but quickly learns to classify neighbouring characters with the same label.

For documents longer than the window size, we simply move to the next window without any overlap. The last window (or the only window if the document were too short) is filled with a padding character, so the network always works on windows of the same size.

We set  $e$ , the size of the embedding layer, to 200. The BiRNN uses a single hidden layer of 500 GRU cells for each direction.

The main model was trained for over 530,000 steps (each step is the processing of one batch of inputs) on a single core of the GeForce GTX Titan Z GPU. The training took around 5 days. The stopping criterion for the training was the error on a development set.

## 4 Training Data

Our goal is to develop an off-the-shelf language recognizer, with no need for retraining by the user and covering as many languages as possible. Finding suitable training data is thus an important part

<sup>3</sup>We set the learning rate to 0.0001 and train with the batch size of 64 windows.

<sup>4</sup>We set the dropout to the probability of 0.5 as customary.

Figure 2: The 131 languages (and HTML) recognized by our system.

of the endeavour.

We start from Wikipedia, as crawled and converted to a large multilingual corpus W2C by Majliš and Žabokrtský (2012). W2C contains 106 languages but we had to exclude a few of them<sup>5</sup> because they contained too little non-repeating text.

We then focussed on finding corpora with at least some languages not covered by the already collected data. Those corpora were added whole, including languages that we already had, to improve the variety of our collection. We made use of the following ones:

**Tatoeba**<sup>6</sup> is a collection of simple sentences for language learners. Tatoeba contains sentences in 307 languages, but for most languages it has only a few hundred sentences.

**Leipzig corpora collection** (Quasthoff et al., 2006) covers 220 languages with newspaper text and other various texts collected from the web.

**EMILLE** (Baker et al., 2002) contains texts in 14 Indian languages and English.

**Haitian Creole training data** (Callison-Burch et al., 2011) were prepared by the organizers of WMT11 shared task on machine translation of SMS messages sent to an emergency hotline in the aftermath of the 2010 Haitian earthquake. We used only the official documents from the training data, not the actual SMS messages because they contained a lot of noise.

<sup>5</sup>Specifically, HAT, IDO, MGL, MRI, VOL, as identified by ISO language codes.

<sup>6</sup><http://tatoeba.org/>

Test Set	Documents	Languages	Encoding	Document Length (bytes)	Avg. # characters
EuroGov	1500	10	1	17460.5 ± 39353.4	17037.3
TCL	3174	60	12	2623.2 ± 3751.9	1686.1
Wikipedia	4963	67	1	1480.8 ± 4063.9	1314.2

Table 1: Summary of testsets for monolingual language identification.

Additionally, we wanted our tool to distinguish HTML tags in the data, since they are the most frequent markup that needs to be separated from the processed data. Therefore, we have downloaded several Github projects in HTML and collected all strings enclosed with angle brackets, as a rather permissive approximation of HTML tags. We have dropped tags which were too long and we put each tag on a separate line. We have not deduplicated them for the training set.

The cleanup of the collected data was mostly manual. We deduplicated each of the sources by dropping identical lines, regardless of what lines correspond to in the individual sources (words, phrases, sentences or even paragraphs). We inspected data files for individual languages and removed lines containing English for languages not using Latin script. We also removed Cyrillic characters from a few languages that should not contain them. This was done mostly in W2C corpora.

For the final dataset, we mixed all sources for a given language at the line level, keeping only languages with more than 500k characters in total. Since the resources for some languages were huge, we decided to set an upper bound on the number of characters per language. In order to roughly reflect the distribution of languages in the world, we divided languages into three groups based on the number speakers of the language according to Wikipedia. The first group were languages with more than 75M speakers, the second with more than 10M speakers and the third group contained the rest. For the first group, we allowed at most 10M characters in the training set, the second group was capped at 5M characters and the third group was allowed only 1M characters per language at most.<sup>7</sup>

In total, our final training set includes 131 + 1 (HTML) languages, see Figure 2.

We divide the corpus into non-overlapping training, development and test sections. We re-

<sup>7</sup>Higher-quality sources such as Tatoeba are generally smaller and since we mixed the sources by interleaving their lines, these smaller sources were likely included in full.

leased the test set <sup>8</sup> but the training part cannot be publicly released because of the restrictive permissions of some of the sources used. The test section is limited to short text. It contains 100 lines for each of the 131 languages (HTML is not included), with the average line length of 142.3 characters.

Each line of the dataset starts with an ISO-3 label of the language presented on that line. All lines were shuffled.

For training and testing, the language labels as well as all line breaks must be ignored, otherwise the model could learn to set language boundaries at the new line character. After dropping all line breaks, we obtain a multilingual text.

This way, we simulate a multilingual text and our algorithm has to learn to identify language boundaries without relying on any particular symbol. We are aware of the fact that the original segmentation of the corpora affects where these language switches are expected, and this will mostly correspond to sentence boundaries.

## 5 Monolingual Language Identification

Most of related research is focused on monolingual language identification, i.e. recognizing the single language of an input document.

We compare our method in this setting with several other algorithms on the dataset presented by Baldwin and Lui (2010). The dataset consists of 3 different test sets, each containing a different number of languages, styles and document lengths collected from different sources, see Table 1 for details:

**EuroGov** contains texts in Western European languages from European government resources.

**TCL** was extracted by the Thai Computational Linguistics Laboratory in 2005 from online news sources and the test set also contains multiple file encodings. Since our method assumes Unicode input, we converted TCL to Unicode encoding.

<sup>8</sup><https://ufal.mff.cuni.cz/tom-kocmi/lanidenn>

System	Trained on	Supported languages	EuroGov	TCL	Wikipedia
LangDetect*	Wikipedia	53	<b>.992</b> <sup>9</sup>	.818	.867
TextCat*	TextCat Dataset	75	.941	.605	.706

Langid.py*	Lui and Baldwin (2011)	97	.987	.904	<b>.913</b>
Langid.py	Lui and Baldwin (2011)	97	.987	.931	<b>.913</b>
CLD2	unknown	83	.979	.837	.854
Our model	Our dataset	<b>136</b>	.977	<b>.954</b>	.893

Table 2: Results of monolingual language identification on the Baldwin and Lui (2010) test set. Entries marked with “\*” are accuracies reported by Lui and Baldwin (2012), the rest are our measurements.

**Wikipedia** are texts collected from a Wikipedia dump.

Table 2 summarizes the accuracies of several algorithms on the three test sets. For some algorithms, we report values as presented by Lui and Baldwin (2012) without re-running<sup>9</sup>. We re-ran the Langid.py as the best algorithm out of them, and got the same results except for the TCL test-set, where we got better results than reported by Lui and Baldwin (2012). After a discussion with the authors, we believe the re-run benefited from the conversion of all texts to Unicode.

We compare our method with two top language recognizers, Langid.py and CLD2. Our model is trained on more languages and we do not restrict it to the languages included in the test set, so we may be losing on detailed dialect labels.

Despite the considerably higher number of languages covered, our model performs reasonably close to the competitors on EuroGov and Wikipedia and best on TCL.

### 5.1 Short-Text Language Identification

In order to demonstrate the ability of our method to identify language of very short texts such as tweets, search queries or user messages, we wanted to use an existing corpus, such as the one released by Twitter.<sup>10</sup> Unfortunately, the corpus contains only references to the actual tweets and most of them are no longer available. We thus have to rely on our own test set, as described in Section 4.

Results on short texts are reported in Table 3. The two other systems, Langid.py and CLD2 cover fewer languages and they were trained on texts unrelated to our collection of data. It is there-

<sup>9</sup>We should mention that LangDetect used EuroGov as a validation set, so its score on this test set is not reliable.

<sup>10</sup><https://blog.twitter.com/2015/evaluating-language-identification-performance>

System	All languages	Common languages

fore not surprising that they perform much worse when averaged over all languages.

For a fairer comparison, we report also accuracies on a restricted version of the test set that included only languages supported by all the three tested tools. Both our competitors are meant to be generally applicable, so they should (and do) perform quite well. Our system nevertheless outperforms them, reaching the accuracy of 95.5. Arguably, we can be benefitting from having trained on (different) texts from the same sources as this test set.

Table 6 lists the most frequent misclassifications of our model on our test set (unordered language pairs) of the 13100 items in the test set. The most common error is confusing Indonesian with Modern Standard Arabic, which indicates some noise in our training data rather than difficulty of separating these two languages. The following pairs are expected: Standard Estonian (ekk) vs. Estonian (est, a macro language which includes Standard Estonian), Bashkir vs. Tatar, Croatian vs. Serbian, Asturian vs. Spanish, ...

Finally, our model is trained to distinguish also

HTML as one additional language. We did not include HTML in our test corpus but to satisfy the requests of one of our reviewers, we checked the performance on our development corpus: only one Portuguese and one Yakut segment was classified as HTML and none of the 100 HTML segments were misclassified.

## 6 Multilingual Language Identification

In multilingual language identification, systems are expected to report the set of languages used in each input document. The evaluation criterion is thus macro- (M) or micro- ( $\mu$ ) averaged precision (P), recall (R) or F-measure (F).<sup>11</sup>

We evaluate our model on two existing test sets for multilingual identification, ALTW2010 shared task and WikipediaMulti. We are mainly interested in the performance of our general model, trained on all our training data, on these test sets. But since both test sets come with training data, we also retrain our model to test its in-domain performance. We limit the training of these specific models to 140,000 training steps for ALTW2010 and 75,000 steps for WikiMulti, keeping other settings identical to the main model. Each training step amounts to the processing of 64 batches of 200 letters of input. The number of steps for both

<sup>11</sup>Note that for comparability with results reported in other works, macro-averaged F-score is calculated as average over individual F-scores instead of the harmonic mean of  $P_M$  and  $R_M$ .  $F_M$  can thus fall out of the range between  $P_M$  and  $R_M$ .

tasks was established by testing the error on the development parts of the datasets.

To interpret the character-level predictions by our model for multilingual identification, we used the ALTW2010 development data to empirically set the threshold: if a language is predicted for more than 3% of characters in the document, it is considered as one of the languages of the document.

### 6.1 ALTW 2010 Shared Task

ALTW 2010 shared task (VRL, 2010) provided 10000 bilingual documents divided as follows: 8000 training, 1000 development and 1000 test documents.

The results on the 1000 test documents are in Table 4. For algorithms SEGLANG and LINGUINI, we only reproduce the results reported by Lui et al. (2014). We use the system by Lui et al. (2014) as a proxy for the comparison: we retrain their system and obtain results similar to those reported by the original authors. The differences are probably due to the Gibbs sampling used in their approach.

Some of the reported methods rely on the fact that the documents in the dataset are bilingual. Other methods, including ours, simply break the bilingual documents into the individual languages and train on this simplified training set. We indicate this by stating “ALTW2010 - mono” in Table 4.

Figure 3: Illustration of text partitioning. The black triangles indicate true boundaries of languages. The black part shows probability with which the language written in gray is detected and the gray part shows complement for the second language, since in this setup we restricted our model to use only the two languages in question. The misclassification of Italian and German as English in the last two examples may reflect increased noise in our English training data.

The main criterion of the ALTW2010 shared task was to maximize the micro-averaged F-score ( $F_\mu$ ). We see that our model trained on the ALTW2010 data outperforms all other models in this criterion ( $F_\mu$  of .965) and so does our non-adapted version, reaching  $F_\mu$  of .941.

## 6.2 WikipediaMulti

WikipediaMulti (Lui et al., 2014) is a dataset of artificially prepared multilingual documents, mixed from monolingual Wikipedia articles from 44 languages. Each of the artificial documents contains texts in  $1 \leq k \leq 5$  randomly selected languages. The average document length is 5500 bytes. The training set consists of 5000 monolingual documents, the development set consists of 5000 multilingual documents and test set consists of 1000 documents for each value of  $k$ .

Table 5 shows that our model performs well, both when trained on the provided data and when trained on our training corpus. The model trained on our dataset performs slightly worse in  $F_\mu$ , but if we simply prevent it from predicting languages

not present in the test set, the score gets on par with the adapted version, see the line labelled “restricted” in Table 5.

## 7 Text Partitioning

Figure 3 illustrates the behaviour of our model on text with mixed languages. We have selected very short (50–130 characters) and challenging segments where the languages mostly share the same script. Finding the boundary between languages written in different scripts is quite easy, as illustrated by the first example.

Only too late, we discovered that King and Abney (2013) provide a test set for word-level identification for 30 languages. We thus have to leave the evaluation of our model on this dataset for future.

## 8 Conclusion

We have developed a language identification algorithm based on bidirectional recurrent neural networks. The approach is designed for identifying

languages on a short texts, allowing to detect code switching including switches to formal markup languages like HTML.

We collected a dataset and trained our model to recognize considerably more languages than other state-of-the-art tools. Our algorithm and the trained model is provided for academic and personal use.<sup>12</sup>

Since there is no established dataset for the novel setting of text partitioning by language, we evaluated our model in several common tasks (monolingual and multilingual language identification for long and short texts) which were previously handled by separate algorithms. Our approach performs well, improving over the state of the art in several cases.

A number of things are planned: (1) improving the implementation, especially the speed of application of a trained model, (2) further extending the set of covered languages and possibly including more artificial or programming languages (e.g. JavaScript, PHP) or common formal notations (URLs, hashtags), (3) evaluating our method on the dataset by King and Abney (2013), possibly extending this dataset to include more languages, (4) training and testing the model on noisy texts like Tweets or forum posts, and (5) experimenting with other network architectures and approaches, possibly also training the model on bytes instead of Unicode characters.

## 9 Acknowledgement

This work has received funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement no. 645452 (QT21), the grant GAUK 8502/2016, and SVV project number 260 333.

This work has been using language resources developed, stored and distributed by the LINDAT/CLARIN project of the Ministry of Education, Youth and Sports of the Czech Republic (project LM2015071)

## Abstract

Most languages have no established writing system and minimal written records. However, textual data is essential for natural language processing, and particularly important for training language models to support speech recognition. Even in cases where text data is missing, there are some languages for which bilingual lexicons are available, since creating lexicons is a fundamental task of documentary linguistics. We investigate the use of such lexicons to improve language models when textual training data is limited to as few as a thousand sentences. The method involves learning cross-lingual word embeddings as a preliminary step in training monolingual language models. Results across a number of languages show that language models are improved by this pre-training. Application to Yongning Na, a threatened language, highlights challenges in deploying the approach in real low-resource environments.

## 1 Introduction

Most of the world’s languages are not actively written, even languages with an official writing system (Bird, 2011). This limits the available textual data to small quantities of phonemic transcriptions prepared by linguists. Since phonemic transcription is time-consuming, such data is scarce. This makes language modeling, which is a key tool for facilitating speech recognition of these languages, a difficult challenge. One of the touted advantages of neural network language models (NNLMs) is their ability to model sparse data (Bengio et al., 2003; Gandhe et al., 2014). However, despite the success of NNLMs

on large datasets (Mikolov et al., 2010; Sutskever et al., 2011; Graves, 2013), it remains unclear whether their advantages transfer to scenarios with extremely limited amounts of data.

Appropriate initialization of parameters in neural network frameworks has been shown to be beneficial across a wide variety of domains, including speech recognition, where unsupervised pre-training of deep belief networks was instrumental in attaining breakthrough performance (Hinton et al., 2012). Neural network approaches to a range of NLP problems have also been aided by initialization with word embeddings trained on large amounts of unannotated text (Frome et al., 2013; Zhang et al., 2014; Lau and Baldwin, 2016). However, in the case of extremely low-resource languages we do not have the luxury of this unannotated text.

As a remedy to this problem we focus on cross-lingual word embeddings (CLWEs), which learn word embeddings using information from multiple languages. Recent advances in CLWEs have shown that high quality embeddings can be learnt even in the absence of bilingual corpora by harnessing bilingual lexicons (Gouws and Søggaard, 2015; Duong et al., 2016). This is useful as some threatened and endangered languages have been subject to significant linguistic investigation, leading to the creation of high-quality lexicons, despite the dearth of transcriptions. For example, the training of a quality speech recognition system for Yongning Na, a Sino-Tibetan language spoken by approximately 40k people, is hindered by this lack of data (Do et al., 2014) despite significant linguistic investigation of the language (Michaud, 2008; Michaud, 2016).

In this paper we address two research questions. First, is the quality of CLWEs dependent on having large amounts of data in multiple languages, or can large amounts of data in a single *source* lan-

guage inform embeddings trained with little *target* language data? Secondly, can such CLWEs improve language modeling in low-resource contexts by initializing the parameters of an NNLM?

To answer these questions, we scale down the available monolingual data of the target language to as few as 1k sentences, while maintaining a large source language dataset. We assess intrinsic embedding quality by considering correlation with human judgment on the WordSim353 test set (Finkelstein et al., 2001). We then perform language modeling experiments where we initialize the parameters of a long short-term memory (LSTM) language model for low-resource language model training across a variety of language pairs.

Results indicate that CLWEs remain resilient when target language training data is drastically reduced in a simulated low-resource environment, and that initializing the embedding layer of an NNLM with these CLWEs consistently leads to better performance of the language model. In light of these results, we explore the method’s application to Na, an actual low-resource language with realistic manually created lexicons and transcribed data. We present a discussion of the negative results found which highlights challenges and future opportunities.

## 2 Related Work

This paper draws on work in three general areas, which we briefly describe in this section.

**Neural network language models and word embeddings** Bengio et al. (2003) and Goodman (2001) introduce word embeddings in the context of an investigation of neural language modeling. One claimed advantage of such models is the ability to cope with sparse data by sharing information among words with similar characteristics. Neural language modeling has since demonstrated powerful capabilities at the word level (Mikolov et al., 2010) and character level (Sutskever et al., 2011). Notably, LSTM models (Hochreiter and Schmidhuber, 1997) for modeling long-ranging statistical influences have been shown to be effective (Graves, 2013; Zaremba et al., 2014).

Word embeddings have become more popular through the application of shallow neural network architectures that allow for training on large quantities of data (Mnih et al., 2009; Bengio et al., 2009; Collobert and Weston, 2008; Mikolov et

al., 2013a), leading to many further investigations (Chen et al., 2013; Pennington et al., 2014; Shazeer et al., 2016; Bhatia et al., 2016). A key application of word embeddings has been in the initializing of neural network architectures for a wide variety of NLP tasks with limited annotated data (Frome et al., 2013; Zhang et al., 2014; Zoph et al., 2016; Lau and Baldwin, 2016).

**Low-resource language modeling and language model adaptation** Bellegarda (2004) review language model adaptation, and argue that small amounts of in-domain data are often more valuable than large amounts of out-of-domain data, but that adapting background models using in-domain data can be even better. Kurimo et al. (2016) present more recent work on improving large vocabulary continuous speech recognition using language model adaptation for low-resource Finno-Ugric languages.

Cross-lingual language modeling has also been explored with work on interpolation of a sparse language model with one trained on a large amount of translated data (Jensson et al., 2008), and integrated speech recognition and translation (Jensson et al., 2009; Xu and Fung, 2013).

Gandhe et al. (2014) investigate NNLMs for low-resource languages, comparing NNLMs with count-based language models, and find that NNLMs interpolated with count-based methods outperform standard n-gram models even with small quantities of training data. In contrast, our contribution is an investigation into harnessing CLWEs learnt using bilingual dictionaries in order to improve language modeling in a similar low-resource setting.

**Cross-lingual word embeddings** Cross-lingual word embeddings have also been the subject of significant investigation. Many methods require parallel corpora or comparable corpora to connect the languages (Klementiev et al., 2012; Zou et al., 2013; Hermann and Blunsom, 2013; Chandar A P et al., 2014; Kočiský et al., 2014; Coulmance et al., 2015; Wang et al., 2016), while others use bilingual dictionaries (Mikolov et al., 2013b; Xiao and Guo, 2014; Faruqui and Dyer, 2014; Gouws and Søgaard, 2015; Duong et al., 2016; Ammar et al., 2016), or neither (Miceli Barone, 2016).

In particular, we build on the work of Duong et al. (2016). Their method harnesses monolingual corpora in two languages along with a bilingual

lexicon to connect the languages and represent the words in a common vector space. The model builds on the continuous bag-of-words (CBOW) model (Mikolov et al., 2013a) which learns embeddings by predicting words given their contexts. The key difference is that the word to be predicted is a target language translation of a source language word centered in a source language context.

Since dictionaries tend to include a number of translations for words, the model uses an iterative expectation-maximization style training algorithm in order to best select translations given the context. This process thus allows for polysemy to be addressed which is desirable given the polysemous nature of bilingual dictionaries.

### 3 Resilience of Cross-Lingual Word Embeddings

Previous work using CLWEs typically assumes a similar amount of training data of each available language, often in the form of parallel corpora. Recent work has shown that monolingual corpora of two different languages can be tied together with bilingual dictionaries in order to learn embeddings for words in both languages in a common vector space (Gouws and Søgaard, 2015; Duong et al., 2016). In this section we relax the assumption of the availability of large monolingual corpora on the source and target sides, and report an experiment on the resilience of such CLWEs when data is scarce in the target language but plentiful in a source language.

#### 3.1 Experimental Setup

Word embedding quality is commonly assessed by evaluating the correlation of the cosine similarity of the embeddings with human judgements of word similarity. Here we follow the same evaluation procedure, except where we simulate a low-resource language by reducing the availability of target English monolingual text while preserving a large quantity of source language text from other languages. This allows us to evaluate the CLWEs intrinsically using the WordSim353 task (Finkelstein et al., 2001) before progressing to downstream language modeling where we additionally consider other target languages.

We trained a variety of embeddings on English Wikipedia data of between 1k and 128k sentences from the training data of Al-Rfou et al. (2013). In terms of transcribed speech data, this roughly

equates to between 1 and 128 hours of speech. For the training data, we randomly chose sentences that include words in the WordSim353 task proportionally to their frequency in the set. As monolingual baselines, we use the *skip-gram* (SG) and CBOW methods of Mikolov et al. (2013a) as implemented in the *Gensim* package (Řehůřek and Sojka, 2010). We additionally used off-the-shelf CBOW Google News Corpus embeddings with 300 dimensions, trained on 100 billion words.

The CLWEs were trained using the method of Duong et al. (2016) since their method addresses polysemy which is rampant in dictionaries. The same 1k-128k sentence English Wikipedia data was used but with an additional 5 million sentences of Wikipedia data in a source language. The source languages include Japanese, German, Russian, Finnish, and Spanish, which represent languages of varying similarity with English, some with great morphological and syntactic differences. To relate the languages, we used the *PanLex* lexicon (Kamholz et al., 2014). Following Duong et al. (2016), we used the default window size of 48 so that the whole sentence’s context is almost always taken into account. This mitigates the effect of word re-ordering between languages. We trained with an embedding dimension of 200 for all data sizes as a larger dimension turned out to be helpful in capturing information from the source side.<sup>1</sup>

#### 3.2 Results

Figure 1 shows correlations with human judgment in the WordSim353 task. The x-axis represents the number of English training sentences. Coloured lines represent CLWEs trained on different languages: Japanese, German, Spanish, Russian and Finnish.<sup>2</sup>

With around 128k sentences of training data, most methods perform quite well, with German being the best performing. Interestingly the CLWE methods all outperform GNC which was trained on a far larger corpus of 100 billion words. With only 1k sentences of target training data, all the CLWEs have a correlation around 0.5, with the exception of Finnish. Interestingly, no consis-

<sup>1</sup>Hyperparameters for both mono and cross-lingual word embeddings: iters=15, negative=25, size=200, window=48, otherwise default. Smaller window sizes led to similar results for monolingual methods.

<sup>2</sup>We also tried Italian, Dutch, German and Serbian, yielding similar results but omitted for presentation.

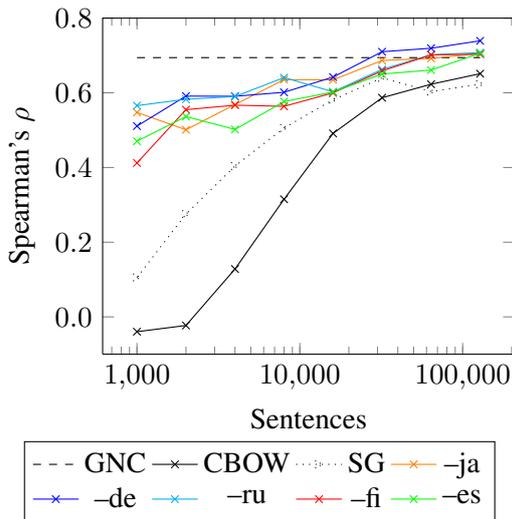

Figure 1: Performance of different embeddings on the WordSim353 task with different amounts of training data. *GNC* is the Google News Corpus embeddings, which are constant. *CBOW* and *SG* are the monolingual word2vec embeddings. The other, colored, lines are all cross-lingual word embeddings harnessing the information of 5m sentences of various source languages.

benefit was gained by using source languages for which translation with English is simpler. For example, Spanish often under-performed Russian and Japanese as a source language, as well as the morphologically-rich Finnish.

Notably, all the CLWEs perform far better than their monolingual counterparts on small amounts of data. This resilience of the target English word embeddings suggests that CLWEs can serve as a method of transferring semantic information from resource-rich languages to the resource-poor, even when the languages are quite different. However, the WordSim353 task is a constrained environment, so in the next section we turn to language modeling, a natural language processing task of much practical importance for resource-poor languages.

#### 4 Pre-training Language Models

Language models are an important tool with particular application to machine translation and speech recognition. For resource-poor languages and unwritten languages, language models are also a significant bottleneck for such technologies as they rely on large quantities of data. In this section, we assess the performance of language models on varying quantities of data, across a number

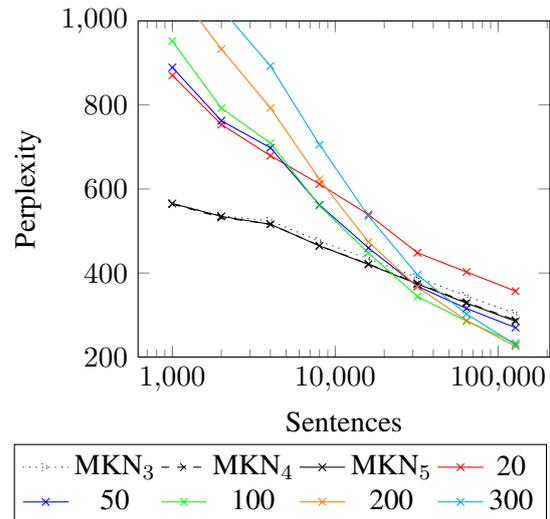

Figure 2: Perplexity of language models on the validation set. Numbers in the legend indicate LSTM language models with different hidden layer sizes, as opposed to Modified Kneser-Ney language models of order 3, 4 and 5.

of different source–target language pairs. In particular, we use CLWEs to initialize the first layer in an LSTM recurrent neural network language model and assess how this affects language model performance. This is an interesting task not simply for the practical advantage of having better language models for low-resource languages. Language modeling is a syntax-oriented task, yet syntax varies greatly between the languages we train the CLWEs on. This experiment thus yields some additional information about how effectively bilingual information can be used for the task of language modeling.

#### 4.1 Experimental Setup

We experiment with a similar data setup as in Section 3. However, target training sentences are not constrained to include words observed in the WordSim353 set, and are random sentences from the aforementioned 5 million sentence corpus. For each language, the validation and test sets consist of 3k randomly selected sentences. The large vocabulary of Wikipedia and the small amounts of training data used make this a particularly challenging language modeling task.

For our NNLMs, we use the LSTM language model of Zaremba et al. (2014). As a count-based baseline, we use Modified Kneser-Ney (MKN) (Kneser and Ney, 1995; Chen and Goodman, 1999) as implemented in KenLM (Heafield,

2011). Figure 2 presents some results of tuning the dimensions of the hidden layer in the LSTM with respect to perplexity on the validation set,<sup>3</sup> as well as tuning the order of n-grams used by the MKN language model. A dimension of 100 yielded a good compromise between the smaller and larger training data sizes, while an order 5 MKN model performed slightly better than its lower-order brethren.<sup>4</sup>

Interestingly, MKN strongly outperforms the LSTM on low quantities of data, with the LSTM language model not reaching parity until between 16k and 32k sentences of data. This is consistent with the results of Chen et al. (2015) and Neubig and Dyer (2016) that show that n-gram models are typically better for rare words, and here our vocabulary is large but training data small since the data are random Wikipedia sentences. However these findings are inconsistent with the belief that NNLMs have the ability to cope well with sparse data conditions because of the smooth distributions that arise from using dense vector representations of words (Bengio et al., 2003). Traditional smoothing stands strong.

## 4.2 English Results

With the parameters tuned on the English validation set as above, we evaluated the LSTM language model when the embedding layer is initialized with various monolingual and cross-lingual word embeddings. Figure 3 compares the performance of a number of language models on the test set. In every case where pre-trained embeddings were used, the embedding layer was held fixed during training. However, we observed similar results when allowing them to deviate from their initial state. For the CLWEs, the same language set was used as in Section 3. The curves for the source languages (Dutch, Greek, Finnish, and Japanese) are remarkably similar, as were those for the languages omitted from the figure (German, Russian, Serbian, Italian, and Spanish). This suggests that the English target embeddings are gleaned similar information from each of the languages, information likely to be more semantic than syntactic, given the syntactic differences between the languages.

<sup>3</sup>We used 1 hidden layer but otherwise the same as the *SmallConfig* of models/rnn/ptb/ptb\_word\_lm.py available in Tensorflow.

<sup>4</sup>Note that all perplexities in this paper include out-of-vocabulary words, of which there are many.

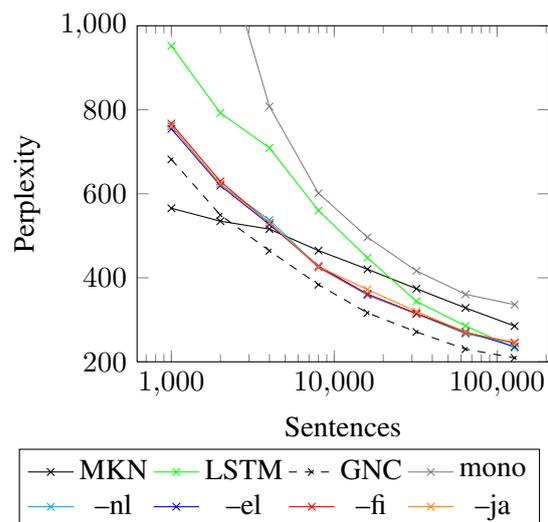

Figure 3: Perplexity of LSTMs when pre-trained with cross-lingual word embeddings trained on the same data. *LSTM* is a neural network language model with no pre-trained embeddings. *mono* is pre-trained with monolingual word2vec embeddings. *GNC* is pre-trained with Google News Corpus embeddings of dimension 300. The rest are pre-trained with CLWEs using information transfer from different source languages. *MKN* is an order 5 Modified Kneser-Ney baseline.

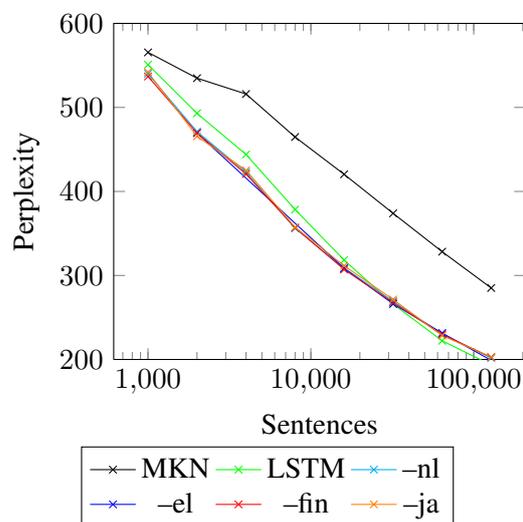

Figure 4: Perplexities when interpolating MKN with LSTMs pre-trained with various cross-lingual word embeddings. *LSTM* interpolates MKN with a neural network language model with no pre-trained embeddings. The rest are interpolations of MKN with LSTMs pre-trained with CLWEs using information transfer from different source languages. *MKN* is an order 5 Modified Kneser-Ney baseline without interpolation.

We compare these language models pre-trained with CLWEs with pre-training using other embeddings. Pre-training with the Google News Corpus embeddings of the method of Mikolov et al. (2013c) unsurprisingly performs the best due to the large amount of English data not available to the other methods, making it a sort of oracle. Monolingual pre-training of word embeddings on the same English data (*mono*) used by the CLWEs yields poorer performance.

The language models initialized with pre-trained CLWEs are significantly better than their un-pre-trained counterpart on small amounts of data, reaching par performance with *MKN* at somewhere just past 4k sentences of training data. In contrast, it takes more than 16k sentences of training data before the plain LSTM language model began to outperform *MKN*. The out-performance of LSTMs by *MKN* with the lowest amounts of training data motivated interpolation of *MKN* probabilities with LSTM language model probabilities, as shown in Figure 4. Such interpolation allows for consistent improvement beyond the performance of *MKN* or CLWE-pre-trained LSTMs alone.

### 4.3 Other Target Languages

In Table 1 we present results of language model experiments run with other languages used as the low-resource target. In this table English is used in each case as the large source language with which to help train the CLWEs. The observation that the CLWE-pre-trained language model tended to perform best relative to alternatives at around 8k or 16k sentences in the English case prompted us to choose these slices of data when assessing other languages as targets.

The pre-trained LSTM language model outperforms its non-pre-trained counterpart for all languages. There is competition between *MKN* and the CLWE-pre-trained models. The languages for which *MKN* tends to do better are typically those further from English or those with rich morphology, making cross-lingual transfer of information more challenging. There seems to be a degree of asymmetry here: while all languages helped English language modeling similarly, English helps the other languages to varying degrees. For all languages, interpolating *MKN* with the CLWE (*Interp.*) yields the best performance, corroborating the findings of Gandhe et al. (2014).

Neural language modeling of sparse data can be improved by initializing parameters with cross-lingual word embeddings. The consistent performance improvements gained by an LSTM using CLWE-initialization is a promising sign for CLWE-initialization of neural networks for other tasks given limited target language data.

## 5 First Steps in an Under-Resourced Language

Having demonstrated the effectiveness of CLWE-pre-training of language models using simulation in a variety of well-resourced written languages, we proceed to a preliminary investigation of this method to a low-resource, unwritten language, Na.

Yongning Na is a Sino-Tibetan language spoken by approximately 40k people in an area in Yunnan, China, near the border with Sichuan. It has no orthography and is tonal with a rich morphophonology. Given the small quantity of manually transcribed phonemic data available in the language, Na provides an ideal test bed for investigating the potential and difficulties this method faces in a realistic setting. In this section we report results in Na language modeling and discuss hurdles to be overcome.

### 5.1 Experimental Setup

The phonemically transcribed corpus<sup>5</sup> consists of 3,039 phonemically transcribed sentences which are a subset of a larger spoken corpus. These sentences are segmented at the level of the word, morpheme and phonological process, and have been translated into French, with smaller amounts translated into Chinese and English. The corpus also includes word-level glosses in French and English. The lexicon of Michaud (2016) contains example sentences for entries, as well as translations into French, English and Chinese.

The lexicon consists of around 2k Na entries, with example sentences and translations into English, French and Chinese. To choose an appropriate segmentation of the corpus, we used a hierarchical segmentation method where words were queried in the lexicon. If a given word was present then it was kept as a token, otherwise the word was split into its constituent morphemes.

We took 2,039 sentences to be used as training data, with the remaining 1k sentences split

	Tones	No tones
MKN	<b>59.4</b>	<b>38.0</b>
LSTM	74.8	46.0
CLWE	76.6	46.2
Lem	76.8	44.7
En-split	76.4	47.0

Table 3: Perplexities on the Na test set using English as the source language. *MKN* is an order 5 Modified Kneser-Ney language model. *LSTM* is a neural network language model without pre-training. *CLWE* is the same LM with pre-trained Na-English CLWEs. *Lem* is the same as CLWE except with English lemmatization. *En-split* extends this by preprocessing the dictionary such that entries with multiple English words are converted to multiple entries of one English word.

equally between validation and test sets. The phonemic transcriptions include tones, so we created two preprocessed versions of the corpus: with and without tones. Table 2 exhibits type and token counts for these two variations. In addition to the CLWE approach used in Sections 3 and 4, we additionally tried lemmatizing the English Wikipedia corpus so that it each token was more likely to be present in the Na-English lexicon.

## 5.2 Results and Discussion

Table 3 shows the Na language modeling results. Pre-trained CLWEs do not significantly outperform that of the non-pre-trained, and *MKN* outperforms both. Given the size of the training data, and the results of Section 4, it is no surprise that *MKN* outperforms the NNLM approaches. But the lack of benefit in CLWE-pre-training the NNLMs requires some reflection. We now proceed to discuss the challenges of this data to explore why the positive results of language model pre-training that were seen in Section 4 were not seen in this experiment.

**Tones** A key challenge arises because of Na’s tonal system. Na has rich tonal morphology. Syntactic relationships between words influence the surface form tone a syllable takes. Thus, semantically identical words may take different surface tones than is present in the relevant lexical entry, resulting in mismatches with the lexicon.

If tones are left present, the percentage of Na tokens present in the lexicon is 62%. Removing tones yields a higher hit rate of 88% and allows tone mismatches between surface forms and lexical entries to be overcome. This benefit is gained in exchange for higher polysemy, with an average of 4.1 English translations per Na entry when tones are removed, as opposed to 1.9 when tones are present. Though this situation of polysemy is what the method of Duong et al. (2016) is designed to address, it means the language model fails to model tones and doesn’t significantly help CLWE-pre-training in any case. Future work should investigate morphophonological

processing for Na, since there is regularity behind these tonal changes (Michaud, 2008) which could mitigate these issues if addressed.

**Polysemy** We considered the polysemy of the tokens of other languages’ corpora in the PanLex dictionaries. Interestingly they were higher than the Na lexicon with tones removed, ranging from 2.7 for Greek–English to 19.5 for German–English. It seems the more important factor is the amount of tokens in the English corpus that were present in the lexicon. For the Na–English lexicon, this was only 18% and 20% when lemmatized and unlemmatized, respectively. However it was 67% for the PanLex lexicon. Low lexicon hit rates of both the Na and English corpora must damage the CLWEs modeling capacity.

**Lexicon word forms** Not all the forms of many English word groups are represented. For example, only the infinitive ‘*to\_run*’ is present, while ‘*running*’, ‘*ran*’ and ‘*runs*’ are not. The limited scope of this lexicon motivates lemmatization on the English side as a normalization step, which may be of some benefit (see Table 3). Furthermore, such lemmatization can be expected to reduce the syntactic information present in embeddings which does not transfer between languages as effectively as semantics.

Some common words, such as ‘*reading*’ are not present in the lexicon, but ‘*to\_read\_aloud*’ is. Additionally, there are frequently entries such as ‘*way\_over\_there*’ and ‘*masculine\_given\_name*’ that are challenging to process. As an attempt to mitigate this issue, we segmented such English entries, creating multiple Na–English entries for each. However, results in Table 3 show that this failed to show improvements. More sophisticated processing of the lexicon is required.

**Lexicon size** There are about 2,115 Na entries in the lexicon and 2,947 Na–English entries, which makes the lexicon especially small in comparison to the PanLex lexicon used in the previous experiments. Duong et al. (2016) report large reductions in performance of CLWEs on some tasks when lexicon size is scaled down to 10k.

To better understand how limited lexicon size could be affecting language model performance, we performed an ablation experiment where random entries in the PanLex English–German lexicon were removed in order to restrict its size. Figure 5 shows the performance of English language

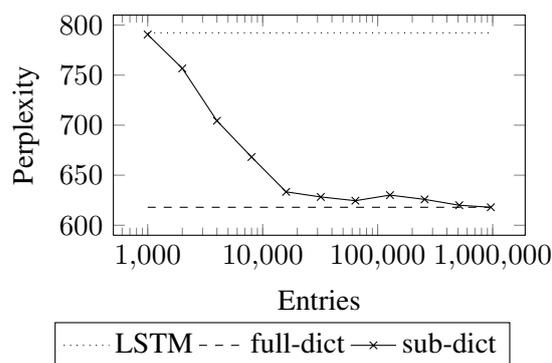

Figure 5: Perplexities of an English–German CLWE-pretrained language model trained on 2k English sentences as the dictionary size available in CLWE training increases to its full size (*sub-dict*). As points of comparison, *LSTM* is a long short-term memory language model with no pre-training and *full-dict* is a CLWE-pretrained language model with the full dictionary available.

modeling when training data is restricted to 2k sentences (to emulate the Na case) and the size of the lexicon afforded to the CLWE training is adjusted. This can only serve as a rough comparison, since PanLex is large and so a 1k entry subset may contain many obscure terms and few useful ones. Nevertheless, results suggest that a critical point occurs somewhere in the order of 10k entries. However, since improvements are demonstrated even with smaller dictionaries, this is further evidence that more sophisticated preprocessing of the Na lexicon is required.

**Domain** Another difference that may contribute to the results is that the domain of the text is significantly different. The Na corpus is a collection of spoken narratives transcribed, while the Wikipedia articles are encyclopaedic entries, which makes the registers very different.

### 5.3 Future Work on Na Language Modeling

Though the technique doesn’t work out of the box, this sets a difficult and compelling challenge of harnessing the available Na data more effectively.

The lexicon is a rich source of other information, including part-of-speech tags, example sentences and multilingual translations. In addition to better preprocessing of the lexical information we have already used, harnessing this additional information is an important next step to improving Na language modeling. The corpus includes translations into French, Chinese and English, as well

as glosses. Some CLWE methods can additionally utilize such parallel data (Coulmance et al., 2015; Ammar et al., 2016) and we leave to future work incorporation of this information as well.

The tonal system is well described (Michaud, 2008), and so further Na-specific work should allow differences between surface form tones and tones in the lexicon to be bridged.

Our work corroborates the observation that MKN performs well on rare words (Chen et al., 2015). Interpolation is an effective means to harness this strength when training data is sparse. Furthermore, hybrid count-based and NNLMs (Neubig and Dyer, 2016) promise the best of both worlds for language modeling for low-resource languages.

## 6 Conclusion

In this paper we have demonstrated that CLWEs can remain resilient when training data in the target language is scaled down drastically. Such CLWEs continue to perform well on the WordSim353 task, as well as demonstrating downstream efficacy across a number of languages through initialization of NNLMs. This work supports CLWEs as a method of transfer of information to resource-poor languages by harnessing distributional information in a large source language. We can expect parameter initialization with CLWEs trained on such asymmetric data conditions to aid in other NLP tasks too, though this should be empirically assessed.

## Abstract

We propose a method to decide whether two occurrences of the same noun in a source text should be translated consistently, i.e. using the same noun in the target text as well. We train and test classifiers that predict consistent translations based on lexical, syntactic, and semantic features. We first evaluate the accuracy of our classifiers intrinsically, in terms of the accuracy of consistency predictions, over a subset of the UN Corpus. Then, we also evaluate them in combination with phrase-based statistical MT systems for Chinese-to-English and German-to-English. We compare the automatic post-editing of noun translations with the re-ranking of the translation hypotheses based on the classifiers' output, and also use these methods in combination. This improves over the baseline and closes up to 50% of the gap in BLEU scores between the baseline and an oracle classifier.

## 1 Introduction

The repetition of a noun in a text may be due to co-reference, i.e. repeated mentions of the same entity, or to mentions of two entities of the same type. But in other cases, two occurrences of the same noun may simply convey different meanings. The translation of repeated nouns depends, among other things, on the conveyed meanings: in case of co-reference or identical senses, they should likely be translated with the same word, while otherwise they should be translated with different words, if the target language distinguishes the two meanings. State-of-the-art machine translation systems do not address this challenge systematically, and translate two occurrences of the same noun inde-

pendently, thus potentially introducing unwanted variations in translation.

We exemplify this issue in Figure 1 for Chinese-to-English and German-to-English translations, with examples of inconsistent translations of a repeated source noun by a baseline SMT system, as opposed to consistent translations in the reference. In Example 1, the system's translation of the second occurrence of *politik* is mistaken and should be replaced by the first one (*policy*, not *politics*). In Example 2, although the first translation differs from the reference, it could be acceptable as a legitimate variation, although the second one (*identity documents*) is more idiomatic and more frequent. Of course, in addition to these two examples, there are other configurations of the six nouns involved in a consistency relation across source, candidate and reference translations, but they will be discussed below when designing the training and test data for our problem.

In this paper, we aim to improve the translation of repeated nouns by designing a classifier which predicts, for every pair of repeated nouns in a source text, whether they should be translated by the same noun, i.e. consistently, and if that is the case, which of the two candidate translations generated by an MT system should replace the other one. We thus address one kind of long-range dependencies between words in texts; such dependencies have been the target of an increasing number of studies, presented briefly in Section 2.

To learn a consistency classifier from the data, we consider a corpus with source texts and reference translations, from the parallel UN Corpora in Chinese, German and English. As we explain in Section 3, we mine the corpus for pairs of repeated nouns in the source texts, and examine human and machine translations in order to learn to predict whether the machine translation of the first noun must replace the second one, or vice-versa, or no

---

**Example 1**

*Source:* nach einföhrung dieser politik [...] die politik auf dem gebiet der informationstechnik [...]

*Reference:* once the policy is implemented [...] the information technology policy [...]

*MT:* after introduction of policy [...] the politics in the area of information technology [...]

---

**Example 2**

*Source:* 欺詐性旅行或身份證件系指有下列情形之一的任何旅行或身份證件

*Reference:* Fraudulent travel or identity document; shall mean any travel or identity document

*MT:* 欺詐性 travel or identity papers. 系指 have under one condition; any travel, or identity document

---

Figure 1: Inconsistent translations of repeated nouns, in blue, from German (Example 1) and Chinese (Example 2) into English. While in both examples one noun is different from the reference, only Example 1 is truly mistaken: the second occurrence of the noun should be replaced with the first one.

change should be made. In Section 4, we present the lexical, syntactic and semantic features used by the classifiers. When presented with previously unseen source texts and baseline MT output, the decisions of the classifiers serve to post-edit or re-rank the repeated nouns of the MT baseline.

As shown in Section 5, the new end-to-end MT system generates improved Chinese-English and German-English translations, with larger improvements on the latter pair. Syntactic features appear to be more useful than semantic ones, for reasons that will be discussed. The case of more than two consecutive occurrences of the same noun will be briefly examined. Finally, a combined re-ranking and post-editing approach appears to be the most effective, covering about 50% of the gap in BLEU scores between the baseline MT and the use of an oracle classifier.

## 2 Related Work

This study is related to several research topics in MT: lexical consistency, caching, co-reference, and long-range dependencies between words in general. Our proposal aims to improve the consistency of noun translation, and thus has a narrower scope than the “one translation per discourse” hypothesis (Carpuat, 2009; Carpuat and Simard, 2012), which aimed to implement for MT the broader hypothesis of “one sense per discourse” (Gale et al., 1992).

We focus on nouns because of their referential properties, which are a strong requirement for consistency in case of co-reference, although in many cases consistency should not be blindly enforced, in order to avoid the “trouble with MT consistency” (Carpuat and Simard, 2012) which may induce translation errors. As indicated in that study, MT systems trained on small datasets are often

more consistent but of lower quality than systems trained on larger and more diverse data sets. In any case, in our study, we never alter consistent translations, but we address inconsistencies, which are often translation errors (Carpuat and Simard, 2012), and attempt to find those that can be corrected simply by enforcing consistency.

Similarly, our scope is narrower than the caching approach (Tiedemann, 2010; Gong et al., 2011), which encourages *a priori* consistent translations of any word, with the risk on propagating cached incorrect translations. In our study, the first and second translation in a pair have equal status.

Noun phrase consistency is often due to co-reference. Several recent studies consider co-reference to improve pronoun resolution, but none of them exploits noun phrase co-reference, likely due to an insufficient accuracy of co-reference resolution systems (?; ?). The improvement of pronoun translation was only marginal with respect to a baseline SMT system in a 2015 shared task (Hardmeier et al., 2015), while the 2016 shared task (Guillou et al., 2016) somewhat shifted its focus to pronoun prediction in a lemmatized reference translation.

This study builds upon and extends our previous work on the translation of compounds (Mascarell et al., 2014; Pu et al., 2015), which constrained the translation of the head of a compound when it was repeated separately after it. The present study is considerably more general, as it makes no assumption on either of the repeated nouns, i.e. it does not require them to be part of compounds.

Our study contributes to a growing corpus of research on modeling longer-range dependencies than those modeled in phrase-based SMT or neural MT, often across different sentences of a document. Ture et al. (2012) used cross-sentence

consistency features in a translation model, while Hardmeier (2012) designed the Docent decoder, which can use document-level features to improve the coherence across sentences of a translated document. Our classifier for repeated nouns outputs decisions that can serve as features in Docent, but as the frequency of repeated nouns in documents is quite low, we use here post-editing and/or re-ranking rather than Docent.

### 3 Datasets for Noun Consistency in MT

#### 3.1 Overview of the Method

Our method flexibly enforces noun consistency in discourse to improve noun phrase translation. We first detect two neighboring occurrences of the same noun in the source text, i.e. closer than a fixed distance, and which satisfy some basic conditions. Then, we consider their baseline translations by a phrase-based statistical MT system, which are identified from word-level alignments. If the two baseline translations of the repeated noun differ, then our classifier uses the source and target nouns and a large set of features (presented in Section 4) to decide whether one of the translations should be edited, and how. This decision will serve to post-edit and/or re-rank the baseline MT’s output (Section 4.4). To design the classifier, we train machine-learning classifiers over examples that are extracted from parallel data and from a baseline MT system, as described in Section 3.3. A separate subset of unseen examples will be used to test classifiers, first intrinsically and then in combination with MT.

#### 3.2 Corpora and Pre-processing

Our data comes from WIT<sup>3</sup> Corpus<sup>1</sup> (Cettolo et al., 2012), a collection of transcripts of TED talks, and the UN Corpora,<sup>2</sup> a collection of documents from the United Nations. The experiments are on Chinese-to-English and German-to-English.

We first build a phrase-based SMT system for each language pair with Moses (Koehn et al., 2007), with its default settings. Both MT systems are trained on the WIT<sup>3</sup> data, and are used to generate candidate translations of the UN Corpora. Then, the ML classifiers are trained on noun pairs extracted from the UN Corpora, using semantic and syntactic features extracted from both source and target sides. The test sets also come

from the UN Corpora, with the same features on the source side. Table 1 presents statistics about the data.

#### 3.3 Extraction of Training/Testing Instances

At this stage, the goal is to automatically extract for training the pairs of repeated nouns in the source texts, noted  $N \dots N$ , which are translated differently by the SMT baseline, noted  $T_1 \dots T_2$ , with  $T_1 \neq T_2$ . Indeed, when the translations are identical, we have no element in the 1-best translation to post-edit them, therefore we do not consider such pairs. We examine the reference translations of  $T_1$  and  $T_2$ , noted  $RT_1$  and  $RT_2$ , from which we derive the answer we expect from the classifiers (as specified below), and which will be used for supervised learning. We obtain the  $T_i$  and  $RT_i$  values using word-alignment with GIZA++.

Prior to the identification of repeated nouns in the source text, we tokenize the texts and identify parts-of-speech (POS) using the Stanford NLP tools<sup>3</sup>. In particular, as Chinese texts are not word-segmented, we first perform this operation and then identify multi-character nouns. We then consider each noun in turn, and look for a second occurrence of the same noun in what follows, limiting the search to the same sentence for Chinese, and to the same and next three sentences for German. The difference in the distance settings is based on observations of the Chinese vs. German datasets: average length of sentences, average distance of repeated nouns, and sentence segmentation issues.

Once the pairs of repeated nouns have been identified, we check the SMT translations of each pair, and if the two translations are different, we include the pair in our dataset. For instance, in Figure 1, the noun 证件 appears twice in the sentence, and the baseline translations of the two occurrences are *papers* and *document*; therefore, this pair is included in our dataset. We extracted from the UN Corpora 3,301 pairs for training and 647 pairs for testing on ZH/EN, and 11,289 pairs for training and 695 pairs for testing on DE/EN. We selected a smaller amount of noun pairs for ZH/EN than DE/EN for reasons of availability, because DE/EN dataset is more than 10 times larger than the ZH/EN one. We kept similar test set sizes to enable comparison.

The word-aligned reference translations are

Table 1: WIT<sup>3</sup> data for building the SMT systems and UN data to train/test the classifiers.

used to set the ground-truth class (or decision) for training the classifiers, as follows. With the notations above (baseline translations of  $N$  noted  $T_1$  and  $T_2$ , with  $T_1 \neq T_2$ ), if the reference translations differ ( $RT_1 \neq RT_2$ ), then we label the pair as ‘none’, i.e. none of  $T_1$  and  $T_2$  should be post-edited and changed into the other, because this would not help to reach the reference translation anyway (recall that the only possible actions knowing the SMT baseline are replacing  $T_1$  by  $T_2$  or vice-versa).

If the reference translations are the same ( $RT_1 = RT_2$ ), then we examine this word, noted  $RT$ . If this word is equal to one of the baseline translations ( $T_1 = RT$  or  $T_2 = RT$ ), then this value should be given to other baseline (e.g., if  $T_1 = RT \neq T_2$ , then  $T_2 := T_1$ ). For classification, we simply label these examples with the index of the word that must be used, 1 or 2. However, if the reference differs from both baseline translations, then the label is again ‘none’, because we cannot infer which of them is a better translation.

After labeling all the pairs, we extract the features in an attribute/value format to be used for machine learning.

## 4 Classifiers for Translation Consistency

### 4.1 Role and Nature of the Classifiers

We describe here the machine learning classifiers that are trained to predict one of the three classes – ‘1’, ‘2’ or ‘none’ – for each pair of identical source nouns with different baseline SMT translations. The sense of the predicted classes is the following: ‘1’ means that  $T_1$  should replace  $T_2$ , ‘2’ means the opposite, and ‘none’ means translations should be left unchanged. For instance, if Example 2 in Figure 1 was classified as ‘2’, we would replace the translation of the first occurrence (*papers*) with the second one (*documents*).

We use the WEKA environment<sup>4</sup> to train and test several different learning algorithms: SVMs (Cortes and Vapnik, 1995), C4.5 Decision Trees (noted J48 in Weka) (Quinlan, 1993), and Random Forests (Breiman, 2001). We use 10-fold cross validation on the training set, and then test them once on the test set, and later on in combination with MT. For performance reasons, we used the Maximum Entropy classifier (Manning and Klein, 2003) from Stanford<sup>5</sup> instead of WEKA’s Logistic Regression.

The hyper-parameters of the above classifiers were set as follows, mostly following the default settings from WEKA, and setting others on the cross-validation sets (not the unseen test sets). For SVMs, the round-off error is  $\epsilon = 10^{-12}$ . For Decision Trees, we set the minimal number of instances per leaf (‘minNumObj’) at 2 and the confidence factor used for pruning to 0.25. For Random Forests, we defined the number of trees to be generated (‘numTree’) as 100 and set their maximal depth (‘maxDepth’) as unlimited. Finally, we set the MaxEnt smoothing ( $\sigma$ ) to 1.0, and the tolerance used for convergence in parameter optimization to  $10^{-5}$ .

We evaluate our proposal in two ways. First, we measure the classification accuracy in terms of *accuracy* and *kappa* ( $\kappa$ ) agreement (Cohen, 1960) with the correct class, either in 10-fold cross-validation experiments, or on the test set. Second, we compare the updated translations with the reference, to check if we obtain a result that is closer to it, using the popular BLEU measure (Papineni et al., 2002).

### 4.2 Syntactic Features

We defined 19 syntactic features, mainly with the assumption that out of a pair of repeated source nouns  $N \dots N$ , the occurrence which is embed-

<sup>4</sup><http://www.cs.waikato.ac.nz/ml/weka/>

<sup>5</sup><http://nlp.stanford.edu/software/classifier.shtml>

ded in a more complex local parse tree, i.e. has more information syntactically bound to it, is more “determined” and has a higher probability of been translated correctly by the baseline MT system, since this information can help the system to disambiguate it. The results tend to confirm this assumption.

The features are listed in Figure 2, left side, with an explicit description of each feature and its value on a Chinese text (top of the figure). In the last line of the table we show the ground-truth class of this example.
