discussed above; 2) changing all the context words to the same gender, while keeping all other features of the words intact. Once the whole context is of the same gender, we essentially lose the gender information altogether as all nouns have similar context, regardless their gender.[6]

5.1 The proposed approaches

We experiment with both lemmatization of context words and gender change of context words.

Lemmatization of Context Words When training word2vec (Mikolov et al., 2013), we use a morphological analyzer to identify the lemmas of words, and replace context words, but not target words, with their lemmas.

Gender Change of Context Words When training word2vec, we choose a gender (for example, masculine) and change all context words to that gender: each word that is identified as being of a different gender (in Italian: feminine, in German: feminine or neutral), is changed to its masculine form. This is also done using a morphological analyzer: when we identify a non-masculine analysis, we search for a masculine one that shares the same lemma and features.

In general, we found Italian to work better with gender change, and German to work better with lemmatization. We report full results in Section 6.

5.2 Challenges

While conceptually simple, fully neutralizing gender information is more challenging than it initially appears, and requires careful attention to "get right". We describe some cases in which gender information can leak.

Human Curator Choices The morphological analyzer sometimes assigns different lemmas to an opposite-gender pair, as a result of human curater design choices. For example, in Italian, "delle" is the feminine of "dei", but they are assigned the lemmas "della" and "del", respectively. Such cases leak gender signal in both cases of lemmatization and gender change: (1) When lemmatizing, each of the words gets a different lemma, manifesting the gender. (2) When changing the gender, the opposite-gender form of the word is not identified as these words do not share lemma, and the words stay unchanged.

This was very prominent in some high-frequency Italian words, and dealt with by fixing the analyzer: we identified all forms without a corresponding gendered-pair, manually aligned them, and assigned each pair a shared and unique lemma. This fix dramatically improved results when using either lemmatization or gender change.

Gender-Ambiguous Word Forms Many word forms have several morphological analyses, resulting in different lemmas. Inspecting this ambiguity reveals two specific issues, in German and in

[6]Context nouns are also kept unchanged since nouns do not agree with other nouns in their context, both in Italian and in German. Notably, in German, we lose the noun-ness information when we lowercase the corpus (as all nouns in German begin with an uppercase letter).

Italian. First, many German words are ambiguous with respect to gender. For example, "eine" has a frequent feminine reading, but also a rare masculine one. When changing words to masculine, this word is identified as potentially masculine, and kept intact. The presence of the context word "eine" now leaks a feminine signal.[7]

Second, Italian has many cases of two words with a similar set of possible lemmas but with different gender. For example, "usato" and "usata" are masculine and feminine, respectively, and both have "usare" and "usato" as possible lemmas. If we select a consistent lemma for each word type, and end up selecting a different lemma for each of "usato" and "usata", we again leak signal regarding the original gender.

One solution would be to use context-sensitive lemmatization, that chooses the correct analysis in context. However, doing this accurately is still an open problem. Our proposed solution is to randomly sample a lemma per word token. This improved lemmatization results in Italian by 25%.

Multiple Opposite-gender Forms for a Word In some cases, a single word might have multiple forms in the opposite gender. For example, the Italian "delle" is the feminine form of both "dei" and "degli", depending on the phonetic context. In this case, the former is much more common than the latter. A naive approach that chooses to convert "delle" to "degli" essentially keeps the feminine signal for these cases: every instance of "delle" changes to "delgli", which marks masculine nouns in much less common cases, while most masculine nouns are usually accompanied with the more common word "dei".

Ideally, when changing the gender of a word, we want to change a word by another word with a similar frequency, otherwise, the gender signal will be manifested in the frequency mismatch, as in the example above.

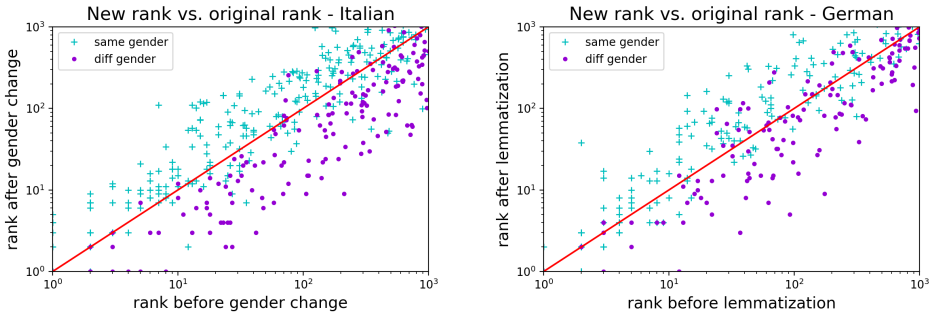
We deal with this issue using the following heuristic: when changing to masculine form (or any other gender form), for each word we first find all its possible masculine forms. Then, we check the frequency of the original word in the corpus, and choose the option with the closest frequency to it. This indeed yields better results: when not addressing the frequency issue in Italian, we are able to reduce the effect only by 35.42% (compared to 91.67%, see Section 6 for more details).

6 Results

We experimented with different schemes for each language, measuring their success at removing gender bias of inanimate nouns with respect to English.[8]

For German, we found lemmatization to work better than gender change. In Italian gender change got better results. Specifically, changing to feminine got much better results than changing to masculine, probably due to less ambiguity when changing to feminine in some very common articles (see full manual mapping in the Appendix), resulting in fewer cases in which the gender signal leaks through the frequencies of the changed words, as explained above. In addition, the manual fixes to the lemmatizer were crucial to get satisfying results for both methods.

While some of these findings depend on the specific morphological analyzer in use, the challenges and issues we demonstrate are relevant in any case.



6.1 Reduction in Gender Bias

Differences in Similarities We repeat the experiment in Section 3.2—computing the average of pair similarities in each of the sets defined in Section 3, this time with the embeddings trained after removing gender signal from the context (debiasing). Table 4 shows the results for Italian and German, compared to English, both for the original and the debiased embeddings (for each language we show the results of the best performing debiased embeddings). As expected, in both languages, the difference between the average of the two sets with the debiased embeddings is much lower. In Italian, we get a reduction of 91.67% of the gap with respect to English. In German, we get a reduction of 100%. Note that for both languages, the main change is in the set of different-gender pairs, and not in the same-gender pairs. This makes sense as same-gender words have similar contexts both before and after our intervention, but different-gender words have different contexts before, but much more similar contexts after.

For comparison, in Italian we got 12.50% reduction when using the lemmatization scheme,

[7] A possible solution would be to replace words with their lemmas whenever we identify both feminine and masculine analyses. This did not improve results in practice.

[8] We used state-of-the-art morphological analyzers for both languages. Full implementation details can be found in the appendix.

(a) (b)

Figure 1: The new rank of a word in the nearest neighbor list of its paired word. In cyan (+) – pairs with the same gender, in purple (·) – pairs with different gender. Most words with same-gender are located above $y = x$ (were drifted apart), while most words with different-gender are located below it (got closer together).

	Italian				German			
	Original	Debiased	English	Reduction	Original	Debiased	English	Reduction
Same Gender	0.442	0.434	0.424	–	0.491	0.478	0.446	–
Different Gender	0.385	0.421	0.415	–	0.415	0.435	0.403	–
difference	0.057	0.013	0.009	**91.67%**	0.076	0.043	0.043	**100%**

Table 4: Averages of similarities of pairs with same vs. different gender in Italian and German compared to English. The last row is the difference between the averages of the two sets. "Reduction" stands for gap reduction when removing gender signals from the context.

and 68.75% reduction when lemmatizing with the addition of the manual mapping. For German, the best result using gender change was a reduction of 48.48%, achieved by changing to neutral.

Rank in Nearest Neighbor List We repeat the experiment shown in Section 3.3—for each pair we compute the rank of the second word in the nearest neighbor list of the first word and vice versa. Then we compare the average ranking in each of the defined sets. Table 2 shows the results for Italian and German, both for the original and the debiased embeddings. As we expect, the difference between the average ranking of the two sets drops significantly for both languages.

In order to get a better picture of how the rankings of the different words change as a result of the gender signal removal, we take all pairs (and the inverted pairs). For each pair we plot the new rank of the second word in the nearest neighbors list of the first word as a function of its original rank before debiasing. Points above $y = x$ are of words that got a higher rank (lower in the list, farther from the first word), while points below this line are of words that got a lower rank (higher in the list, closer to the first word). Figure 1 shows these plots for Italian and German. As expected, most words of same-gender pairs are located above the line (were drifted apart), while most words of different-gender pairs are located below the line (got closer together).

6.2 Improvement in Word Similarities

Qualitative Evaluation As a qualitative evaluation, we take several words for SimLex-999 and look at their top-10 nearest neighbor lists, before and after applying our method. In Table 5 we show the top-10 lists for the words *vaso* ("*jar*"-masculine) in Italian, and *welt* ("*world*"-feminine) in German. It is evident that the words that are added to the list, are better correlated with the target word than those that are removed. Two additional words appear in the Appendix.

Evaluation on Simlex and WordSim-353 We evaluate the quality of the grammatical-gender-neutralized embeddings using two datasets for each language: SimLex-999 (Hill et al., 2015; Leviant and Reichart, 2015) and WordSim-353 (Finkelstein et al., 2002; Leviant and Reichart, 2015). Table 6 shows the results for Italian and German for both datasets, compared to the original embeddings. In both cases, the new embeddings perform better than the original ones.

Cross-lingual Word Embeddings Studies in language and cognition suggest that humans share

Italian		German

Table 7: Cross-lingual embedding alignment in Italian and in German, before and after debiasing.

a common semantic space, regardless of their native language (Youn et al., 2016). To the extent that embeddings capture the semantics of words, we can thus expect embedding spaces to have a similar structure across languages. Youn's statement concerns concepts and not words, however, and concepts can surface in many different forms in language, which interferes with how well embedding spaces align across languages (Søgaard et al., 2018). Thus, we expect grammatical gender to have a negative impact on alignability.

We explore this matter through the task of cross-lingual embedding alignment, wherein a cross-lingual embedding space is learned through an alignment of independently pre-trained monolingual embeddings for a directed pair of languages. The quality of cross-lingual embeddings learned this way can be evaluated intrinsically on the task of bilingual dictionary induction (BDI). BDI queries the cross-lingual embedding space with a seed of words in one language, retrieves their counterparts among the words in the other language[9] and evaluates the precision of the produced translations against a set of gold standard targets. We carry out experiments using the supervised variant of the MUSE embedding alignment system (Conneau et al., 2018) and report results on the inanimate portion of SimLex-999. We train a cross-lingual embedding alignment between English and either German or Italian, using the original and the debiased embeddings for these two languages. The results reported in Table 7 show that precision on BDI indeed increases as a result of the reduced effect of grammatical gender on the embeddings for German and Italian, i.e. that the embeddings spaces can be aligned better with the debiased embeddings.

7 Conclusion

We show that grammatical gender impacts word embeddings of inanimate nouns, both in Italian and in German, causing the similarities between words to change according to having same or different gender: the representations of same-gender words are closer together than representations of different-gender words.

We show that this effect can be almost completely removed when neutralizing gender signals in the context during training of the word embeddings. While most works in our field nowadays try to be language-independent, this is not always the right way to go: successfully removing those gender signals is not trivial to do and a language-specific morphological analyzer, to-

[9]This is done by minimizing a distance metric, most commonly, CSLS (Conneau et al., 2018).

gether with careful usage of it, are essential for achieving good results.[10]

In addition, this work serves as a reminder that languages other than English have different properties that are rarely dealt with when processing English. These aspects should be taken into account when dealing with morphologically reach languages, as not all models and algorithms for English can transfer directly to other languages.

Abstract

Active learning (AL) is a technique for reducing manual annotation effort during the annotation of training data for machine learning classifiers. For NLP tasks, pool-based and stream-based sampling techniques have been used to select new instances for AL while generating new, artificial instances via Membership Query Synthesis was, up to know, considered to be infeasible for NLP problems. We present the first successful attempt to use Membership Query Synthesis for generating AL queries for natural language processing, using Variational Autoencoders for query generation. We evaluate our approach in a text classification task and demonstrate that query synthesis shows competitive performance to pool-based AL strategies while substantially reducing annotation time.

1 Introduction

Active learning (AL) has the potential to substantially reduce the amount of labeled instances needed to reach a certain classifier performance in supervised machine learning. It works by selecting new instances that are highly informative for the classifier, so that comparable classification accuracies can be obtained on a much smaller training set. AL strategies can be categorized into pool-based sampling, stream-based sampling and Membership Query Synthesis (MQS). The first two strategies sample new instances either from a data pool or from a stream of data. The third, MQS, generates artificial AL instances from the region of uncertainty of the classifier. While it is known that MQS can reduce the predictive error rate more quickly than pool-based sampling (Ling and Du, 2008), so far it has not been used for NLP tasks because artificially created textual instances are uninterpretable for human annotators.

We provide proof of concept that generating highly informative artificial training instances for text classification is feasible. We use Variational Autoencoders (VAE) (Kingma and Welling, 2013) to learn representations from unlabeled text in an unsupervised fashion by encoding individual sentences as low-dimensional vectors in latent space. In addition to mapping input sequences into latent space, the VAE can also learn to generate new instances from this space. We utilize these abilities to generate new examples for active learning from a region in latent space where the classifier is most uncertain, and hand them over to the annotator who then provides labels for the newly created instances.

We test our approach in a text classification setup with a real human annotator in the loop. Our experiments show that query synthesis for NLP is not only feasible but can outperform other AL strategies in a sentiment classification task with respect to annotation time.

The paper is structured as follows. We first review related work (§2) and introduce a formal description of the problem (§3). Then we describe our approach (§4), present the experiments (§5) and analyze the results (§6). We discuss limitations and possible further experiments (§7) and finally conclude our findings (§8).

2 Related work

Membership query synthesis was introduced by Angluin (1988) and describes a setting where the model generates new queries instead of selecting existing ones. Early experiments in image processing (Lang and Baum, 1992), however, showed that the generated queries are hard to interpret by human annotators. This holds true even for recent approaches using Generative Adversarial Networks (GANs) (Goodfellow et al., 2014) to create uncertain instances (Zhu and Bento, 2017; Huijser and van Gemert, 2017). In contrast to im-

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 472–481
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

age processing, discrete domains like natural language do not exhibit a direct mapping from feature to instance space. Strategies that circumvent this problem include the search for nearest (observed) neighbors in feature space (Wang et al., 2015) or crafting queries by switching words (Awasthi and Kanade, 2012).

Sentence representation learning (Kiros et al., 2015; Conneau et al., 2017; Subramanian et al., 2018; Wang et al., 2019) in combination with new methods for semi-supervised learning (Kingma et al., 2014; Hu et al., 2017; Xu et al., 2017; Odena, 2016; Radford et al., 2017) have shown to improve classification tasks by leveraging unlabeled text. Methods based on deep generative models like GANs or VAEs are able to generate sentences from any point in representation space. Mehrjou et al. (2018) use VAEs to learn structural information from unlabeled data and use it as an additional criterion in conventional active learning to make it more robust against outliers and noise.

We use VAEs to generate AL queries from specific regions in latent space. To ensure that the generated instances are not only informative for the ML classifier but also meaningful for the human annotator, we adapt the approach of Wang et al. (2015) (see §3.1). In contrast to their work, however, we do not *sample* existing instances from the pool that are similar to the synthetic ones but directly *generate* the new queries. To our best knowledge, our work is the first to present positive results for Membership Query Synthesis for text classification.

3 Background

3.1 Query Synthesis and Nearest Neighbors

Arbitrary points in feature space are hard to interpret for humans. To evade this problem, Wang et al. (2015) use the nearest neighbor in a pool of unlabeled data as a representative which is then presented to the human annotator. To identify uncertain points along the separating hyperplane of an SVM the following approach is proposed. First the location of the decision boundary is approximated by a binary-search like procedure. An initial *Opposite Pair* (z_+, z_-) is formed by centroid c_+ and centroid c_- of positive and negative labeled instances respectively. The mid point z_s is queried and, depending on the annotated label l, replaces the corresponding z_l. This step is repeated b times, reducing the distance between the initial centroids by a factor of 2^b. Figure 1a depicts this process. Then the mid-perpendicular vector of the *Opposite Pair* is calculated by using the Gram-Schmidt process to orthogonalize a random vector z_r and normalize its magnitude to λ. The new point $z_s = z_r + (z_+ + z_-)/2$ is close to the decision boundary and queried for its class. Depending on the receive label the point z_s replaces z_+ or z_- in the *Opposite Pair*. This process (Figure 1b) is repeated until $n - b$ points along the separating hyperplane are queried.

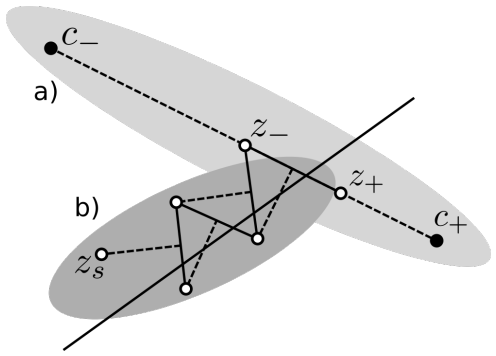

Figure 1: **a)** finds *Opposite Pair* close to the decision boundary. **b)** identify points close to the decision boundary.

3.2 VAE for Sentence Generation

The Variational Autoencoder is a generative model first introduced by Kingma and Welling (2013). Like other autoencoders, VAEs learn a mapping $q_\theta(z|x)$ from high dimensional input x to a low dimensional latent variable z. Instead of doing this in a deterministic way, the encoder learns the parameters of e.g. a normal distribution. The desired effect is that each area in the latent space has a semantic meaning and thus samples from $p(z)$ can be decoded in a meaningful way. The decoder $p_\theta(x|z)$, also referred to as $dec(z)$, is trained to reconstruct the input x based on the latent variable z. In order to approximate θ via gradient descent the reparametrization trick (Kingma and Welling, 2013) was introduced. This trick allows the gradient to flow through non-deterministic z by separating the discrete sampling operation. Let μ and σ be deterministic outputs of the encoder $q_\theta(\mu, \sigma|x)$:

$$z = \mu + \sigma \odot \epsilon \quad \text{where } \epsilon \sim \mathcal{N}(0, I) \qquad (1)$$

and $\odot$ is the element-wise product. To prevent the model from pushing σ close to 0 and thus falling back to a deterministic autoencoder, the objective is extended by the Kullback-Leibler (KL) diver-

gence between prior $p(z)$ and $q(z|x)$:

$$\mathcal{L}(\theta; x) = -KL(q_\theta(z|x)||p(z)) + \mathbb{E}_{q_\theta(z|x)}[logp_\theta(x|z)]. \quad (2)$$

Bowman et al. (2016) apply this idea for sentence generation using an RNN as encoder and decoder. They observe that a strong auto-regressive language modeling ability in the decoder reduces the information stored in the latent variable, right up to a complete collapse of the KL term. They explore different techniques to weaken the decoder, like word dropout or KL term weight annealing, as possible solutions. This guarantees a semantically rich latent variable and good sentence generation ability. Below, we describe how to combine both techniques in order to generate meaningful queries for Membership Query Synthesis.

4 Active Learning Schedule

We train a Variational Autoencoder on an unlabeled corpus of sentences. The text classification task is performed on a binary sentiment dataset split into training, development and test set. As depicted in Figure 2, the sentences in the classification dataset are vectorized using the VAE encoder which generates the latent variable z for each sentence x. This is done deterministically by dropping the σ term in Equation 1, further referred to as $z = enc(x)$.

Next, a *Learner* is trained to fit a linear hyperplane to separate the positive from the negative instances. We use the procedure described in §3.1 to select new query points for AL. But instead of searching for the nearest neighbor in the pool, we decode the point $x = dec(z)$ into a human readable sentence which is then handed over to the human annotator. The annotator assigns a binary label to the instance and the next query point is calculated.

One important parameter for active learning determines how many new instances are to be selected in each AL iteration. Wang et al. (2015) use a predefined number of instances to be selected along the hyperplane. Because we know that a Gaussian prior is imposed on the feature space, we instead stop the selection process when the magnitude of z_s exceeds the expectation. The expected distance of a point sampled from the k-dimensional Gaussian prior to the origin is $\sqrt{\mathbb{E}[\chi^2_k]} = \sqrt{k}$. Then the schedule restarts, learning a new decision boundary, and ultimately terminates when the annotation budget is exhausted. We refer to this method as *gen_wang*. When nearest neighbor search is used instead, we refer to the selection method as *nn_wang*.

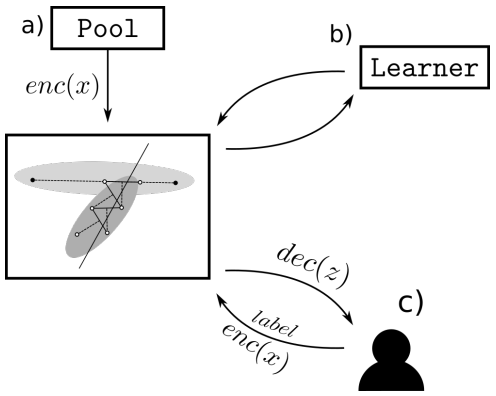

Figure 2: **a)** Instances in corpus are encoded to latent space. **b)** Learner fits a hyperplane to separate points. **c)** Query points selected by method described in Fig.1. Decoder translates point in latent space to human readable sequence. Annotator chooses label for instance.

In addition, we explore a method, *gen_uniform*, where step b) in Figure 1 is reduced to generating only one midperpendicular vector with a magnitude drawn from a uniform distribution. In each iteration this vector will point to a random direction with a different magnitude, selecting diverse points close to the hyperplane. The maximum magnitude is set in a way that the resulting point is not further away than $\sqrt{k}$ from the origin. Similar to above we refer to this method as *nn_uniform* when using nearest neighbor search. The number of possible directions along the hyperplane grows with the size of the latent variable. With this modification we expect to explore more diverse points than following the same direction for several steps.

5 Experiments

In this section we want to explore how the ability to generate human readable sentences from arbitrary points in the feature space affects active learning performance. We compare our approach to a number of baselines (§5.3), where in each experiment we select/generate 500 instances, present them to a human annotator to get a label and evaluate the performance of each setting in a sentiment classification task. We start the active learning process with two utterances in the seed set, namely '*good movie*' and '*bad movie*'. The classifier is trained to separate instances with positive sentiment from negative ones. The human anno-

epochs	20

Table 1: Training parameters for the Variational Autoencoder.

tator can skip neutral or uninterpretable instances. These skip actions also count towards the annotation budget.

5.1 Data

The data used in our experiments comes from two sources, (i) the SST2 (Socher et al., 2013) and (ii) SAR14 (Nguyen et al., 2014). We limit sentence length to a maximum of 15 words. This is motivated by lower training times and the tendency of vanilla VAEs not to perform well on longer sentences (Shen et al., 2019).

Sentiment task SST2 (Socher et al., 2013) is a binary sentiment classification dataset compiled from *rottentomatoes.com*. As we only consider sentences with up to 15 words, the sizes of the training, development and test sets are 3103, 380 and 814 instances, respectively.

Sentence pool The active learning pool consists of 1.2M unique sentences from the SAR14 dataset (Nguyen et al., 2014). SAR14 contains 234k movie reviews from IMDB. The data is annotated on review level, which prevents us from removing single neutral sentences. Although the datasets stem from different sources, there is a small overlap. These sentences are removed from the pool.

5.2 Training

Variational Autoencoder Table 1 lists the parameter used for the VAE. For training we limit the vocabulary of the VAE to the top 20k words. Encoder and decoder RNN have layer normalized (Ba et al., 2016) LSTM cells (Hochreiter and Schmidhuber, 1997) with size 512. As additional regularization we set weight dropout to 0.3 (Srivastava et al., 2014). Input embeddings are also of size 512, which allows us to share the embedding weights with the softmax weights of the output layer (Press and Wolf, 2016). To prevent posterior collapse we use logistic annealing of the KL term weight and weaken the decoder by applying word dropout with probability 0.5 (Bowman et al., 2016). The model is trained using the Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of 0.005. Once the KL term weight is close to 1, the learning weight is linearly decreased to 0. The training stops after 20 epochs and the latent variable z has $k = 50$ dimensions. The trained VAE achieves a reconstruction loss of 45.3 and KL divergence of 13.2 on the SST2 training set.

Learner The *Learner* is an SVM[1] with linear kernel. Each instance is represented as the latent variable z learned by the autoencoder. The latent variable is a vector with 50 dimensions and the SVM is trained on this representation. We calculate classification performance on the reduced SST2 test set and report F1-scores.

Generator The generator is the decoder of the VAE described above. Once a point z in feature space is selected, it is used as the input of the decoder $x = dec(z)$ which generates the human readable sentence x in an autoregressive way.

5.3 Baselines

We compare our approach to Membership Query Synthesis for text classification to four baselines. The first baseline selects instances from the pool by *random* choice. The *least confidence* baseline computes the distance of the instances in the pool to the separating hyperplane and chooses the one closest to the hyperplane. The third and fourth baseline follow the procedure described in §4 but search for the nearest neighbor (*nn_uniform*, *nn_wang*) instead of synthesising the exact query point. Nearest neighbor is defined by the minimal euclidean distance between the query point and the latent representation of the pool instance.

5.4 Annotation

The instances selected or generated by any model or baseline are annotated manually by one human coder.[2] Although the pool data has labels on the review level, we do not use these labels in our experiments. Positive reviews can include negative

[1] https://scikit-learn.org/stable/modules/generated/sklearn.svm.SVC.html

[2] The first author of this paper.

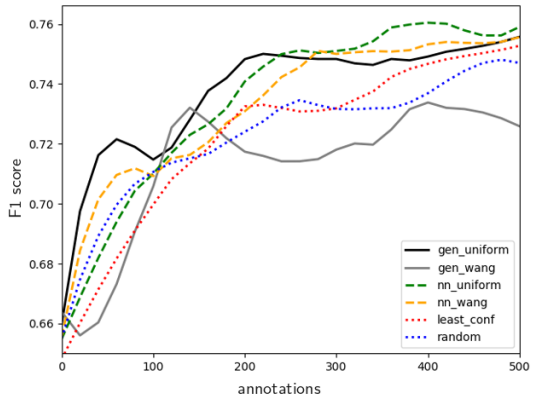

Figure 3: F1-Score as a function of annotation steps (including skipped queries). Averaged over 3 runs.

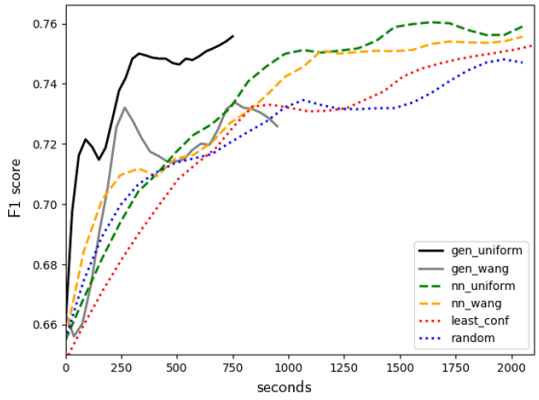

Figure 4: F1-scores as a function of annotation time. Results averaged over 3 runs.

sentences and vice versa. This means that using document-level labels would introduce noise and might impair the baselines. During each of the three experimental runs, all models and baselines are annotated simultaneously by the same person. The annotator is presented with one instance at a time and has no information which of the models has produced each particular instance. Once a label is selected, it is transmitted to the corresponding model and triggers the selection/generation of the next instance. Thus, at any given time there is one unlabeled instance for each model or baseline. From this set of unlabeled instances, one instance is chosen randomly and presented to the annotator. This procedure is repeated until 500 instances are labeled for each model or baseline. Hiding the instance source from the annotator is intended to prevent any bias during the annotation process.

6 Results and Analysis

6.1 Classification Performance

F-scores as a function of annotated instances Figure 3 shows learning curves for the different AL strategies and baselines as a function of the number of annotation instances added to the training data. The *random* and *least_conf* baselines perform reasonably well. *Least_conf* struggles in the beginning, likely attributed to the minimal seed set. Once enough instances are labeled it catches up. *Gen_uniform* has a strong start but, after around 200 instances, is outperformed by the *nearest neighbor* approaches which yield the highest F1-scores. Among the nearest neighbor approaches, the *uniform* schedule ranks better than *wang*. The same behaviour is observed for the *generation* methods, although *gen_wang* produces the worst results overall. Overall, *gen_uniform* is competitive with respect to F1-scores and shows that sentences generated from points in the feature space are informative and useful for training a text classifier.

F-scores as a function of annotation time AL simulations have often been criticized for reporting unrealistic results, based merely on the number of annotated instances (see, e.g., Settles (2009), pp. 37 ff.). It is well known, however, that the number of annotated instances is often not a good predictor for the real annotation costs. AL strategies tend to select the *hard nuts* for human annotators and it is not unreasonable to assume that the annotation of N instances in an AL setup might take longer and thus might be more expensive than annotating the same number of *randomly* selected instances. Therefore, we also show learning curves as a function of annotation time (Figure 4).

The results show a clear advantage for the *generation* models. The reduction in annotation time is due to shorter query length and less neutral or noisy instances, as shown in Table 2. This speeds up the annotation by a significant margin while providing the *Learner* with informative instances, despite their short length.

Figure 5 shows that the length of generated instances increase over time and further exploration also hints that the generated length is correlated with the length of the sentences in the seed set.

As listed in Table 2, the *random* baseline reveals that 36.8 percent of sentences in the pool are neutral/artifacts and positive sentences outweigh negative ones by a factor of 2.6. This means that random sampling results in unbalanced datasets with far more positive examples. Our generation

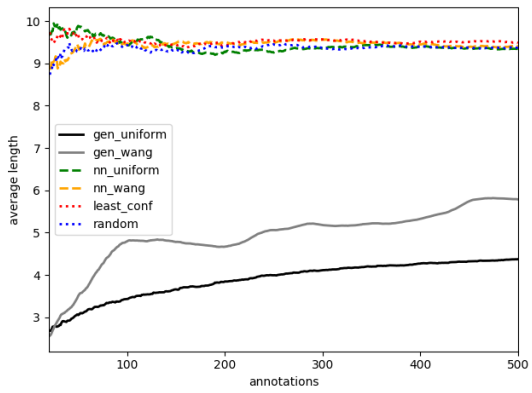

Figure 5: Development of average length of selected/generated instances as more instances are annotated.

method does not show this disadvantage. In contrast, the generated instances maintain a more balanced distribution of class labels and are less likely to be skipped. These are indicators that the selected points are close to the hyperplane and the VAE is able to generate coherent and highly informative sentences from them.

6.2 Computational Complexity

To assure a seamless annotation procedure, the supply of new instances has to be reasonably fast. The generation and selection of the next instance is dependant on the label of the previous instance. Because of this, there is no way to pre-fetch the next instance in the background and the annotator has to wait for the selection/generation process to finish before the next instance is presented for annotation. However, the runtime for pool-based AL methods is increasing with the pool's size. In contrast, the generation method presented in this work does not have this limitation.

The *least confidence* baseline has a complexity of $\mathcal{O}(n)$ where n is the number of instances in the pool. The complexity of *nearest neighbor* search without any approximation techniques like preclustering is also $\mathcal{O}(n)$. Query generation from an exact point with the decoder has a complexity of $\mathcal{O}(m)$ where m is the length of the sentence and $n >> m$. Because sentences have a natural length limit and in this work are capped to 15 words, one could argue that the complexity is $\mathcal{O}(1)$.

6.3 Generated Instances

Table 3 shows examples of generated instances using the *gen_uniform* method. Example 1-6 show prototypical positive and negative instances. Example 7 is ambiguous, caused by the decoder generating an unknown (UNK) token at the position where one would normally expect an evaluative adjective. We see this as an indicator that the point is positioned close to the hyperplane and thus the sentiment of the latent variable is ambiguous. We also observe instances with UNK token which still express a sentiment, as seen in Example 8 an 9. This can be interpreted as a placeholder for a named entity or, in other cases, a specifier like movie genre and does not impact the annotation process.

To explore the ability of the model to generate unseen instances we calculate the percentage of instances not seen in the pool. We only look at instances with an annotated sentiment label, because skipped examples often include noise and thus are unlikely to be present in the pool. 41 and 51 percent of labeled instances are newly generated by *gen_uniform* and *gen_wang* respectively. This provides more evidence that the model is capable of generating new and informative instances.

	% skips	M sec	M len	p/n
gen_uniform	28.1	1.4	4	1.7
gen_wang	20.9	1.9	5	1.2
nn_uniform	34.2	4.1	9	1.9
nn_wang	35.8	4.1	10	2.4
least_conf	39.0	4.2	10	2.1
random	36.8	4.1	9	2.6

Table 2: Percentage of skips (neutral or noisy sentences); Median annotation time in seconds; Median number of words in query; Ratio of positive to negative labels.

No.	Instance	Label
1.	the acting is excellent	1
2.	powerful and moving	1
3.	this movie is very enjoyable	1
4.	a complete mess	0
5.	nothing spectacular	0
6.	absolutely terrible !	0
7.	the plot is UNK	skip
8.	well done by UNK	1
9.	the UNK is a disappointment	0

Table 3: Example instances generated by *gen_uniform*. Label 1 for positive and 0 for negative class.

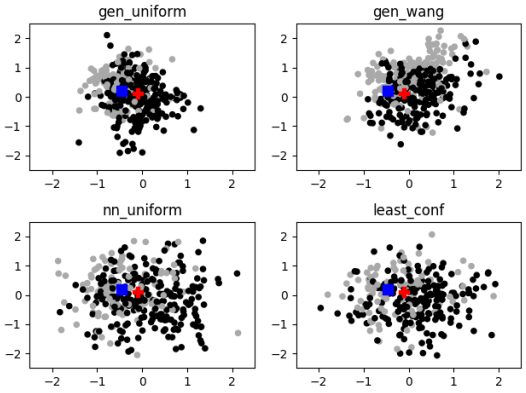

Figure 6: Plot of the 2 *most important* dimensions of selected/generated instances in latent space. Gray points indicate negative, black points positive labels. The blue square denotes '*bad movie*' and the red cross '*good movie*'.

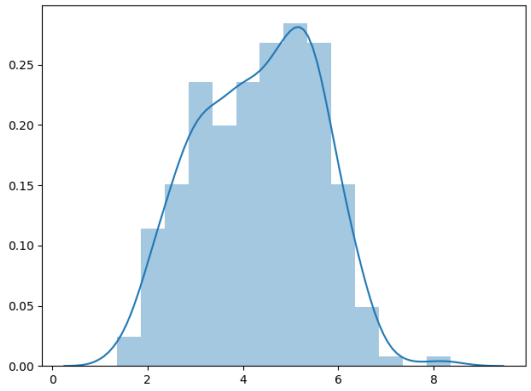

Figure 7: Distribution of euclidean distances between z before and $\hat{z}$ after re-encoding during *gen_uniform*.

6.4 Latent Space

To further analyze the behavior of the different AL strategies, we apply dimensionality reduction and visualize the instances in latent space (Figure 6).

The two largest absolute coefficients of the trained SVM's linear kernel identify the *most important* dimensions. Figure 6 plots the points, represented by theses two dimensions, selected by different active learning schedules. The generated instances lie densely around the seed points, while pool instances are more distributed. In *gen_wang* one can see how the instances are loosely following one direction similar to Figure1.

As indicated in Figure 2 a pool instance is represented as $z = enc(x)$. The same is true for the instances in the development, test and seed set. For the generated instances there are two options. If z is a point selected in feature space and $x = dec(z)$ is the decoded query sequence, the annotated instance can either be represented as z or as $\hat{z} = enc(x)$. In a perfect VAE z and $\hat{z}$ should be nearly identical. In practice however $\hat{z}$ ends up at a different location in feature space. Figure 7 depicts the distribution of distances between z and $\hat{z}$ generated with the *gen_uniform* method. We observe that models trained on $\hat{z}$ perform better than those trained on z, presumably because the test instances are represented the same way. To evaluate if $\hat{z}$ is still an informative point and not just positioned randomly in feature space, we train a model on actual randomly sampled points. The sampled point $z \sim \mathcal{N}(0, I)$ is decoded to query sequence x, labeled and subsequently re-encoded to $\hat{z} = enc(x)$. With the same amount of instances, this model performs much worse than *gen_uniform*, indicating that point $\hat{z}$ still preserves some of the informativeness of z. We thus assume that the closer $\hat{z}$ is to selected point z, the better the generation based active learning schedules will work.

7 Discussion

Related work in the context of semi-supervised learning has focused on developing methods to generate synthetic training instances for different tasks (Sennrich et al., 2016; Hayashi et al., 2018; Alberti et al., 2019; Winata et al., 2019), in order to accelerate the learning process. Sennrich et al. (2016) create artificial training instances for machine translation, using monolingual data paired with automatic back-translations. Their work obtains substantial improvements for several languages and has triggered many follow-up studies that apply the idea of back-translation to different tasks.

For example, Hayashi et al. (2018) augment the training data for attention-based end-to-end automatic speech recognition with synthetic instances, and Winata et al. (2019) generate artificial training examples to improve automatic speech recognition on code-switching material. Alberti et al. (2019) use a large number of synthetic instances to pre-train a Question Answering (QA) model that is then fine-tuned on the target QA dataset. Their approach results in significant improvements over models that are trained without the synthetic datapoints.

While these studies show that huge amounts of synthetic training data can crucially improve the

learning process, our approach uses a different paradigm. Instead of generating millions of synthetic data points, our method is data-lean and only needs a few hundred instances to improve the classifier. Another difference is that we do not rely on automatically generated labels but use human annotations instead. Due to the practical constraints of the active learning process, we need to keep the training time short enough so that the human annotator does not have to wait for the next set of instances to annotate. This rules out the use of computation-intensive models and large training sets. Given that we use an SVM for classification, we do not expect a strong effect for adding large numbers of additional training instances, given that the majority of those data points will not be positioned close to the decision boundary.

One of the main drawbacks of our work is its limitation to binary sentence classification. However, multi-class classification in an one-vs-rest schema is compatible with our method and worth further exploration. Another interesting direction for future work is the synthesis of data for more complex tasks like Natural Language Inference (NLI) or QA. This, however, requires modifications to the structure of the autoencoder and exceeds the scope of this work.

Membership Query Synthesis might also be an interesting approach for tasks where the automatic extraction of large amounts of unlabelled data is not straight-forward. One example that comes to mind is the detection of offensive language or 'hate speech', where we have to deal with highly unbalanced training sets with only a small number of positive instances, and attempts to increase this number have been shown to result in systematically biased datasets (Davidson et al., 2019; Wiegand et al., 2019). Table 2 suggests that the generator produces instances with a more balanced class ratio (1.7 and 1.2) than the pool data (2.6) it was trained on. It might be worthwhile to explore whether the generation of synthetic training instances can help to mitigate the problem to select instances from both classes in an highly imbalanced data pool.

8 Conclusion

This work is the first to show that Membership Query Synthesis in an NLP setting is feasible. Our approach uses a Variational Autoencoder as a representation learner and generates informative active learning queries from latent space. The classification performance for the generated instances is competitive with pool-based active learning strategies and outperforms other AL strategies with regard to annotation cost (time) and computational complexity.

The main advantage of Membership Query Synthesis for active learning is that it allows us to target specific points along the separating hyperplane and thus to provide the classifier with information on specific areas of uncertainty in the data space. While pool-based active learning has the same objective, Membership Query Synthesis gives us a more precise tool to explore the data space and to generate exactly those instances that we need, making MQS a promising approach for future work in active learning.

A General-Purpose Algorithm for Constrained Sequential Inference

Abstract

Inference in structured prediction involves finding the best output structure for an input, subject to certain constraints. Many current approaches use sequential inference, which constructs the output in a left-to-right manner. However, there is no general framework to specify constraints in these approaches. We present a principled approach for incorporating constraints into sequential inference algorithms. Our approach expresses constraints using an *automaton*, which is traversed in lockstep during inference, guiding the search to valid outputs. We show that automata can express commonly used constraints and are easily incorporated into sequential inference. When it is more natural to represent constraints as a set of automata, our algorithm uses an *active set method* for demonstrably fast and efficient inference. We experimentally show the benefits of our algorithm on constituency parsing and semantic role labeling. For parsing, unlike unconstrained approaches, our algorithm always generates valid output, incurring only a small drop in performance. For semantic role labeling, imposing constraints using our algorithm corrects common errors, improving F_1 by 1.5 points. These benefits increase in low-resource settings. Our active set method achieves a 5.2x relative speed-up over a naive approach.[1]

1 Introduction

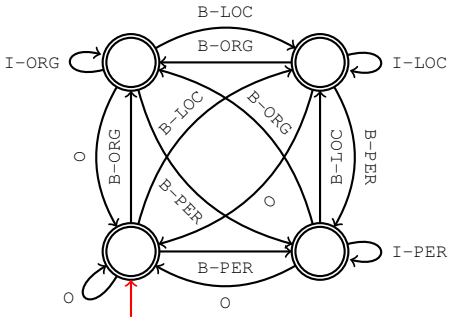
The key challenge in structured prediction problems (like sequence tagging and parsing) is *inference* (also known as *decoding*), which involves identifying the best output structure $\mathbf{y}$ for an input instance $\mathbf{x}$ from an exponentially large search space $\mathcal{Y}$ (Taskar, 2004; Tsochantaridis et al., 2005). The search is restricted to set of valid $\mathbf{y} \in \mathcal{Y}_\mathbf{x} \subseteq \mathcal{Y}$ for $\mathbf{x}$ by imposing *constraints* during inference. Figure 1 shows examples of constraints used in Semantic Role Labeling (SRL) (Gildea and Jurafsky, 2002).

input:	Alice Smith gave a flower to Bob
gold tags:	B-A0 I-A0 O O B-A1 O B-A2
predicate:	gave
legal args:	A0, A1, A2 (from PropBank)
spans:	[Alice Smith] gave a [flower] to [Bob]
invalid tags:	B-A0 I-A0 O O **B-A0** O B-A2
reason:	duplicate A0
invalid tags:	**B-A5** **I-A5** O O B-A1 O B-A2
reason:	illegal arg A5 for predicate "gave"
invalid tags:	B-A0 **O** O O B-A1 O B-A2
reason:	span [Alice Smith] should have single label

Figure 1: An example SRL instance (input, predicate, gold tags) with different invalid tag sequences and the constraints they violate (details in §4.2).

Currently, inference for most structured prediction problems is solved *sequentially*, predicting the output in a left-to-right manner (Sutskever et al., 2014; Luong et al., 2016). Such *sequential inference* approaches enforce constraints in different ways. For example, a shift-reduce parser consults a stack to determine which action sequences produce valid trees (Nivre et al., 2014), while an SRL model penalizes tag sequences which violate constraints during inference (Punyakanok et al., 2008; Täckström et al., 2015).

At present, inference algorithms are designed to handle task-specific constraints, and there is no general formulation for constrained sequential inference. This contrasts with the state of affairs in NLP before deep learning, when constrained inference approaches used general formulations like Integer Linear Programming (ILP) (Roth and Yih, 2004; Clarke and Lapata, 2008, inter alia).



We present a simple, general-purpose sequential inference algorithm that takes a model and

(a) A FSA for BIO tag sequences for NER.

(b) A PDA that accepts valid parse trees like `(S (NP XX) (VP XX XX))` and `(S (VP XX))`. The edge label "P/Q/R, A" denotes consuming either P, Q or R as input and changing the stack per A. "If T" indicates that edge is only valid if T is on top of the stack.

Figure 2: An example FSA and PDA. Red arrows mark start states, and double circles mark accepting states.

an *automaton* expressing the constraints as input, and outputs a structure that satisfies the constraints (§2.2). The automaton guides the inference to always produce a valid output by reshaping the model's probability distribution such that actions deemed invalid by the automaton are not taken.

In some situations, it is more natural to express the constraints as a *set* of automata. However, naively enforcing multiple automata by fully intersecting them is potentially expensive. Instead, our algorithm lazily intersects the automata using an efficient active set method, reminiscent of the cutting-plane algorithm (Tsochantaridis et al., 2005) (§2.4).

The choice of using automata to express constraints has several benefits. First, automata are capable of expressing constraints used in a wide variety of NLP tasks. Indeed, in §3, we show that task-specific constrained inference approaches implicitly use an automaton. Second, automata can be naturally incorporated into any sequential inference algorithm such as beam search. Finally, automata make enforcing multiple constraints straightforward — only the automata for individual constraints need to be specified, which are then intersected at inference time.

Our algorithm is a principled approach for enforcing constraints and has many desirable properties. It decouples the constraints from the inference algorithm, making it generally applicable to many problems. Further, it guarantees valid output and allows for the seamless addition of constraints at inference time without modifying the inference code. We experimentally demonstrate the benefits of our algorithm on two structured prediction tasks, constituency parsing (§5.1) and semantic role labeling (§5.2). Our results in constituency parsing show that our algorithm always outputs valid parses, incurring only a small drop in F_1. In SRL, constrained inference using our algorithm corrects common errors produced by unconstrained inference, resulting in a 1.5 F_1 improvement. This increase in performance is more prominent in low-resource settings. Finally, the active set method for enforcing multiple constraints achieves a 5.2x speed-up over the naive approach of fully intersecting the relevant automata.

2 Constrained Inference with Automata

We briefly review automata that we use for representing constraints in our algorithm.

2.1 Brief Review of Automata Theory

For the purposes of this work, an automaton is a (possibly weighted) directed graph that compactly encodes a set of strings, known as its *language*. The two types of automata used in this work are finite-state automata (FSA) and push-down automata (PDA).[2]

In an FSA, each edge is labeled with a symbol y from an alphabet Σ, and any traversal from the starting state to the final state(s) represents a unique string $\mathbf{y}$ in the language. A PDA is an extension of an FSA in which the traversal can maintain a stack that is used for computation, and the edges may manipulate or examine the state of the stack. Any language that can be expressed using regular expressions or context-free grammars

[2]We only consider deterministic automata.

has an equivalent accepting FSA or PDA, respectively (Sipser, 1997). An example of each type of automata is depicted in Figure 2.

Our inference algorithm views an automaton as an abstract stateful function, denoted as $\mathcal{A}$, which accepts strings from its language $L(\mathcal{A})$. After consuming the prefix $\mathbf{y}_{1:i}$ of a string $\mathbf{y}$, $\mathcal{A}$ provides a score $\mathcal{A}(y_{i+1} \mid \mathbf{y}_{1:i})$ for every symbol $y \in \Sigma$. Invoking $\mathcal{A}$.accepts(s) tests if a string s is in $L(\mathcal{A})$.

2.2 Sequential Inference

The traditional inference problem for structured prediction can be formalized as solving

$$\hat{\mathbf{y}} = \underset{\mathbf{y} \in \mathcal{Y}_\mathbf{x}}{\operatorname{argmax}} \log p_\theta(\mathbf{y} \mid \mathbf{x}) \tag{1}$$

where $\mathbf{x}$ and $\mathbf{y}$ are the input and output structures, $\mathcal{Y}_\mathbf{x}$ is the set of valid output structures for $\mathbf{x}$, and θ are the parameters of the model $p_\theta(\mathbf{y} \mid \mathbf{x})$. A common way to solve this problem is to decompose the objective as follows:

$$\hat{\mathbf{y}} = \underset{\mathbf{y} \in \mathcal{Y}_\mathbf{x}}{\operatorname{argmax}} \sum_i \log p_\theta(y_i \mid \mathbf{x}, \mathbf{y}_{1:i-1}) \tag{2}$$

This decomposition is adopted by popular approaches, such as seq2seq models, SEARN (Daumé et al., 2009), etc. Under this decomposition, the inference problem is often solved by an inexact sequential inference algorithm, such as beam search.

2.3 Imposing Constraints with Automata

We are interested in versions of Equation 2 in which the output space is described by the language of an automaton. Formally,

$$\begin{aligned} \hat{\mathbf{y}} = \underset{\mathbf{y}}{\operatorname{argmax}} & \sum_i \log p_\theta(y_i \mid \mathbf{x}, \mathbf{y}_{1:i-1}) \\ \text{such that} \quad & \mathbf{y} \in L(\mathcal{A}_\mathbf{x}) \end{aligned} \tag{3}$$

where $L(\mathcal{A}_\mathbf{x})$ is the language of an automaton $\mathcal{A}_\mathbf{x}$ describing the valid output space for instance $\mathbf{x}$. This framework is capable of expressing many constraints which are common in NLP applications, described in detail in §3.

Equation 3 can be rewritten as:

$$\hat{\mathbf{y}} = \underset{\mathbf{y}}{\operatorname{argmax}} \sum_i \log \tilde{p}_\theta(y_i \mid \mathbf{x}, \mathbf{y}_{1:i-1}) \tag{4}$$

$$\begin{aligned} \log \tilde{p}_\theta(y_i \mid \mathbf{x}, \mathbf{y}_{1:i-1}) \triangleq & \log p_\theta(y_i \mid \mathbf{x}, \mathbf{y}_{1:i-1}) \\ & + \mathcal{A}_\mathbf{x}(y_i \mid \mathbf{y}_{1:i-1}) \end{aligned}$$

Algorithm 1 Constrained Sequential Greedy Inference

Input: Model p_θ, automaton $\mathcal{A}_\mathbf{x}$, sequence $\mathbf{x}$
Output: Prediction $\hat{\mathbf{y}} \in L(\mathcal{A}_\mathbf{x})$

1: **procedure** CONSTRAINED-SEARCH(p_θ, $\mathcal{A}_\mathbf{x}$, $\mathbf{x}$)
2: $\quad\hat{\mathbf{y}} \leftarrow$ [BOS] ▷ *Beginning of sequence token*
3: $\quad$**while** $\hat{\mathbf{y}}$ is not finished **do**
4: $\quad\quad\log \tilde{p}_\theta(y' \mid \mathbf{x}, \hat{\mathbf{y}}) = \log p_\theta(y' \mid \mathbf{x}, \hat{\mathbf{y}}) + \mathcal{A}_\mathbf{x}(y' \mid \hat{\mathbf{y}})$
5: $\quad\quad y \leftarrow \arg\max_{y'} \log \tilde{p}_\theta(y' \mid \mathbf{x}, \hat{\mathbf{y}})$
6: $\quad\quad\hat{\mathbf{y}} \leftarrow \hat{\mathbf{y}} + y$ ▷ *Extend current sequence*
7: $\quad$**return** $\hat{\mathbf{y}}$

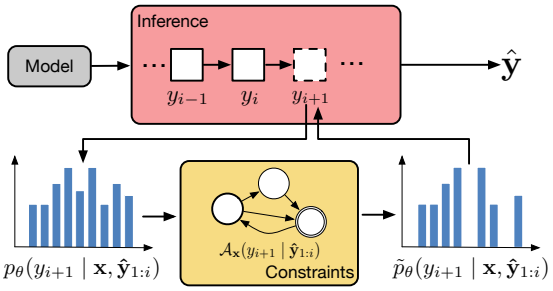

Figure 3: At each time step, the automata $\mathcal{A}_\mathbf{x}$ reshapes the model's probability distribution p_θ to $\tilde{p}_\theta$, from which the next output label y_{i+1} is determined.

where $\mathcal{A}_\mathbf{x}$ reshapes p_θ to $\tilde{p}_\theta$ at each time step. To impose hard constraints, we set this score to $-\infty$ for invalid y_i and constant for all valid y_i.[3] Equation 4 allows natural extensions of sequential inference algorithms, where an automaton is traversed in lock-step to guide the search to always output a valid structure. The necessary extension of greedy search is presented in Algorithm 1. Concretely, when predicting y_i, the inference selects the most probable action under the reshaped probability distribution $\tilde{p}_\theta$ (line 5). It is straightforward to similarly extend other sequential inference algorithms.

2.4 Imposing Multiple Constraints

The formulation above assumes that the constraints are described using a single automaton. However, in some scenarios, it is more natural to impose multiple constraints by representing them as a set of automata.

A Motivating Example. Consider Figure 1 which illustrates the SRL problem. The following constraints should be obeyed by the tag sequence: the predicate cannot have multiple arguments of the same type ($\texttt{A}_0$–$\texttt{A}_5$), each predicate may only accept a certain set of argument types, and certain spans derived from a constituency parse should re-

[3] Soft constraints can also be imposed, but are not explored in this work.

ceive the same label.[4] Each of these constraints can be easily expressed using a separate automaton. In contrast, directly writing a single automaton to enforce these constraints simultaneously could be impractical and difficult.

Issues with Naive Approaches. Naively extending sequential inference algorithms to impose a set of constraints by traversing multiple automata in parallel fails. There is no guarantee that a valid structure will be found, even if the intersection of the automata's languages is non-empty (a proof by counter-example is provided in Appendix A). The alternative solution of intersecting the automata into a single automaton may be intractable, as the size of the intersected automaton grows exponentially in the number of constraints (Hopcroft and Ullman, 1979).

An Active Set Method. Intuitively, intersecting all of the automata may not be necessary because it is possible for a constraint to be satisfied without it being enforced. This is the basis for *active set* methods (such as the cutting-plane algorithm (Kelley, 1960; Tsochantaridis et al., 2005)), which maintain a set during inference that contains currently active (i.e., enforced) constraints. When a constraint is violated by the current output, it enters (i.e., is added to) the active set.

We present an active set method for imposing multiple constraints represented by a set of automata $\mathcal{S}_{\mathbf{x}}$ in Algorithm 2. Our algorithm is inspired by the active set algorithm of Tromble and Eisner (2006) for finite-state transducers.

For an instance $\mathbf{x}$, Algorithm 2 maintains a active set[5] $\mathcal{W}$ corresponding to all violated constraints so far. $\mathcal{W}$ is represented by the intersection $\mathcal{A}_{\mathcal{W}}$ of the relevant automata, which is initialized with an automata Σ^* that accepts any sequence (line 1). On each iteration, the algorithm runs a constrained inference algorithm (such as Algorithm 1) that uses $\mathcal{A}_{\mathcal{W}}$ (line 3) to find an output $\hat{\mathbf{y}}$. Then, FIND-VIOLATION checks if $\hat{\mathbf{y}}$ violates any of the constraints that are not currently in the active set, $\mathcal{S}_{\mathbf{x}} \setminus \mathcal{W}$ (line 4). If $\hat{\mathbf{y}}$ is accepted by all of the automata (line 5), it is valid and subsequently returned (line 6). Otherwise, the first violated constraint is added to $\mathcal{W}$ (line 8), its automaton $\mathcal{A}'$ intersected with $\mathcal{A}_{\mathcal{W}}$ (line 9), and constrained inference is re-run (line 3).

[4]These constraints are described in detail in §4.

[5]Also known as a *working set*.

Algorithm 2 An Active Set Method for Multiple Constraints

Input: Model p_θ, set of automata $\mathcal{S}_{\mathbf{x}}$, sequence $\mathbf{x}$
Output: Prediction $\hat{\mathbf{y}} \in \bigcap_{\mathcal{A} \in \mathcal{S}_{\mathbf{x}}} L(\mathcal{A})$

1: $\mathcal{W} \leftarrow \emptyset$, $\mathcal{A}_{\mathcal{W}} \leftarrow \Sigma^*$
2: **while** True **do**
3: $\quad \hat{\mathbf{y}} \leftarrow$ CONSTRAINED-SEARCH(p_θ, $\mathcal{A}_{\mathcal{W}}$, $\mathbf{x}$)
4: $\quad \mathcal{A}' \leftarrow$ FIND-VIOLATION($\mathcal{S}_{\mathbf{x}} \setminus \mathcal{W}$, $\hat{\mathbf{y}}$)
5: $\quad$ **if** $\mathcal{A}'$ is null **then** ▷ *No constraint is violated*
6: $\quad\quad$ **return** $\hat{\mathbf{y}}$ ▷ *return current output*
7: $\quad$ **else**
8: $\quad\quad \mathcal{W} \leftarrow \mathcal{W} \cup \{\mathcal{A}'\}$ ▷ *update working set*
9: $\quad\quad \mathcal{A}_{\mathcal{W}} \leftarrow \mathcal{A}_{\mathcal{W}} \cap \mathcal{A}'$ ▷ *automata intersection*
10: **procedure** FIND-VIOLATION(K, $\mathbf{y}$)
11: $\quad$ **for** each $\mathcal{A}$ in K **do**
12: $\quad\quad$ **if** not $\mathcal{A}$.accepts($\mathbf{y}$) **then**
13: $\quad\quad\quad$ **return** $\mathcal{A}$ ▷ *the first violated constraint*
14: $\quad$ **return** null

Algorithm 2 is guaranteed to terminate with a valid output. In the worst case, all of the constraints will be eventually enter the active set and inference will run with a fully intersected automata. Although the cost of this worst case is exponential in the number of constraints, this occurs infrequently in practice. Moreover, we found that Algorithm 2 is faster than naively computing the full intersection despite running inference multiple times.

3 Representing Constraints as Automata

We now illustrate the expressibility of automata by showing how they can represent commonly used constraints in various NLP applications.

Text Generation. Text generation tasks like image captioning, machine translation, sentence simplification, etc., often require that the output must contain specific words or phrases (Anderson et al., 2017; Hokamp and Liu, 2017; Post and Vilar, 2018; Zhang et al., 2017) in order to incorporate prior knowledge (e.g., the caption must have the word "chair" as the object was detected in the image). Similarly, constraints can disallow invalid sequences, such as words which do not rhyme (Ghazvininejad et al., 2016, 2018) or do not appear in a dictionary (Deutsch et al., 2018). These constraints can be represented as FSAs where all paths to an accepting state contain the required sequences and do not contain any disallowed sequences. Note that the size of the automata is not a function of the output vocabulary but the vocabulary that participates in the constraints.

Sequence Tagging. Many sequence tagging problems (such as NER, shallow parsing, etc.) require that the output tags are valid under the specific tagging scheme, such as BIO, which marks each token as beginning, inside, or outside of a phrase. One can easily write an FSA that recognizes the language of valid tag sequences for these schemes, such as the automaton in Figure 2a.

Other constraints commonly applied to sequence tagging are specific to the particular task. In SRL, each argument type can appear exactly one time. For instance, for the label $\texttt{A}_0$, an FSA with 3 states (before-$\texttt{A}_0$, emitting-$\texttt{A}_0$ and after-$\texttt{A}_0$) can be written to enforce this constraint. See Tromble and Eisner (2006) for examples.

Syntactic Parsing. Syntactic parsing (dependency or constituency) tasks require that the output forms a valid tree, a constraint commonly enforced using the shift-reduce algorithm (Zhu et al., 2013; Nivre et al., 2014; Dyer et al., 2016). Shift-reduce inference inspects the state of a stack to decide which next actions are valid (e.g., if the stack is empty, reduce is invalid). Shift-reduce inference is implicitly using an automaton which is the intersection of a PDA (that counts how many shift and reduce actions have occurred) and an FSA (that restricts the maximum number of actions based on the input sentence length).

Semantic Parsing and Code Generation. In semantic parsing and code generation, constraints ensure both the syntactic validity and the executability of the output. For instance, for the predicate ISADJACENT (which compares two countries for adjacency) the syntactic constraint ensures the predicate receives two arguments, whereas the executability ensures they are properly typed (e.g., that they are countries). Krishnamurthy et al. (2017) use a type-constrained grammar to ensure the output logical form is well-typed. Similarly, Ling et al. (2016) use a stack while decoding to ensure the validity of the generated code. Both these constraints can be encoded in a PDA derived from the grammar of the language (Sipser, 1997).

4 Experimental Setup

We elaborate on two constrained inference tasks from the previous section, constituency parsing and semantic role labeling, which serve as case studies for showing the applicability and versatility of our approach. Our goal is not to beat the state-of-the-art, but to illustrate the practicality and benefits of our approach.

4.1 Models, Datasets, and Evaluation

Constituency Parsing. We follow the experimental setup of Vinyals et al. (2015) and train a seq2seq model with attention using standard splits on the Penn Treebank. This setup was chosen to ensure that no constraints are built into the model for a truly unconstrained baseline. The input is a sequence of tokens, and the model outputs a linearized parse tree ("gold parse" in Figure 4).

We compare our approach (CONSTRAINED) to unconstrained inference (UNCONSTRAINED), which runs beam search and selects the highest-scoring output. We also compare to Vinyals et al. (2015)'s inference approach (henceforth POSTHOC). Vinyals et al. (2015) removes parses without the correct number of preterminals at the end of beam search and adds parentheses to almost-valid parses.[6] The algorithms are evaluated using F_1 as reported by EVALB, a standard evaluation toolkit.[7] However, because EVALB ignores invalid trees during evaluation (which can artificially improve the performance of models which violate constraints), we also report coverage, the percentage of valid outputs. We use a beam size of 10.

Semantic Role Labeling. For SRL, the unconstrained model is an off-the-shelf implementation of He et al. (2017). The input to the model is the sentence and the predicate for which the arguments need to be identified, and the model outputs a tag sequence (such as Figure 1). To isolate the effect of constraints, we assume the gold predicates are available, unlike He et al. (2017). We use the standard train and development splits from the CoNLL 2005 shared task and the same model parameters as He et al. (2017). We report the CoNLL F_1 score[8] computed for the core arguments (namely $\texttt{A}_0$–$\texttt{A}_5$) and use greedy inference.

4.2 Constraints

Constituency Parsing. The constraints used in parsing disallow invalid parses, such as the examples in Figure 4. The constraints ensure that **(i)** the parentheses are balanced (BAL), **(ii)** there is exactly one preterminal per input token

[6] personal communication with Vinyals et al. (2015)
[7] nlp.cs.nyu.edu/evalb/
[8] www.lsi.upc.es/~srlconll/srl-eval.pl

input:	John kissed Mary
gold parse:	`(S (NP XX) (VP XX (NP XX)))`
invalid parse: **reason**:	`(S (NP ) (VP XX XX (NP XX)))` empty phrase
invalid parse: **reason**:	`(S (VP XX (NP XX)))` incorrect number of preterminals
invalid parse: **reason**:	`(S (NP XX) (VP XX (NP XX)))` unbalanced parentheses

Figure 4: An example parsing instance with different invalid parses and the constraints they violate (details in §4.2). XX denotes POS tags.

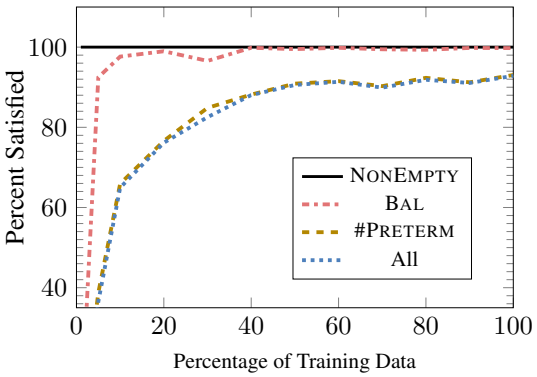

Figure 5: Percentage of output test parses that satisfy the constituency parsing constraints in §4.2 when using unconstrained inference as the amount of training data is increased. "All" measures the percent of parses which satisfy all of the constraints. Even with 100% of the training data, the model fails to always output the correct number of preterminals.

(#Preterm), and **(iii)** every phrase contains at least one preterminal (NonEmpty).

Semantic Role Labeling. The constraints used in SRL disallow invalid sequences, such as the ones in Figure 1. The constraints ensure that **(i)** a predicate cannot have multiple arguments of the same type (NoDup). This constraint is expressed using one FSA per argument label for a total of 5 automata; **(ii)** a predicate can only take a certain set of argument types (LegalArgs), according to PropBank v3.1 (Palmer et al., 2005). This constraint is expressed using one FSA; **(iii)** certain spans in the sentence should be assigned the same argument label type (SpanLabel). These spans are identified from the predicate and the constituency parse of the sentence using the heuristic of Xue and Palmer (2004).[9] This constraint is expressed using one FSA.

Ease of Implementation. All of the constraints were expressed using an FSA, with the exception of Bal which requires a PDA. The automata were implemented using Pynini (Gorman, 2016). We use the same inference code for both tasks, except for the automata generation.

5 Experimental Results

We show the practicality of our approach and the benefits over unconstrained inference in the experiments below. In order to illustrate the benefits of constrained inference in low-resource settings, we simulate different levels of supervision.

5.1 Constituency Parsing

We experimentally show the need for constraints and compare inference strategies for parsing.

Necessity of Constraints. In order to demonstrate that constraints are necessary to guarantee structurally valid output, we vary the amount of training data for a seq2seq model and measure how frequently the output is an invalid parse tree.

The results in Figure 5 show that while the model learns some constraints with little data, others are frequently violated even with full supervision. For instance, the model outputs parse trees with balanced parentheses for over 94% of instances, after training on as little as 5% of the training data. However, the model frequently violates the #Preterm constraint, outputting an incorrect number of preterminals on about 7% of parses even after training on 100% of the data. Therefore, we cannot expect seq2seq models to learn to produce valid outputs, even when it has access to 40k labeled parse trees, let alone in low-resource settings.

Comparing Inference Approaches. Figure 6 shows the performance of all the three inference techniques discussed in §4.1, namely, Unconstrained, PostHoc, and Constrained.

At first glance, it appears that Unconstrained is slightly better than both PostHoc and Constrained at 100% supervision. However, EVALB ignores any invalid parse trees when computing F_1, and therefore it is necessary to take coverage (the percent of valid output parses) into account when comparing inference approaches. It is evident from Figure 6 (left) that Constrained always ensures 100% coverage, and PostHoc only reaches near-100% coverage with full supervision. In contrast, Unconstrained

[9] We use Kitaev and Klein (2018)'s parser.

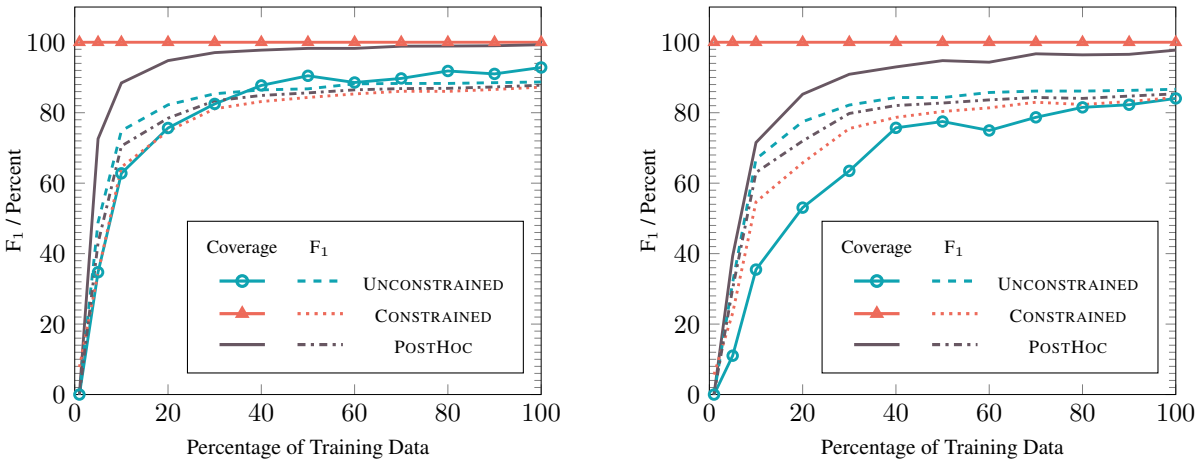

Figure 6: F_1 and coverage (# valid output parses / # test instances) for UNCONSTRAINED, POSTHOC, and CONSTRAINED on the entire test data (**left**) and test sentences of length ≥30 (**right**). The UNCONSTRAINED and POSTHOC inference algorithms have a harder time producing valid parse trees for the longer input sentences.

achieves consistently low coverage, with the best model reaching 7% lower coverage than the CONSTRAINED.

The increased coverage explains the apparent drop in F_1 for constrained approaches. Intuitively, longer sentences are inherently harder to parse. CONSTRAINED and POSTHOC produce a valid, but potentially incorrect parse for these sentences and get penalized. In contrast, UNCONSTRAINED is more likely to produce invalid parses for these sentences, and is thus effectively evaluated on a test set containing short sentences. To verify this, we re-evaluated the inference approaches on test sentences which are ≥30 tokens (Figure 6, right). Under this setting, every approach has worse F_1 and coverage at all levels of supervision (Figure 6 left vs right).

5.2 Semantic Role Labeling

We show that we can improve the performance of a trained model by incorporating constraints at inference time which address common errors (Daza and Frank, 2018) made by SRL models. This experiment also shows the efficiency of the active set method in enforcing multiple constraints.

Correcting Common Errors. We now show how some common SRL errors like the ones discussed in Figure 1, can be corrected using constraints added at inference time. Starting with an unconstrained baseline model (UNCONSTRAINED), we successively add the NODUP, LEGALARGS and SPANLABEL constraints, in that order.

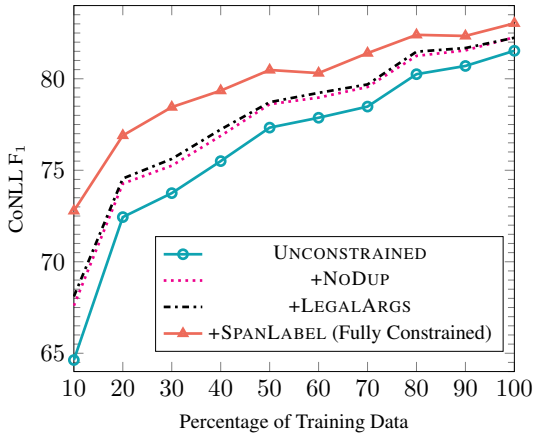

Figure 7: Learning curve for SRL. Starting with unconstrained inference, we incrementally add NODUP, LEGALARGS and SPANLABEL constraints. The constraints improve performance at all levels of supervision, with the largest improvements in low supervision settings.

Figure 7 shows that using the constraints improves performance over UNCONSTRAINED in all settings. Constraints like NODUP and SPANLABEL give significant gains, demonstrating their value. At 100% supervision, fully constrained inference improves by 1.5 F_1 points over unconstrained inference (83.03 vs 81.53). In fact, constrained inference at only 50% data achieves similar F_1 score as UNCONSTRAINED at 100%, with larger gains in low supervision regimes (≤40%).

Active Set Size and Efficiency. For SRL, the maximum possible size of the active set $\mathcal{W}$ is 7 for any test instance. Intersecting all 7 automata would lead to an automaton with 1043 states and

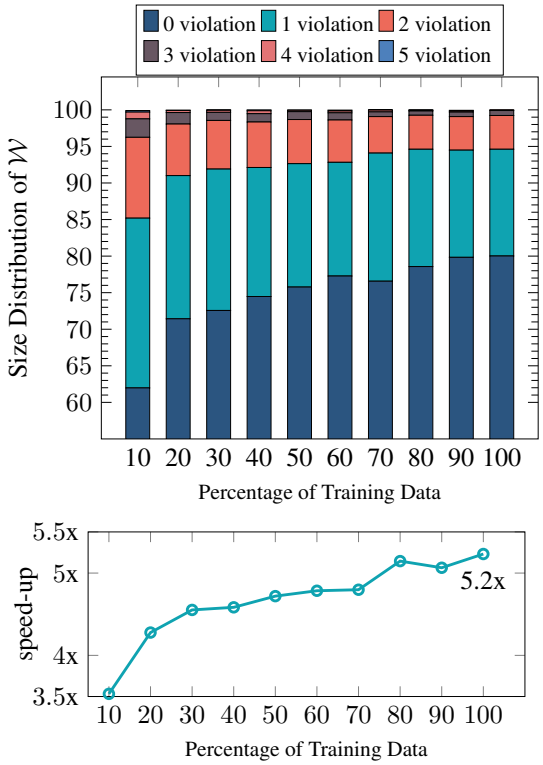

Figure 8: **Top**: Size distribution of the final working set for the active set method. With a model trained on 30% of the data, 72% of the test instances have an empty final working set (i.e., with 0 violations). **Bottom**: Relative speed-up in decoding time using the active set method over naively computing the full intersection.

2022 arcs. We now measure the size of the active set observed in practice.

Figure 8 shows the size distribution of the final $\mathcal{W}$ under different amounts of supervision. With a fully supervised model, 80% of the test instances had an empty $\mathcal{W}$ when inference terminated (i.e., no constraints entered $\mathcal{W}$). Under the same setting, $\mathcal{W}$ contains 1 and 2 constraints for 10.6% and 8.6% of the instances, respectively. Under any setting, $\mathcal{W}$ was empty for >60% of the instances. On average, the active set automaton had 34 states and 66 arcs, a 30x reduction over the full intersection.

To evaluate the efficiency of Algorithm 2, Figure 8 (bottom) plots the relative decoding times of the active set method over naively computing the full intersection. The active set method is consistently faster, with the largest speed-up (5.2x) at the highest level of supervision as the average active set size is the smallest at this setting.

Factors Affecting Speed-up. In general, the amount of speed-up provided by the active set method depends on several factors, including the number of constraints, the size of the constraint automata, and the cost of computing the softmax during inference. The largest gains will come when the former two factors are most expensive, as the active set will only incur the intersection cost as needed. If the output vocabulary is large, softmax computation may outweigh the cost of fully intersecting the constraint automata.

6 Related Work

Traditional Constrained Inference. Traditional constrained inference approaches enforced constraints using general combinatorial optimization frameworks, for instance linear (Taskar et al., 2004) and integer linear programs (Roth and Yih, 2005, 2007; Clarke and Lapata, 2008; Martins et al., 2009), SAT solvers (Richardson and Domingos, 2006; Poon and Domingos, 2008), etc. Unlike these approaches which find the best output that satisfies a set of constraints, our work attempts to provide a similar general framework for sequential inference algorithms that will find the approximate-best output.

Unconstrained Data-driven Approaches. Many sequential inference approaches do not enforce constraints at all, in the hope that they will be learned from data (Lample et al., 2016; Choe and Charniak, 2016; Suhr et al., 2018). While the model can potentially "impose" some constraints which are well-represented in the data, there is no guarantee that the output structure will be valid. In contrast, our work guarantees valid output.

Post-Hoc Constraint Satisfaction. Some approaches first run unconstrained inference to find the top-k structures and then identify valid structures in a post-hoc manner (Andreas et al., 2013; Vinyals et al., 2015; Kiddon et al., 2016; Upadhyay et al., 2018). Such techniques also cannot guarantee validity of the output structure when all top-k structures are invalid, whereas our model ensures all top-k are valid.

Our Work. We draw from work in NLP that uses automata (Mohri, 1997; Karttunen, 2000, inter alia) and recent work in constrained text generation (discussed in §3). Our work is also related to Anderson et al. (2017) who impose lexical constraints for image captioning by maintaining a beam for *each* state in an FSA, an impractical strategy for automata with thousands of states (like those in §5.2). Tromble and Eisner (2006)

was the inspiration for the active set method. A very recent work, Lee et al. (2019), also impose constraints in sequential inference by including them in the objective function and modifying the model's weights until the constraints are satisfied.

7 Conclusion and Future Work

We presented a principled, general-purpose constrained sequential inference algorithm. Key to our algorithm is using automata to represent constraints, which we showed are capable of expressing popularly used constraints in NLP. Our approach is an attractive alternative to task-specific constrained inference approaches currently in use. Using a fast active set method, we can seamlessly incorporate multiple constraints at inference time without modifying the inference code. The experimental results showed the value of our approach over unconstrained inference, with the gains becoming more prominent in low-resource settings.

Abstract

Automated fact-checking based on machine learning is a promising approach to identify false information distributed on the web. In order to achieve satisfactory performance, machine learning methods require a large corpus with reliable annotations for the different tasks in the fact-checking process. Having analyzed existing fact-checking corpora, we found that none of them meets these criteria in full. They are either too small in size, do not provide detailed annotations, or are limited to a single domain. Motivated by this gap, we present a new substantially sized mixed-domain corpus with annotations of good quality for the core fact-checking tasks: document retrieval, evidence extraction, stance detection, and claim validation. To aid future corpus construction, we describe our methodology for corpus creation and annotation, and demonstrate that it results in substantial inter-annotator agreement. As baselines for future research, we perform experiments on our corpus with a number of model architectures that reach high performance in similar problem settings. Finally, to support the development of future models, we provide a detailed error analysis for each of the tasks. Our results show that the realistic, multi-domain setting defined by our data poses new challenges for the existing models, providing opportunities for considerable improvement by future systems.

1 Introduction

The ever-increasing role of the Internet as a primary communication channel is arguably the single most important development in the media over the past decades. While it has led to unprecedented growth in information coverage and distribution speed, it comes at a cost. False information can be shared through this channel reaching a much wider audience than traditional means of disinformation (Howell et al., 2013).

While human fact-checking still remains the primary method to counter this issue, the amount and the speed at which new information is spread makes manual validation challenging and costly. This motivates the development of automated fact-checking pipelines (Thorne et al., 2018a; Popat et al., 2017; Hanselowski and Gurevych, 2017) consisting of several consecutive tasks. The following four tasks are commonly included in the pipeline. Given a controversial claim, *document retrieval* is applied to identify documents that contain important information for the validation of the claim. *Evidence extraction* aims at retrieving text snippets or sentences from the identified documents that are related to the claim. This evidence can be further processed via *stance detection* to infer whether it supports or refutes the claim. Finally, *claim validation* assesses the validity of the claim given the evidence.

Automated fact-checking has received significant attention in the NLP community in the past years. Multiple corpora have been created to assist the development of fact-checking models, varying in quality, size, domain, and range of annotated phenomena. Importantly, the successful development of a full-fledged fact-checking system requires that the underlying corpus satisfies certain characteristics. First, training data needs to contain a large number of instances with *high-quality annotations* for the different fact-checking sub-tasks. Second, the training data should not be limited to a particular domain, since potentially wrong information sources can range from official statements to blog and Twitter posts.

We analyzed existing corpora regarding their adherence to the above criteria and identified several drawbacks. The corpora introduced by Vlachos and Riedel (2014); Ferreira and Vlachos (2016); Derczynski et al. (2017) are valuable for the analysis of the fact-checking problem and pro-

vide annotations for stance detection. However, they contain only several hundreds of validated claims and it is therefore unlikely that deep learning models can generalize to unobserved claims if trained on these datasets.

A corpus with significantly more validated claims was introduced by Popat et al. (2017). Nevertheless, for each claim, the corpus provides 30 documents which are retrieved from the web using the Google search engine instead of a document collection aggregated by fact-checkers. Thus, many of the documents are unrelated to the claim and important information for the validation may be missing.

The FEVER corpus constructed by Thorne et al. (2018a) is the largest corpus available for the development of automated fact-checking systems. It consists of 185,445 validated claims with annotated documents and evidence for each of them. The corpus therefore allows training deep neural networks for automated fact-checking, which reach higher performance than shallow machine learning techniques. However, the corpus is based on synthetic claims derived from Wikipedia sentences rather than *natural* claims that originate from heterogeneous web sources.

In order to address the drawbacks of existing datasets, we introduce a new corpus based on the Snopes[1] fact-checking website. Our corpus consists of 6,422 validated claims with comprehensive annotations based on the data collected by Snopes fact-checkers and our crowd-workers. The corpus covers multiple domains, including discussion blogs, news, and social media, which are often found responsible for the creation and distribution of unreliable information. In addition to validated claims, the corpus comprises over 14k documents annotated with evidence on two granularity levels and with the stance of the evidence with respect to the claims. Our data allows training machine learning models for the four steps of the automated fact-checking process described above: document retrieval, evidence extraction, stance detection, and claim validation.

The contributions of our work are as follows:

1) We provide a substantially sized mixed-domain corpus of natural claims with annotations for different fact-checking tasks. We publish a web crawler that reconstructs our dataset including all annotations[2]. For research purposes, we are allowed to share the original corpus[3].

2) To support the creation of further fact-checking corpora, we present our methodology for data collection and annotation, which allows for the efficient construction of large-scale corpora with a substantial inter-annotator agreement.

3) For evidence extraction, stance detection, and claim validation we evaluate the performance of high-scoring systems from the FEVER shared task (Thorne et al., 2018b)[4] and the Fake News Challenge (Pomerleau and Rao, 2017)[5] as well as the Bidirectional Transformer model BERT (Devlin et al., 2018) on our data. To facilitate the development of future fact-checking systems, we release the code of our experiments[6].

4) Finally, we conduct a detailed error analysis of the systems trained and evaluated on our data, identifying challenging fact-checking instances which need to be addressed in future research.

2 Related work

Below, we give a comprehensive overview of existing fact-checking corpora, summarized in Table 1. We focus on their key parameters: fact-checking sub-task coverage, annotation quality, corpus size, and domain. It must be acknowledged that a fair comparison between the datasets is difficult to accomplish since the length of evidence and documents, as well as the annotation quality, significantly varies between the corpora.

PolitiFact14 Vlachos and Riedel (2014) analyzed the fact-checking problem and constructed a corpus on the basis of the fact-checking blog of Channel 4[7] and the Truth-O-Meter from PolitiFact[8]. The corpus includes additional evidence, which has been used by fact-checkers to validate the

claims, as well as metadata including the speaker ID and the date when the claim was made. This is early work in automated fact-checking and Vlachos and Riedel (2014) mainly focused on the analysis of the task. The corpus therefore only contains 106 claims, which is not enough to train high-performing machine learning systems.

Emergent16 A more comprehensive corpus for automated fact-checking was introduced by Ferreira and Vlachos (2016). The dataset is based on the project Emergent[9] which is a journalist initiative for rumor debunking. It consists of 300 claims that have been validated by journalists. The corpus provides 2,595 news articles that are related to the claims. Each article is summarized into a headline and is annotated with the article's stance regarding the claim. The corpus is well suited for training stance detection systems in the news domain and it was therefore chosen in the Fake News Challenge (Pomerleau and Rao, 2017) for training and evaluation of competing systems. However, the number of claims in the corpus is relatively small, thus it is unlikely that sophisticated claim validation systems can be trained using this corpus.

PolitiFact17 Wang (2017) extracted 12,800 validated claims made by public figures in various contexts from Politifact. For each statement, the corpus provides a verdict and meta information, such as the name and party affiliation of the speaker or subject of the debate. Nevertheless, the corpus does not include evidence and thus the models can only be trained on the basis of the claim, the verdict, and meta information.

RumourEval17 Derczynski et al. (2017) organized the RumourEval shared task, for which they provided a corpus of 297 rumourous threads from Twitter, comprising 4,519 tweets. The shared task was divided into two parts, *stance detection* and *veracity prediction* of the rumors, which is similar to claim validation. The large number of stance-annotated tweets allows for training stance detection systems reaching a relatively high score of about 0.78 accuracy. However, since the number of claims (rumours) is relatively small, and the corpus is only based on tweets, this dataset alone is not suitable to train generally applicable claim validation systems.

Snopes17 A corpus featuring a substantially larger number of validated claims was introduced by Popat et al. (2017). It contains 4,956 claims annotated with verdicts which have been extracted from the Snopes website as well as the Wikipedia collections of proven hoaxes[10] and fictitious people[11]. For each claim, the authors extracted about 30 associated documents using the Google search engine, resulting in a collection of 136,085 documents. However, since the documents were not annotated by fact-checkers, irrelevant information is present and important information for the claim validation might be missing.

CLEF-2018 Another corpus concerned with political debates was introduced by Nakov et al. (2018) and used for the CLEF-2018 shared task. The corpus consists of transcripts of political debates in English and Arabic and provides annotations for two tasks: identification of check-worthy statements (claims) in the transcripts, and validation of 150 statements (claims) from the debates. However, as for the corpus **PolitiFact17**, no evidence for the validation of these claims is available.

FEVER18 The FEVER corpus introduced by Thorne et al. (2018a) is the largest available fact-

[9] http://www.emergent.info/

[10] https://en.wikipedia.org/wiki/List_of_hoaxes#Proven_hoaxe

[11] https://en.wikipedia.org/wiki/List_of_fictitious_people

checking corpus, consisting of 185,445 validated claims. The corpus is based on about 50k popular Wikipedia articles. Annotators modified sentences in these articles to create the claims and labeled other sentences in the articles, which support or refute the claim, as evidence. The corpus is large enough to train deep learning systems able to retrieve evidence from Wikipedia. Nevertheless, since the corpus only covers Wikipedia and the claims are created synthetically, the trained systems are unlikely to be able to extract evidence from heterogeneous web-sources and validate claims on the basis of evidence found on the Internet.

As our analysis shows, while multiple fact-checking corpora are already available, no single existing resource provides full fact-checking sub-task coverage backed by a substantially-sized and validated dataset spanning across multiple domains. To eliminate this gap, we have created a new corpus as detailed in the following sections.

3 Corpus construction

This section describes the original data from the Snopes platform, followed by a detailed report on our corpus annotation methodology.

3.1 Source data

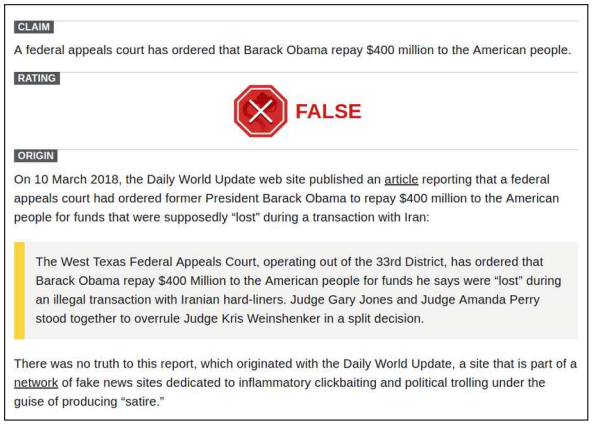

Figure 1: Snopes fact-checking data example

Snopes is a large-scale fact-checking platform that employs human fact-checkers to validate claims. A simple *fact-checking instance* from the Snopes website is shown in Figure 1. At the top of the page, the *claim* and the *verdict* (rating) are given. The fact-checkers additionally provide a *resolution* (origin), which backs up the verdict. Evidence in the resolution, which we call *evidence text snippets* (ETSs), is marked with a yellow bar. As additional validation support, Snopes fact-checkers provide URLs[12] for *original documents* (ODCs) from which the ETSs have been extracted or which provide additional information.

Our crawler extracts the *claims*, *verdicts*, *ETSs*, the *resolution*, as well as *ODCs* along with their URLs, thereby enriching the ETSs with useful contextual information. Snopes is almost entirely focused on claims made on English speaking websites. Our corpus therefore only features English fact-checking instances.

3.2 Corpus annotation

While ETSs express a stance towards the claim, which is useful information for the fact-checking process, this stance is not explicitly stated on the Snopes website. Moreover, the ETSs given by fact-checkers are quite coarse and often contain detailed background information that is not directly related to the claim and consequently not useful for its validation. In order to obtain an informative, high-quality collection of evidence, we asked crowd-workers to label the stance of ETSs and to extract sentence-level evidence from the ETSs that are directly relevant for the validation of the claim. We further refer to these sentences as *fine grained evidence* (FGE).

Stance annotation. We asked crowd workers on Amazon Mechanical Turk[13] to annotate whether an ETS *agrees* with the claim, *refutes* it, or has *no stance* towards the claim. An ETS was only considered to express a stance if it explicitly referred to the claim and either expressed support for it or refuted it. In all other cases, the ETS was considered as having *no stance*.

FGE annotation. We filtered out ETSs with *no stance*, as they do not contain supporting or refuting FGE. If an ETS was annotated as supporting the claim, the crowd workers selected only supporting sentences; if the ETS was annotated as refuting the claim, only refuting sentences were selected. Table 2 shows two examples of ETSs with annotated FGE. As can be observed, not all information given in the original ETS is directly relevant for validating the claim. For example, sentence (1c) in the first example's ETS simply provides additional background information and is therefore not considered FGE.

[12] underlined words in the resolution are hyperlinks

[13] https://www.mturk.com/

ETS stance: support
Claim: The Fox News will be shutting down for routine maintenance on 21 Jan. 2013.
Evidence text snippet: (1a) *Fox News Channel announced today that it would shutdown for what it called "routine maintenance".* (1b) *The shutdown is on 21 January 2013.* (1c) Fox News president Roger Ailes explained the timing of the shutdown: "We wanted to pick a time when nothing would be happening that our viewers want to see."

ETS stance: refute
Claim: Donald Trump supported Emmanuel Macron during the French election.
Evidence text snippet: (2a) In their first meeting, the U.S. President told Emmanuel Macron that he had been his favorite in the French presidential election saying "You were my guy". (2b) *In an interview with the Associated Press, however, Trump said he thinks Le Pen is stronger than Macron on what's been going on in France.*

Table 2: Examples of FGE annotation in supporting (top) and refuting (bottom) ETSs, sentences selected as FGE in italic.

4 Corpus analysis

4.1 Inter-annotator agreement

Stance annotation. Every ETS was annotated by at least six crowd workers. We evaluate the inter-annotator agreement between groups of workers as proposed by Habernal et al. (2017), i.e. by randomly dividing the workers into two equal groups and determining the aggregate annotation for each group using MACE (Hovy et al., 2013). The final inter-annotator agreement score is obtained by comparing the aggregate annotation of the two groups. Using this procedure, we obtain a Cohen's Kappa of $\kappa = 0.7$ (Cohen, 1968), indicating a substantial agreement between the crowd workers (Artstein and Poesio, 2008). The gold annotations of the ETS stances were computed with MACE, using the annotations of all crowd workers. We have further assessed the quality of the annotations performed by crowd workers by comparing them to expert annotations. Two experts labeled 200 ETSs, reaching the same agreement as the crowd workers, i.e. $\kappa = 0.7$. The agreement between the experts' annotations and the computed gold annotations from the crowd workers is also substantial, $\kappa = 0.683$.

FGE Annotation. Similar to the stance annotation, we used the approach of Habernal et al. (2017) to compute the agreement. The inter-annotator agreement between the crowd workers in this case is $\kappa = 0.55$ Cohen's Kappa. We compared the annotations of FGE in 200 ETSs by experts with the annotations by crowd workers, reaching an agreement of $\kappa = 0.56$. This is considered as *moderate* inter-annotator agreement (Artstein and Poesio, 2008).

In fact, the task is significantly more difficult than stance annotation as sentences may provide only partial evidence for or against the claim. In such cases, it is unclear how large the information overlap between sentence and claim should be for a sentence to be FGE. The sentence (1a) in Table 2, for example, only refers to one part of the claim without mentioning the time of the shutdown. We can further modify the example in order to make the problem more obvious: *(a) The channel announced today that it is planing a shutdown. (b) Fox News made an announcement today.*

As the example illustrates, there is a gradual transition between sentences that can be considered as essential for the validation of the claim and those which just provide minor negligible details or unrelated information. Nevertheless, even though the inter-annotator agreement for the annotation of FGE is lower than for the annotation of ETS stance, compared to other annotation problems (Zechner, 2002; Benikova et al., 2016; Tauchmann et al., 2018) that are similar to the annotation of FGE, our framework leads to a better agreement.

4.2 Corpus statistics

Table 3 displays the main statistics of the corpus. In the table, *FGE sets* denotes groups of FGE extracted from the same ETS. Many of the ETSs have been annotated as *no stance* (see Table 5) and, following our annotation study setup, are not used for FGE extraction. Therefore, the number of FGE sets is much lower than that of ETSs. We have found that, on average, an ETS consists of 6.5 sentences. For those ETS that have support/refute stance, on average, 2.3 sentences are selected as FGE. For many of the ETSs, no original documents (ODCs) have been provided (documents from which they have been extracted). On

the other hand, in many instances, links to ODCs are given that provide additional information, but from which no ETSs have been extracted.

entity:	claims	ETSs	FGE sets	ODCs
count:	6,422	16,509	8,291	14,296

Table 3: Overall statistics of the corpus

The distribution of verdicts in Table 4 shows that the dataset is unbalanced in favor of false claims. The label *other* refers to a collocation of verdicts that do not express a tendency towards declaring the claim as being false or true, such as *mixture, unproven, outdated, legend,* etc.

verdict:	false	true	most. false	most. true	other
count	2,943	659	334	93	2,393
%	45.8	10.3	5.2	1.4	37.3

Table 4: Distribution of verdicts for claims

Table 5 shows the stance distribution for ETSs. Here, supporting ETSs and ETSs that do not express any stance are dominating.

stance:	support	refute	no stance
ETSs:			
count	6,734	2,266	7,508
%	40.8	13.7	45.5
FGE sets:			
count	6,178	2,113	–
%	74.5	25.5	–

Table 5: Class distribution of ETSs the FGE sets

For supporting and refuting ETSs annotators identified FGE sets for 8,291 out of 8,998 ETSs. ETSs with a stance but without FGE sets often miss a clear connection to the claim, so the annotators did not annotate any sentences in these cases. The class distribution of the FGE sets in Table 5 shows that supporting ETSs are more dominant.

To identify potential biases in our new dataset, we investigated which topics are prevalent by grouping the fact-checking instances (claims with their resolutions) into categories defined by Snopes. According to our analysis, the four categories *Fake News*, *Political News*, *Politics* and *Fauxtography* are dominant in the corpus ranging from more than 700 to about 900 instances. A significant number of instances are present in the categories *Inboxer Rebellion (Email hoax)*, *Business*, *Medical*, *Entertainment* and *Crime*.

We further investigated the sources of the collected documents (ODCs) and grouped them into a number of classes. We found that 38% of the articles are from different news websites ranging from mainstream news like CNN to tabloid press and partisan news. The second largest group of documents are false news and satirical articles with 30%. Here, the majority of articles are from the two websites *thelastlineofdefense.org* and *worldnewsdailyreport.com*. The third class of documents, with a share of 11%, are from social media like Facebook and Twitter. The remaining 21% of documents come from diverse sources, such as debate blogs, governmental domains, online retail, or entertainment websites.

4.3 Discussion

I this subsection, we briefly discuss the differences of our corpus to the FEVER dataset as the most comprehensive dataset introduced so far. Due to the way the FEVER dataset was constructed, the claim validation problem defined by this corpus is different compared to the problem setting defined by our corpus. The verdict of a claim for FEVER depends on the stance of the evidence, that is, if the stance of the evidence is agree the claim is necessarily true, and if the stance is disagree the claim is necessarily false. As a result, the claim validation problem can be reduced to stance detection. Such a transformation is not possible for our corpus, as the evidence might originate from unreliable sources and a claim may have both supporting and refuting ETSs. The stance of ETSs is therefore not necessarily indicative of the veracity of the claim. In order to investigate how the stance is related to the verdict of the claim for our dataset, we computed their correlation. In the correlation analysis, we considered how a claims' verdict, represented by the classes *false*, *mostly false*, *other*, *mostly true*, *true*, correlates with the number of supporting ETSs minus the number of refuting ETSs. More precisely, the verdicts of the claims are considered as one variable, which can take 5 discreet values ranging from *false* to *true*, and the stance is considered as the other variable, which is represented by the difference between the number of supporting versus the number of refuting evidence. We found that the verdict is only weakly correlated with the stance, as indicated by the Pearson correlation coefficient of 0.16. This illustrates that the fact-checking problem setting

for our corpus is more challenging than for the FEVER dataset.

5 Experiments and error analysis

The annotation of the corpus described in the previous section provides supervision for different fact-checking sub-tasks. In this paper, we perform experiments for the following sub-tasks: (1) detection of the stance of the ETSs with respect to the claim, (2) identification of FGE in the ETSs, and (3) prediction of a claim's verdict given FGE.

There are a number of experiments beyond the scope of this paper, which are left for future work: (1) retrieval of the original documents (ODCs) given a claim, (2) identification of ETSs in ODCs, and (3) prediction of a claim's verdict on the basis of FGE, the stance of FGE, and their sources.

Moreover, in this paper, we consider the three tasks independent of each other rather than as a pipeline. In other words, we always take the gold standard from the preceding task instead of the output of the preceding model in the pipeline. For the three independent tasks, we use recently suggested models that achieved high performance in similar problem settings. In addition, we provide the human agreement bound, which is determined by comparing expert annotations for 200 ETSs to the gold standard derived from crowd worker annotations (Section 4.1).

5.1 Stance detection

In the stance detection task, models need to determine whether an ETS *supports* or *refutes* a claim, or expresses *no stance* with respect to the claim.

5.1.1 Models and Results

We report the performance of the following models: `AtheneMLP` is a feature-based multi-layer perceptron (Hanselowski et al., 2018a), which has reached the second rank in the Fake News Challenge. `DecompAttent` (Parikh et al., 2016) is a neural network with a relatively small number of parameters that uses decomposable attention, reaching good results on the Stanford Natural Language Inference task (Bowman et al., 2015). `USE+Attent` is a model which uses the Universal Sentence Encoder (USE) (Cer et al., 2018) to extract representations for the sentences of the ETSs and the claim. For the classification of the stance, an attention mechanism and a MLP is used.

The results in Table 6 show that `AtheneMLP` scores highest. Similar to the outcome of the Fake News Challenge, feature-based models outperform neural networks based on word embeddings (Hanselowski et al., 2018a). As the comparison to the human agreement bound suggests, there is still substantial room for improvement.

model	recall	precision	F1m
agreement bound	0.770	0.837	0.802
random baseline	0.333	0.333	0.333
majority vote	0.150	0.333	0.206

USE+Attent	0.380	0.505	0.434

Table 6: Stance detection results (F1m = F1 macro)

5.1.2 Error analysis

We performed an error analysis for the best-scoring model `AtheneMLP`. The error analysis has shown that *supporting* ETSs are mostly classified correctly if there is a significant lexical overlap between the claim and the ETS. If the claim and the ETSs use different wording, or if the ETS implies the validity of the claim without explicitly referring to it, the model often misclassifies the snippets (see example in the Appendix A.2.1). This is not surprising, as the model is based on bag-of-words, topic models, and lexica.

Moreover, as the distribution of the classes in Table 5 shows, *support* and *no stance* are more dominant than the *refute* class. The model is therefore biased towards these classes and is less likely to predict *refute* (see confusion matrix in the Appendix Table 11). An analysis of the misclassified *refute* ETSs has shown that the contradiction is often expressed in difficult terms, which the model could not detect, e.g. "the myth originated", "no effect can be observed", "The short answer is no".

5.2 Evidence extraction

We define evidence extraction as the identification of fine-grained evidence (FGE) in the evidence text snippets (ETSs). The problem can be approached in two ways, either as a *classification problem*, where each sentence from the ETSs is classified as to whether it is an evidence for a given claim, or as a *ranking problem*, in the way defined in the FEVER shared task. For FEVER, sentences in introductory sections of Wikipedia articles need to be ranked according to their relevance for the validation of the claim and the 5 highest ranked sentences are taken as evidence.

5.2.1 Models and Results

We consider the task as a ranking problem, but also provide the human agreement bound, the random baseline and the majority vote for evidence extraction as a *classification problem* for future reference in Table 10 in the Appendix.

To evaluate the performance of the models in the *ranking* setup, we measure the precision and recall on five highest ranked ETS sentences (precision @5 and recall @5), similar to the evaluation procedure used in the FEVER shared task. Table 7 summarizes the performance of several models on our corpus. The `rankingESIM` (Hanselowski et al., 2018b) was the best performing model on the FEVER evidence extraction task. The `Tf-Idf` model (Thorne et al., 2018a) served as a baseline in the FEVER shared task. We also evaluate the performance of `DecompAttent` and a simple `BiLSTM` (Hochreiter and Schmidhuber, 1997) architecture. To adjust the latter two models to the ranking problem setting, we used the hinge loss objective function with negative sampling as implemented in the `rankingESIM` model. As in the FEVER shared task, we consider the recall @5 as a metric for the evaluation of the systems.

The results in Table 7 illustrate that, in terms of recall, the neural networks with a small number of parameters, `BiLSTM` and `DecompAttent`, perform best. The `Tf-Idf` model reaches best results in terms of precision. The `rankingESIM` reaches a relatively low score and is not able to beat the random baseline. We assume this is because the model has a large number of parameters and requires many training instances.

model	precision @5	recall @5
random baseline	0.296	0.529
BiLSTM	0.451	**0.637**
DecompAttent	0.420	0.627
Tf-Idf	**0.627**	0.601
rankingESIM	0.288	0.507

Table 7: Evidence extraction: ranking setting

5.2.2 Error analysis

We performed an error analysis for the `BiLSTM` and the `Tf-Idf` model, as they reach the highest recall and precision, respectively. `Tf-Idf` achieves the best precision because it only predicts a small set of sentences, which have lexical overlap with the claim. The model therefore misses FGE that paraphrase the claim. The `BiLSTM` is better able to capture the semantics of the sentences. We believe that it was therefore able to take related word pairs, such as "*Israel*" - "*Jewish*", "*price*"-"*sold*", "*pointed*"-"*pointing*", "*broken*"-"*injured*", into account during the ranking process. Nevertheless, the model fails when the relationship between the claim and the potential FGE is more elaborate, e.g. if the claim is not paraphrased, but reasons for it being true are provided. An example of a misclassified sentence is given in the Appendix A.2.2.

5.3 Claim validation

We formulate the claim validation problem in such a way that we can compare it to the FEVER *recognizing textual entailment* task. Thus, as illustrated in Table 8, we compress the different verdicts present on the Snopes webpage into three categories of the FEVER shared task. In order to form the *not enough information* (NEI) class, we compress the three verdicts *mixture*, *unproven*, and *undetermined*. We entirely omit all the other verdicts like *legend, outdated, miscaptioned*, as these cases are ambiguous and difficult to classify. For the classification of the claims, we provide only the FGE as they contain the most important information from ETSs.

FEVER	Snopes
refuted:	false, mostly false
supported:	true, mostly true
NEI:	mixture, unproven, undetermined

Table 8: Compression of Snopes verdicts

5.3.1 Experiments

For the claim validation, we consider models of different complexity: `BertEmb` is an MLP classifier which is based on BERT pre-trained embeddings (Devlin et al., 2018); `DecompAttent` was used in the FEVER shared task as baseline; `extendedESIM` is an extended version of the ESIM model (Hanselowski et al., 2018b) reaching the third rank in the FEVER shared task; `BiLSTM` is a simple BiLSTM architecture; `USE+MLP` is the Universal Sentence Encoder combined with a MLP; `SVM` is an SVM classifier based on bag-of-words, unigrams, and topic models.

The results illustrated in Table 9 show that `BertEmb`, `USE+MLP`, `BiLSTM`, and `extendedESIM` reach similar performance, with `BertEmb` being the best. However, compared to the FEVER claim validation problem,

Labeling method	recall m	prec. m	F1 m
random baseline	0.333	0.333	0.333
majority vote	0.198	0.170	0.249
BertEmb	0.477	**0.493**	**0.485**
USE+MLP	0.483	0.468	0.475
BiLSTM	0.456	0.473	0.464
extendedESIM	**0.561**	0.503	0.454
featureSVM	0.384	0.396	0.390
DecompAttent	0.336	0.312	0.324

Table 9: Claim validation results (m = macro)

where systems reach up to 0.7 F1 macro, the scores are relatively low. Thus, there is ample opportunity for improvement by future systems.

5.3.2 Error analysis

We performed an error analysis for the best-scoring model `BertEmb`. The class distribution for claim validation is highly biased towards *refuted* (false) claims and, therefore, claims are frequently labeled as *refuted* even though they belong to one of the other two classes (see confusion matrix in the Appendix in Table 12).

We have also found that it is often difficult to classify the claims as the provided FGE in many cases are contradicting (e.g. Appendix A.2.3). Although the corpus is biased towards false claims (Table 5), there is a large number of ETSs that support those false claims (Table 4). As discussed in Section 4.2, this is because many of the retrieved ETSs originate from false news websites.

Another possible reason for the lower performance is that our data is heterogeneous and, therefore, it is more challenging for a machine learning model to generalize. In fact, we have performed additional experiments in which we pre-trained a model on the FEVER corpus and fine-tuned the parameters on our corpus and vice versa. However, no significant performance gain could be observed in both experiments

Based on our analysis, we conclude that heterogeneous data and FGE from unreliable sources, as found in our corpus and in the real world, make it difficult to correctly classify the claims. Thus, in future experiments, not just FGE need to be taken into account, but also additional information from our newly constructed corpus, that is, the stance of the FGE, FGE sources, and documents from the Snopes website which provide additional information about the claim. Taking all this information into account would enable the system to find a consistent configuration of these labels and thus potentially help to improve performance. For instance, a claim that is *supported* by evidence coming from an *unreliable* source is most likely *false*. In fact, we believe that modeling the meta-information about the evidence and the claim more explicitly represents an important step in making progress in automated fact-checking.

6 Conclusion

In this paper, we have introduced a new richly annotated corpus for training machine learning models for the core tasks in the fact-checking process. The corpus is based on heterogeneous web sources, such as blogs, social media, and news, where most false claims originate. It includes validated claims along with related documents, evidence of two granularity levels, the sources of the evidence, and the stance of the evidence towards the claim. This allows training machine learning systems for document retrieval, stance detection, evidence extraction, and claim validation.

We have described the structure and statistics of the corpus, as well as our methodology for the annotation of evidence and the stance of the evidence. We have also presented experiments for stance detection, evidence extraction, and claim validation with models that achieve high performance in similar problem settings. In order to support the development of machine learning approaches that go beyond the presented models, we provided an error analysis for each of the three tasks, identifying difficulties with each.

Our analysis has shown that the fact-checking problem defined by our corpus is more difficult than for other datasets. Heterogeneous data and evidence from unreliable sources, as found in our corpus and in the real world, make it difficult to correctly classify the claims. We conclude that more elaborate approaches are required to achieve higher performance in this challenging setting.

Detecting Frames in News Headlines and Its Application to Analyzing News Framing Trends Surrounding U.S. Gun Violence

{liusiyi, guolei, kkmays, betke, wijaya}@bu.edu

Abstract

Different news articles about the same topic often offer a variety of perspectives: an article written about gun violence might emphasize gun control, while another might promote 2nd Amendment rights, and yet a third might focus on mental health issues. In communication research, these different perspectives are known as "frames", which, when used in news media will influence the opinion of their readers in multiple ways. In this paper, we present a method for effectively detecting frames in news headlines. Our training and performance evaluation is based on a new dataset of news headlines related to the issue of gun violence in the United States. This Gun Violence Frame Corpus (GVFC) was curated and annotated by journalism and communication experts. Our proposed approach sets a new state-of-the-art performance for multiclass news frame detection, significantly outperforming a recent baseline by 35.9% absolute difference in accuracy. We apply our frame detection approach in a large scale study of 88k news headlines about the coverage of gun violence in the U.S. between 2016 and 2018.

1 Introduction

The political climate in the United States is increasingly polarized (Pew Research Center, 2018a). To many media scholars and pundits, the main reason that liberals and conservatives inhabit different worlds is that news media of varied political orientations have been depicting two distinct versions of social reality (Mitchell et al., 2014; Stroud, 2011). To address this problem, one needs to assess the ways in which news reporters frame important public affairs. In communication research, "to frame" means "to select some aspects of a perceived reality and make them more salient in a communicating text" (Entman, 1993). Like any type of communication, news involves framing. In a polarized media environment, partisan media outlets intentionally frame news stories in a way to advance certain political agendas (Jamieson et al., 2007; Levendusky, 2013). Even when journalists make their best efforts to pursue objectivity, media framing often favors one side over another in political disputes, thus always resulting in some degree of bias (Entman, 2010). Hence, a news framing analysis is helpful because it not only tells us whether a news article is left- or right-leaning (or positive or negative), but also reveals how the article is structured to promote a certain side of the political spectrum.

In communication research, manual identification of media frames is a challenging task due to the large amount of media data in this news-saturated environment. More importantly, there is a high level of complexity in framing analysis that often requires a careful investigation of nuances in news coverage, which is time-consuming. In the field of Natural Language Processing (NLP), automated news framing analysis is a relatively unexplored area. Existing sentiment-analysis techniques fall short of addressing the nuances needed for framing analysis, which requires the detection of perspectives beyond positive and negative.

In this paper, we develop a neural network based approach for classifying frames in news article headlines by fine-tuning a state-of-the-art language representation model (BERT: Bidirectional Encoder Representations from Transformers (Devlin et al., 2018)) for the task of frame detection.

Here, we focus on the application of news frame detection on one prominent public affairs issue in the United States, namely, gun violence. Some of the deadliest mass shootings have happened during the past few years. In fact, the United States has the highest rate of gun-related homicides in the developed world. However, Republicans and Democrats remain divided on whether gun vio-

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 504–514
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

lence is an important issue and disagree on most gun-related policies, making gun violence one of the most polarized issues in the country. (Pew Research Center, 2018b). As a result, despite the seriousness of the issue in reality, it is not considered a priority that should be tackled at the Congressional level. One factor that potentially explains the divergence of public opinion is how different politically oriented news media cover gun violence. It is likely that liberal-leaning and conservative-leaning media frame the issue in different ways, which may ultimately determine different publics' perception of the issue.

We use our frame detection approach to automatically detect frames of news article headlines related to gun violence during the past few years, which enables large scale analysis of framing trends surrounding this issue in the United States. Specifically, we focus on the years 2016, 2017, and 2018 because these three years have witnessed a number of high-profile mass shootings, which often reignited national gun debate.

Overall, our analysis results in interesting findings about U.S. media coverage of gun violence that speak to the divided media and political landscape in the country. Our contributions are twofold: Firstly, we have developed a state-of-the-art news frame detection approach by fine-tuning BERT language model to perform the multiclass (frame) classification on news article headlines. Our approach significantly outperforms a recent baseline in automated news frame detection (Field et al., 2018) and other neural network baselines.

Secondly, we have curated a new dataset of news articles related to U.S. gun violence: the Gun Violence Frame Corpus (GVFC), which contains news headlines and their frame annotations from 21 major U.S. news organizations. This dataset is the first of its kind in that it is carefully curated and contains domain-expert annotations of frames in news headlines. We use our model trained on GVFC to do a large scale analysis of U.S. gun violence framing trends in the U.S. between 2016 and 2018.

2 Related Work

2.1 News Framing

Framing is a subtle form of media manipulation in which some aspects of a topic are highlighted in order to promote a particular interpretation. It is related to the word choice and labeling by journalists (Hamborg et al., 2019) for example, by choosing "illegal alien" instead of "undocumented immigrant", journalists can highlight different aspects of an immigration issue.

Communication researchers have developed a variety of approaches to analyzing media framing. One popular quantitative approach is to first identify a list of frames and then manually classify news articles into one of the identified frames. Journalists often use generic frames that are common across a range of issues, such as human interest, conflict, and economic consequences (Russell Neuman et al., 1993; Nisbet, 2010; Semetko and Valkenburg, 2000), on top of issue-specific frames in their reporting. There are a number of issue-specific frames that have been particularly related to the issue of gun violence in the United States. On a basic level, the debate about guns has been framed as a threat to *public safety* (Haider-Markel and Joslyn, 2001; Lawrence and Birkland, 2004), enabled by weak *gun laws* (Birkland and Lawrence, 2009), versus an individual right to have access to guns secured by the *2nd Amendment*'s "right to bear arms" (Haider-Markel and Joslyn, 2001). Lawrence and Birkland (2004); Birkland and Lawrence (2009) also described how, after the Columbine shooting, the media discourse framed violent *popular culture* (e.g., movies and video games that glorify violence) as a culprit. Beyond the issue itself, the debate surrounding gun violence has also been framed as a Democrat vs. Republican *political contest* (Schnell, 2001).

In health communication, researchers have also examined the extent to which the news media frame the issue from the perspective of "dangerous people" (e.g., those with mental illness) wielding weapons as compared to "dangerous weapons" (e.g., large-capacity assault rifles) causing gun violence (McGinty et al., 2013). The *mental illness* of gunmen is often a focal point in the coverage of mass shootings (McGinty et al., 2014). Related to the issue of mental health are broader concerns about troubled individuals who lack the social support and resources to receive the help that they need (DeFoster and Swalve, 2018). The discussion about *race and ethnicity* has also emerged as a salient frame, in that news coverage of gun violence may differ somewhat depending on who the perpetrators are (Leavy and Maloney, 2009).

For our dataset, we detect these issue-specific frames typically found in media coverage of gun

violence, as well as generic frames like *economic consequences*. While it would be beneficial to automate the framing analysis across a variety of issues, here we argue that developing issue-specific tools will allow for a more nuanced understanding of each issue. Using our approach of combining expert-chosen frames for a particular issue and an automatic detection of these frames, communication researchers can further investigate how different news media influence public opinion in subtle ways *and* at scale, and thus be able to help prepare stronger arguments for journalistic practice and ultimately policy changes about the issue.

2.2 News Frame Detection

Media Frame Corpus (MFC) (Card et al., 2015) is one of the first large-scale datasets of frame annotations. It contains 11,900 hand-annotated English news articles for media framing that cover three issues: immigration, tobacco, and same-sex marriage. Undergraduate student annotators highlight the span of text that covers a frame following an annotation codebook. MFC has 15 generic media frames, which are defined in the *Policy Frames Codebook* by Boydstun et al. (2014), such as economics, political, quality of life, and also an "other" label for news articles that cannot be covered by any of the 15 frames. These news articles have been collected using keyword search from 13 national U.S. newspapers from 1990 to 2012 and contains 38,283 news articles. Duplicate and near-duplicate articles were removed and 20,037 of these articles were randomly selected for manual framing annotation. Aside from spans of text, headlines and entire news text are also annotated with the headline and primary frames respectively.

Naderi and Hirst (2017) detect news frames at the sentence-level using deep recurrent neural networks, specifically LSTM, BiLSTM, and GRU. They used news articles from MFC dataset (Card et al., 2015) to train and evaluate their model. They show that their results for frame detection are better than classifiers that rely on topics models for detecting frames (Tsur et al., 2015; Nguyen et al., 2015). Our work is different from theirs in that we focus on detecting the frame in the news article headline, which unlike a complete sentence, is typically a short phrase. We implement these deep recurrent networks in our experiments as baselines and find that our approach performs better for detecting frames in headlines, both in MFC and our GVFC. We also implement a recent word-based method for detecting frames in English and Russian news articles (Field et al., 2018) as another baseline. We detail these baseline approaches and their results in our experiment section (section 4).

3 Dataset Creation

3.1 News Article Collection

We drew our sample of news articles from a list of top U.S. news websites defined in terms of traffic to the websites. We cross-referenced several sources that had "top news sites" of their own: the Pew Research Center (2018b), Statista (2017), Alexa (2018), and MediaCloud, which is an open-source online platform. We synthesized these lists towards creating one list that contained news sites from the left, center, and right sides of the ideological spectrum based on categories defined in MediaCloud; Pew Research Center (2016); Ad Fontes Media (2019). We started with list of 30 media outlets based on these references.

We collected articles from these outlets from four time periods over the course of 2018 in order to capture a diversity of articles. Some articles were collected over periods during or immediately after a mass shooting (e.g., the Parkland School shooting in 02/2018). Other articles were collected when gun violence was not necessarily the most salient current event. We also included articles from several months before the 2018 U.S. midterm elections as the gun-related issue was a central topic for political discussion during this period. The articles were retrieved using Crimson Hexagon's ForSight social media analytics platform (Hexagon, 2018), retrieving articles that had at least one keyword in their headlines from the following list: {"gun," "firearm," "NRA," "2nd amendment," "second amendment," "AR15," "assault weapon," "rifle," "Brady act," "Brady bill," "mass shooting"}. We came up with the list of keywords based on the previous literature and on the review of a sample of our data. After collecting the articles, news articles with duplicate titles were removed and the rest sampled to be analyzed and annotated. After sampling and annotation, the final dataset contains frame annotations of news articles from a total of 21 media outlets[1].

[1]For reproducibility and future research, we make our dataset and annotation codebook publicly available at https://derrywijaya.github.io/GVFC.html

3.2 News Article Annotation

Quantitative content analysis (QCA) in communication research is a commonly used method to derive "replicable and meaningful inferences from texts (or other meaningful matter)" (Krippendorff, 2004). To perform QCA, one draws a representative sample of text (or other types of content), on which two or more trained *coders* (i.e., annotators) apply a codebook protocol, which should include all of the variables for annotation and their definitions. Prior to coding the entire sample independently, coders are first trained on the codebook, and their agreement on how to apply the codes is measured with inter-coder reliability (ICR). High ICR values implies that two or more coders consistently categorized the content similarly, which signals a high validity of the coded results. Once coders have reached an acceptable ICR (above 90% agreement or 0.70 Krippendorff α (Krippendorff, 2004)), they can code the rest of the sample independently.

Codebook Creation Our codebook was developed by drawing from the literature on framing gun violence, described earlier, as well as from a preliminary analysis of the data. This resulted in 9 frames, including both generic: "Politics", "Public opinion", "Society/Culture", and "Economic consequences" and issue-specific: "2nd Amendment" (Gun Rights), "Gun control/regulation", "Mental health", "School/Public space safety", and "Race/Ethnicity".

Unit of Annotation We choose our unit of annotation to be a news headline for several reasons. Firstly, psychologists have long argued that first impressions are lasting impressions (Digirolamo and Hintzman, 1997). This thesis applies to news reading behavior as well. Media framing researchers often identify and measure frames in news headlines (e.g., (Bleich et al., 2015; Trimble and Sampert, 2004), which are seen by the audience first and can determine the perception of the text that follows (Tankard Jr, 2001). As Pan and Kosicki (1993) suggests, a headline is "the most salient cue to activate certain semantically related concepts in readers minds; it is thus the most powerful framing device of the syntactical structure".

Secondly, the analysis of news headlines became more relevant in the emerging (i.e. digital) media environment where a large portion of people only read headlines but nothing else (Gabielkov et al., 2016). Further, driven by the attention economy, many online media even use news headlines as "clickbait", presenting sensational but misleading information that deviates from the content included in the actual news story (Chen et al., 2015). That is, a news story may be framed differently in its headline and the rest of the article. In cases like this, research shows that even reading through the article cannot necessarily correct the headlines misdirection (Ecker et al., 2014). Taken together, detecting frames through news headlines provides the most direct clue to the potential influence of the news coverage.

Annotation Process Two communication graduate students were recruited to annotate a sample of the collected news articles. They were instructed to first determine whether the news headline was relevant to gun violence in the United States. If yes, they were asked to identify up to two dominant frames in the headline. They were trained on the codebook during the training sessions. In the first training session, the students were given a 100-headline sample to code, and ICR was not met. Hence, a second training session was held to further clarify the codebook and resolve any confusion. The students coded another 100-headline sample, for which ICR was met on all variables: relevance (99% agreement, 0.97 α), frame A (94.10% agreement, 0.90 α) and frame B (96.04% agreement, 0.82 α). Following QCA, once the ICR was met, one student continued to code another 2,790 news headlines, resulting in a total of 2,990 annotated news headlines.

3.3 Dataset Properties

GVFC includes 2,990 news headlines, 1,300 of which are annotated as relevant to the gun violence issue in the United States. Out of the relevant headlines, only 319 are found to have 2 frames. Examples of headlines with 2 frames are "It's Time to Hand the Mic to Gun Owners", annotated with "Public opinion" (frame A) and "2nd Amendment" (frame B); and "Trevor Noah: 'The Second Amendment Is Not Intended for Black People", annotated with "2nd Amendment" (frame A) and "Race/Ethnicity" (frame B).

We use frame A annotations to train our frame classification model but find that our model also identifies some of frame B annotations in its top predictions (Section 4.2). Table 1 shows frame A class distribution in GVFC that reflects the varying

coverage of different frames in the U.S. media.

4 Experiments

We use the most recent method for automatic news frame detection (Field et al., 2018) as one of our baselines. They devise a word-based method for detecting the frames in English and Russian news. They use MFC to derive a lexicon for each frame F by computing pointwise mutual information $I(F, w)$ (Church and Hanks, 1990) for each word w and each frame F in the corpus. Each frame F's lexicon contains the top 250 words with the highest $I(F, w)$ for frame F. A news article has a frame F if it contains at least 3 instances of a word from F's lexicon with the primary frame being the most common frame, based on the number of words from each frame's lexicon in the document. We create lexicons for the 9 frames in our GVFC dataset and use them to compute the primary frames of news headlines.

We also implement LSTM-based neural networks for a more comprehensive evaluation. Long short-term memory (LSTM) is a recurrent neural network (RNN) architecture that is widely used today in text classification tasks. There are plenty of variants from this type of architecture: Gated Recurrent Unit (GRU), Bi-directional LSTM, and Bi-directional GRU. We implement these networks with attention mechanism (Bahdanau et al., 2015) and use 100-dimensional pre-trained Glove embeddings (Pennington et al., 2014) as our initial word representations. We train and evaluate these networks for headlines frame classification with 128 units of RNN cells and one layer of attention mechanism at the end, a batch size of 128 for 2000 steps. We use Adam optimizer with a learning rate of 0.01.

As the results in Table 1 show, Bi-directional GRU with attention achieves the highest accuracy among our baselines. The reason behind this could be the fact that we have a small dataset and GRU needs fewer data points to generalize (Kaiser and Sutskever, 2015; Yin et al., 2017). Furthermore, the attention mechanism and bi-directionality allows for more contextual interpretation of the headlines and better detection of their frames.

4.1 News Frame Detection with BERT

Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) take this idea of attention and bi-directionality further by building on the Transformer's encoder model that solely relies on multi-layer self-attention to compute contextual representations of its input, dispensing with any kinds of recurrence (Vaswani et al., 2017). The encoder is composed of a stack of identical layers, where each layer contains a self-attention mechanism, which allows the encoder to look at other words in the input sentence as it encodes the contextual representation of each word in the sentence, and a fully connected feed-forward network. The self-attention mechanism computes three vectors from the embedding of each word in the input sentence: the query q, key k, and value v vectors. It then computes the contextual representation of each word w in the sentence as the weighted sum of the value vectors of all the words in the sentence, where the weights are the scaled then normalized dot products between w's query vector and the key vectors of all the words in the sentence. The weights essentially determine how much focus to place on other parts of the input sentence as the encoder encodes a word at a certain position. Given that the query, key, and value vectors are computed by multiplying the input word embeddings matrix X with weight matrices learned during training, W^Q, W^K, W^V, the self-attention output can be formulated in matrix form as: $\text{Attention}(Q, K, V) = \text{softmax}(QK^T/\sqrt{d_k})V$ where $Q = XW^Q$, $K = XW^K$, $V = XW^V$.

BERT's encoder implements the Transformer's multi-layer self-attention mechanisms and fully utilizes its strength in storing the left and right context of each token by using a "masked language model" (MLM) pre-training objective, inspired by the Cloze task (Taylor, 1953). In its pre-training, BERT randomly masks some of the tokens from its input, and predicts the original vocabulary id of the masked word based only on its context. Unlike left-to-right language model pre-training, the MLM objective enables the representation to fuse the left and the right context, which allows BERT to pre-train a deep bidirectional Transformer representations from unlabeled large text corpora.

We fine-tune the pre-trained BERT-based uncased model on our multiclass frame classification by adding a frame classification layer on top of the model and fine-tune all the parameters end-to-end. Given a headline, BERT tokenizes the headline to tokens based on WordPiece tokens (Wu et al., 2016) and appends a special classification token

Frame Class	# Headlines	Baseline	LSTM	Bi-LSTM	Bi-LSTM w/ Attention	Bi-GRU w/ Attention	BERT
2nd Amendment	38	44.74	23.68	21.05	44.74	26.32	65.79
Gun control/regulation	215	50.23	63.72	66.51	72.09	76.28	84.19
Politics	373	40.48	78.28	77.75	84.18	85.79	89.54
Mental health	65	35.38	50.77	40.00	58.46	60.00	78.46
School/Public space safety	137	39.42	48.91	50.36	54.74	58.39	78.10
Race/Ethnicity	114	67.54	75.44	71.93	84.21	81.28	92.11
Public opinion	237	63.29	70.46	72.15	75.53	77.22	86.08
Society/Culture	41	43.90	24.39	19.51	36.59	21.95	58.54
Economic consequences	80	38.75	45.00	51.25	61.25	60.00	80.00
Overall	1300	48.38	64.37	64.48	72.15	72.76	84.23

Table 1: Class distribution of frame A annotations and micro-accuracies for the baseline (Field et al., 2018), LSTM, bi-directional LSTM, bi-directional LSTM and bi-directional GRU with attention, and our method based on fine tuning BERT.

([CLS]) at the beginning of the headline. We use the final hidden vector $C \in \mathbb{R}^H$ corresponding to [CLS] as the aggregate representation of the headline that is input to the classification layer (since encoding this token with self-attention effectively includes attention to all the tokens in the headline). The only new parameters are our classification layer weights $W \in \mathbb{R}^{K \text{x} H}$, where K = 9, the number of our frame classes. Given the imbalance in our class distribution, we compute a focal loss (FL) (Lin et al., 2017) that improves our classification performance compared to the standard cross entropy loss. We compute $\text{FL}(p) = -\alpha(1-p)^{\gamma}\log(p)$, where $p \in \mathbb{R}^K$ contains the probabilities of classifying the headline into each of the K frames i.e., $p = \text{softmax}(CW^T)$ and $\alpha \in \mathbb{R}^K$ contains the weighting factors, which we set for each frame to be its normalized inverse class frequency $\in [0, 1]$: the smaller the class, the higher the α and vice versa, which balances the importance of each class' examples. The modulating factor: $(1-p)^{\gamma}$ in FL down-weights the loss contribution of the easy examples – those that are well classified (i.e. have high p_k) – and thus focuses the training on hard-to-classify examples. Following Lin et al. (2017), we use $\gamma = 2$.

We train for 10 epochs with a batch size of 4, 2e-5 learning rate, and maximum sequence length of 128 tokens. Training and testing on the same stratified folds that we use for all our baselines, we achieve a 5-fold cross validation micro-accuracy of 84.23%. Our method based on BERT significantly outperforms not only the most recent news frame classification baseline, but also some state-of-the-art deep classification models, including bi-directional LSTM/GRU with attention on every frame of our GVFC dataset (Table 1).

We also evaluate our method to classify frames of news headlines in another dataset (MFC). As

MFC Issue	# Headlines	Bi-GRU w/ Attention	BERT
Immigration (I)	7231	40.84	52.38
Tobacco (T)	3959	57.20	67.94
Samesex (SS)	3842	61.57	71.50
I (top-5 frames)	4175	53.65	67.28
T (top-5 frames)	2759	71.44	82.32
SS (top-5 frames)	2937	74.94	83.07

Table 2: 10-fold cross-validation micro-accuracy on the MFC dataset for our best baseline from previous evaluation, and our model based on BERT.

Table 2 shows, our method significantly outperforms our top-performing baseline, both on the 15-frame classification task and on the top-5 (most frequent) frame classification on all issues: immigration, tobacco, and same-sex marriage. This shows that our method can perform well for detecting frames in headlines in different datasets and across a diverse range of issues.

4.2 Discussion

Our results show that fine-tuning on BERT performs well even on a small dataset like GVFC, which agrees with the findings of Devlin et al. (2018) that fine-tuning on BERT's pre-trained model can lead to large improvements even on very small scale tasks. Part of the reasons may be due to BERT's deep attention mechanism. Attention mechanism has been shown to be data-efficient and helps improve performance significantly even when the dataset is small (Vinyals et al., 2015). Even adding standard attention improves the accuracy of our LSTM-based baselines significantly (Table 1). BERT's success can also be traced to its design of bidirectional Transformer that offers richer contextual information. Furthermore, BERT was pre-trained on a large corpus to produce this representation. Fine-tuning on BERT allows us to transfer this contextual knowledge to

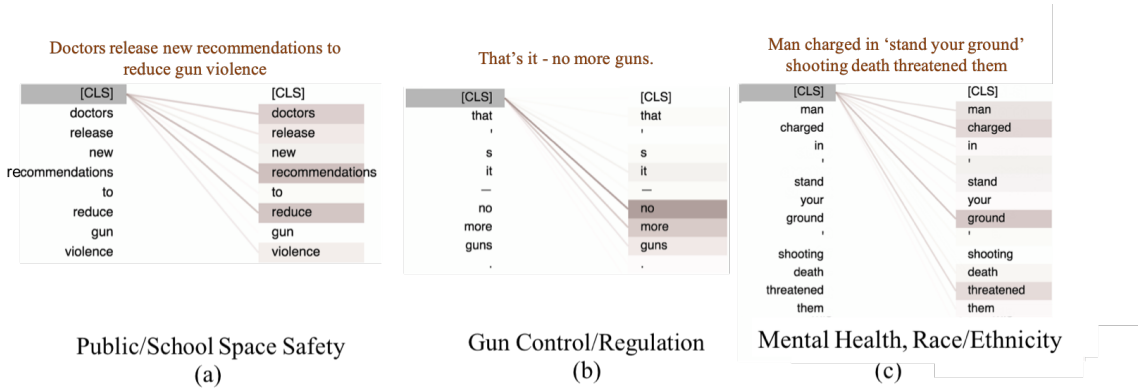

Figure 1: Visualization of our fine-tuned model, the headlines and the predicted frames. The thicker the line, the more attention placed on the token for computing the aggregate i.e., [CLS] representation for the classification

classifying frames in headlines, which are very short compared to the entire news text. The ability to transfer contextual knowledge from a large corpus leads to better representation for these short pieces of texts and better generalization of our model compared to the lexicon-baseline that only relies on word-frame co-occurrences in GVFC.

We use a visualization tool (Vig, 2019) to obtain insights into *what* our fine-tuned model is attending to when making decisions. For example, we observe that pre-training on a large corpus may have helped our model predict the frame "School/Public Space Safety" for the headline: "Doctors release new recommendations to reduce gun violence" by attending to words like "Doctors" and "recommendations" (Figure 1(a)). Although these words do not co-occur frequently with this specific frame in GVFC, they may be related to school/public safety in general. The lexicon model, on the other hand, incorrectly predicts the "Gun control/regulation" frame due to the words "release" and "gun" in the headline.

Because news framing is closely related to journalists' word choice (Hamborg et al., 2019), we find that on frames such as "Race/Ethnicity," which has a specific set of keywords that the model can attend to like "black", "white", or "anti-semitic", both our model and the lexicon-baseline perform the best on this frame.

On the other hand, the performance of our model and the baseline differ significantly for generic frames such as "Politics," whose keywords may overlap with issue-specific frames such as "Gun control/regulation". Since BERT is pre-trained to take context into consideration, words like "gun", which appears with all the frames, can have different contextual representation depending on its context i.e., "gun lobby" vs. "gun permit". For example, the headline "That's it – no more guns" is classified correctly by BERT as having "Gun control/regulation" frame by attending to the context "no more" of "guns" (Figure 1(b)).

Also, despite not being trained to predict multiple frames, some of BERT's predictions of what it believes to be top frames align with that of human experts. There are 319 headlines in GVFC that were annotated with two frames: frame A and B, meaning that the headline is equally likely to belong to either frame. In our experiments, we only train our model with frame A annotations. However, we notice that out of the 319 headlines that have two frames, 164 of them have both frames predicted in the top-2 predictions of our model, showing the potential to fine-tune BERT for multi-label multi-class frame classification, which we will explore in the future. Furthermore, the accuracy of our model on GVFC increases to 87.92% if we consider our model's prediction to be correct if it predicts either frame for these 319 headlines.

More interestingly, we observe that our model can predict additional frames that may be applicable to the headlines but are not annotated. In Figure 1(c) for example, for the headline "Man charged in 'stand your ground' shooting death threatened them", our model first attends to the word "ground" and then "threatened" and predicts the frame "Race/Ethnicity" and then "Mental health". Even though this headline was only annotated with the "Mental health" frame (possibly due to the word "threatened" which, in the "Mental Health" description of the annotation codebook, may be referring to an individual's behaviors that indicate instability, impulsivity, anger, etc.), we believe that in this particular headline the

"Race/Ethnicity" frame is more applicable given the presence of 'stand your ground', a legislation that has been shown to have a quantifiable racial bias (Ackermann et al., 2015).

Overall, what we observe from visualizing our model suggests that the model is able to generalize beyond word-frame co-occurrences in the limited annotations by virtue of the contextual knowledge transfer obtained by pre-training on a large corpus.

5 Framing Trends, Analysis, and Conclusion

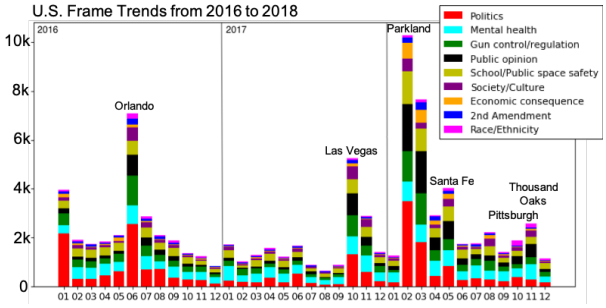

Figure 2: The number of times each frame is represented in new article headlines related to gun violence across the 3-year (per month) period. Some of the peaks represent the deadliest mass shootings in the U.S. since 1949 (CNN Library, 2019).

We used the same search words to retrieve news article headlines from the 21 U.S.news media outlets from 2016 to 2018. To apply our framing analysis, we first train a model to predict whether a news headline is relevant to the issue of U.S. gun violence by fine-tuning BERT-base uncased using the relevance annotations in GVFC. This relevance prediction model achieves a 10-fold cross validation precision of 0.93, 0.95 recall, and 0.94 F-score. We apply this model to find relevant headlines among the 88,470 collected, and apply our frame classification on the relevant headlines.

Several patterns emerged from the framing analysis. It appears that news media of all types have largely politicized the gun violence issue right after each major mass shooting (Figure 2). The focus on party politics, the divide between Democrats and Republicans on the issue dominated the coverage. This finding speaks to the highly polarized political environment in the U.S.

We also observe in Figure 2 that right after the Parkland school shooting in 02/2018, the discussion surrounding "Public opinion", "School/Public space safety", and "Economic consequences" frames increases. The increase in "Public opinion" and "School/Public space safety" frames is due to the growth of student activism in the wake of the shooting. Meanwhile, the increase in the "Economic Consequence" frame is due to the decision of several major companies such as Dick's Sporting Goods to stop selling assault-style weapons in the wake of the event.

We also observe in Figure 2 that frames that spike during every major shooting event, such as "Politics"/"Public opinion", are not the most persistent. Their frequency peaked during the month but dropped, often drastically, after. Notably, the "Mental health" frame (the cyan bar) appears to be the most persistent, appearing consistently over time in coverage about gun violence.

Another noticeable cross-media pattern in the U.S. media coverage of the gun violence issue is that the conservative-leaning and neutral media emphasized the mental health of individual gunmen to a greater extent than liberal-leaning media (see the cyan bar representing the "Mental health" frame in the left, center, and right plots of Figure 3). About a quarter of news articles from neutral and conservative-leaning media in 2017 are classified as having the "Mental Health" frame (27% and 22% of the articles respectively). In comparison, only 8% of news articles from liberal-leaning media are classified as having this "Mental Health" frame.

This finding about the conservative media (Figure 3 right) is not surprising because connecting mental illness and mass shooting has been a common stance among pro-gun Republican leaders (i.e., "guns don't kill people, people kill people"). More surprisingly though (and contrary to the common perception of mainstream media such as NYT, CNN, and CBS being liberal-leaning), our study suggests that these neutral, mainstream media (Figure 3 center) has also largely framed the issue from the aspect of mental health, often *more* than the conservative media, which may indicate conservative media's strong agenda-setting power in the U.S. media ecosystem.

Media framing scholars have also pointed out the importance of examining what aspects of the story has been left out. In our analysis, the frame of "Society/Culture" – a frame that is important and yet would not attract much web traffic – has not been a focus of gun violence coverage in the U.S. As the results demonstrate (Figure 3), major

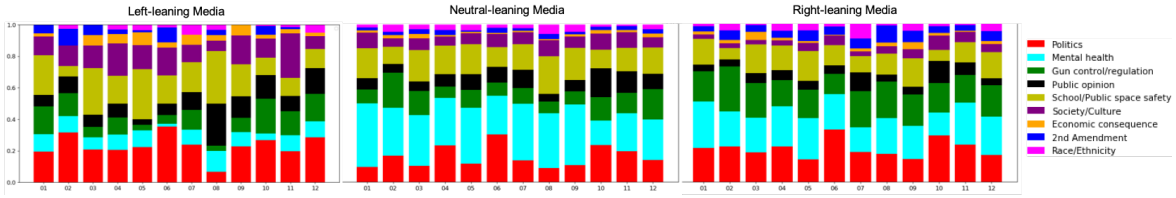

Figure 3: The proportion of each frame occurring in the 2017 news from news sites of different political leanings.

shootings were only able to trigger liberal-leaning media to pay more attention to this frame. 16% of articles from liberal-leaning media in 2017 are classified as having the "Society/Culture" frame, while only 9% of articles from neutral media (and only 5% from conservative-leaning media) are classified as having this "Society/Culture" frame. The lack of framing focus on the underlying cultural/societal issues as well as the aforementioned focus on party politics and strong agenda-setting speak to the status quo of the current U.S. news environment: profit-driven, sensational, and highly partisan.

In conclusion, we have presented in this paper a method for news headline frame classification that achieves state-of-the-art performance. We also release the codebook and a carefully curated Gun Violence Frame Corpus (GVFC) news articles whose headlines have been annotated with their corresponding frames by domain experts. We demonstrate the application of our framing detection to analyze a large corpus of news headlines for framing trends surrounding the U.S. gun violence coverage. We observe interesting findings and believe that frame detection and analysis can potentially be used to gain a deeper understanding of various issues of public affairs. Automatically detected frames in news headlines can also be used to curate more balanced news collections on various issues and perspectives.

Abstract

Named entity recognition (NER) identifies typed entity mentions in raw text. While the task is well-established, there is no universally used tagset: often, datasets are annotated for use in downstream applications and accordingly only cover a small set of entity types relevant to a particular task. For instance, in the biomedical domain, one corpus might annotate genes, another chemicals, and another diseases—despite the texts in each corpus containing references to all three types of entities. In this paper, we propose a deep structured model to integrate these "partially annotated" datasets to *jointly* identify all entity types appearing in the training corpora. By leveraging multiple datasets, the model can learn robust input representations; by building a joint structured model, it avoids potential conflicts caused by combining several models' predictions at test time. Experiments show that the proposed model significantly outperforms strong multi-task learning baselines when training on multiple, partially annotated datasets and testing on datasets that contain tags from more than one of the training corpora.[1]

1 Introduction

Named Entity Recognition (NER), which identifies the boundaries and types of entity mentions from raw text, is a fundamental problem in natural language processing (NLP). It is a basic component for many downstream tasks, such as relation extraction (Hasegawa et al., 2004; Mooney and Bunescu, 2005), coreference resolution (Soon et al., 2001), and knowledge base construction (Craven et al., 1998; Craven and Kumlien, 1999).

One problem in NER is the diversity of entity types, which vary in scope for different domains and downstream tasks. Traditional NER for the news domain focuses on three coarse-grained entity types: *person*, *location*, and *organization* (Tjong Kim Sang and De Meulder, 2003). However, as NLP technologies have been applied to a broader set of domains, many other entity types have been targeted. For instance, Ritter et al. (2011) add seven new entity types (e.g., *product*, *tv-show*) on top of the previous three when annotating tweets. Other efforts also define different but partially overlapping sets of entity types (Walker et al., 2006; Ji et al., 2010; Consortium, 2013; Aguilar et al., 2014). These non-unified annotation schemas result in *partially annotated datasets*: each dataset is only annotated with a subset of possible entity types.

One approach to this problem is to train individual NE taggers for each partially annotated dataset and combine their results using some heuristics. Figure 1 shows an example that demonstrates the possible shortcomings of this approach, using the biomedical domain as a case study.[2] Here, we train four separate models on four partially annotated datasets: AnatEM (Pyysalo and Ananiadou, 2013) annotated for the *anatomy* type, BC2GM (Smith et al., 2008) for the *gene* type, JNLPBA (Kim et al., 2004) for *cell* types, and Linnaeus (Gerner et al., 2010) for the *species* type. We can see that the models' predictions contradict each other when applied to the same test sentence—making it a challenge to accurately combine them.

In this paper, we propose a deep structured model to leverage multiple partially annotated datasets, allowing us to jointly identify the union

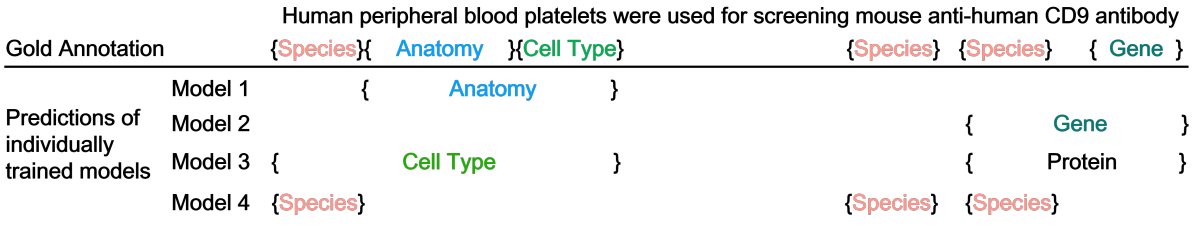

Figure 1: An example sentence from the CellFinder corpus (Neves et al., 2012) showing the challenges in combining the output of individual NE taggers. The *Gold* row is the human annotations in CellFinder. The rows below are predictions made by models trained on datasets that each contain only a subset of the CellFinder types. Note that the individual taggers' predictions can conflict with each other, making it challenging to combine them. (Note: we renamed CellFinder's *Cell Component* to *Cell Type* to fit it in the space above.)

of all entity types presented in the training data. The model leverages supervision signals across diverse datasets to learn robust input representations, thus improving the performance for each entity type. Moreover, it makes *joint* predictions to avoid potential conflicts among models built on different entity types, allowing further improvement for cross-type NER.

Experiments on both real-world and synthetic datasets show that our model can efficiently adapt to new corpora that have more types than any individual dataset used for training and that it achieves significantly better results compared to strong multi-task learning baselines.

2 Problem Statement

We formally define the problem by first defining our terminology.

Global Tag Space. Let C_i denote a corpus, and T_{C_i} denote the set of entity types that are tagged in corpus C_i. When there are a set of corpora $\mathbb{C} = \{C_1, C_2, ..., C_n\}$, each has its own tag space concerning different entity types, the global tag space is defined as the union of the local tag space. Formally, $T_{\mathbb{C}} = T_{C_1} \cup T_{C_2} \cup ... \cup T_{C_n}$.

Partially Annotated Corpus. If $T_{C_i} \subsetneqq T_{\mathbb{C}}$, then C_i is a partially annotated corpus.

Global Evaluation. When a model is trained on a set of partially annotated corpora $\mathbb{C}$ and predicts tags for the whole global tag space $T_{\mathbb{C}}$, we say it is making *global predictions*. Accordingly, the evaluation of the models' performance on $T_{\mathbb{C}}$ is called *global evaluation*.

Our goal is to train a single unified NE tagger from several *partially annotated* corpora for efficient adaptation to new corpora that have more types than any individual dataset used during training. Formally, we have a set of corpora $\mathbb{C} = \{C_1, C_2, ..., C_n\}$, and we propose to train a joint model on $\mathbb{C}$ such that it makes predictions for the *global tag space* $T_{\mathbb{C}}$. One benefit of this joint model is that it can be easily adapted to a new tag space T_{C_u} where $T_{C_u} \subseteq T_{\mathbb{C}}$, and $T_{C_u} \nsubseteq T_{C_i}, \forall C_i \in \mathbb{C}$.

3 Background and Related Work

In this section, we first introduce neural architectures for NER which our work builds upon and then summarize previous work on imperfect annotation problems.

3.1 Neural Architectures for NER

With recent advances using deep neural networks, bi-directional long short-term memory networks with conditional random fields (BiLSTM-CRF) have become standard for NER (Lample et al., 2016). A typical architecture consists of a BiLSTM layer to learn feature representations from the input and a CRF layer to model the interdependencies between adjacent labels and perform joint inference. Ma and Hovy (2016) introduce additional character-level convolutional neural networks (CNNs) to capture subword unit information. In this paper, we use a BiLSTM-CRF with character-level modeling as our base model. We now briefly review the BiLSTM-CRF model.

BiLSTMs. Long Short Term Memory networks (LSTMs) (Hochreiter and Schmidhuber, 1997) are a variation of RNNs that are designed to avoid the vanishing/exploding gradient problem (Bengio et al., 1994). Specifically, BiLSTMs take as input a sequence of words $\boldsymbol{x} = \{x_k | k \in \mathcal{N}\}$ and output a sequence of hidden vectors: $\boldsymbol{H} = \{h_k | k \in \mathcal{N}\}$ BiLSTMs combine a left-to-right (forward) and a right-to-left (backward) LSTM to capture both left and right context. Formally, they produce a hidden vector $\tilde{\boldsymbol{h}}_i = [\overrightarrow{\boldsymbol{h}_i}; \overleftarrow{\boldsymbol{h}_i}]$ for each input, where $\overrightarrow{\boldsymbol{h}_i}$ and

$\overleftarrow{\boldsymbol{h}_i}$ are produced by the forward and the backward LSTMs respectively; $[;]$ denotes vector concatenation.

Character-level Modeling. Following Wang et al. (2018), we use a BiLSTM for character-level modeling. We concatenate the hidden vector of the space after a word from the forward LSTM and the hidden vector of the space before a word from the backward LSTM to form a character-level representation of the word: $\boldsymbol{h}_i^c = [\overrightarrow{\boldsymbol{h}_i^c}; \overleftarrow{\boldsymbol{h}_i^c}]$. The word-level BiLSTM then takes the concatenation of $\boldsymbol{h}_i^c$ and the word embedding as input $\boldsymbol{x}_i = [\boldsymbol{e}_i; \boldsymbol{h}_i^c]$ to learn contextualized representations.

Neural-CRFs. Conditional Random Fields (CRFs) (Lafferty et al., 2001) are sequence tagging models that capture the inter-dependencies between the output tags; they have been widely used for NER (McCallum and Li, 2003; Lu et al., 2015; Peng and Dredze, 2015, 2016, 2017). Given a set of training data $\{\boldsymbol{x}_i, \boldsymbol{y}_i\}^N$, a CRF minimizes negative log-likelihood:

$$\min_{\Theta} -\sum_i \log P(\boldsymbol{y}_i \mid \boldsymbol{x}_i; \Theta), \tag{1}$$

$$P(\boldsymbol{y}_i \mid \boldsymbol{x}_i; \Theta) = \frac{Gold\,Energy}{Partition} = \frac{St(\boldsymbol{y}_i)}{\sum_{\boldsymbol{y}'} St(\boldsymbol{y}')} \tag{2}$$

where $\boldsymbol{y}'$ is any possible tag sequence with the same length as $\boldsymbol{y}_i$, $St(\boldsymbol{y}')$ is the potential of the tag sequence $\boldsymbol{y}'$, and $St(\boldsymbol{y}_i)$ is the potential of the gold tag sequence. The numerator $St(\boldsymbol{y}_i)$ is called the *gold energy function*, and the denominator $\sum_{\boldsymbol{y}'} St(\boldsymbol{y}')$ is the *partition function*. The likelihood function using globally annotated data is illustrated in Figure 2a. The potential of a tag sequence can be computed as:

$$St(\boldsymbol{y}) = \prod_{t=1}^{|\boldsymbol{y}|} Score(\boldsymbol{y}[t], \boldsymbol{y}[t-1]) \tag{3}$$

where $\boldsymbol{y}[t]$ is the tth element in $\boldsymbol{y}$ ($\boldsymbol{y}[-1]$ is the start of the sequence), and

$$Score(\boldsymbol{y}[t], \boldsymbol{y}[t-1]) = \exp\left(tr(\boldsymbol{y}[t], \boldsymbol{y}[t-1])\right) * \exp\left(em(\boldsymbol{y}[t])\right) \tag{4}$$

where $tr(\boldsymbol{y}[t], \boldsymbol{y}[t-1])$ is the transition score from $\boldsymbol{y}[t-1]$ to $\boldsymbol{y}[t]$, and $em(\boldsymbol{y}[t])$ is the emission score of $\boldsymbol{y}[t]$ computed based on the output $\tilde{\boldsymbol{h}}_t$ of the BiLSTM.

3.2 Learning from Imperfect Annotations

Learning from multiple partially annotated datasets could be more generally thought of as learning from imperfect annotations. In that broad sense, there are several notable areas of prior work. One of the most prominent concerns learning from *incomplete annotations* (noisy labels), where some occurrences of entities are neglected in the annotation process and falsely labeled as non-entities (negative). A related problem is learning from *unlabeled data* with distant supervision.

A major challenge of all these settings, including ours, is that a positive instance might be labeled as negative. A well-explored solution to this problem is proposed by Tsuboi et al. (2008), which instead of maximizing the likelihood of the gold tag sequence, we maximize the total likelihood for all possible tag sequences consistent with the gold labels. Tsuboi et al. (2008); Yang and Vozila (2014) applied this idea to the *incomplete annotation* setting; Shang et al. (2018); Liu et al. (2014) applied it to the *unlabeled data* with distant supervision setting; and Greenberg et al. (2018) applied it to the *partial annotation* setting. While this is a general solution, its primary drawback is that it assumes a uniform prior on all labels consistent with the gold labels. This may have the result of overly encouraging the prediction of entities, resulting in low precision.

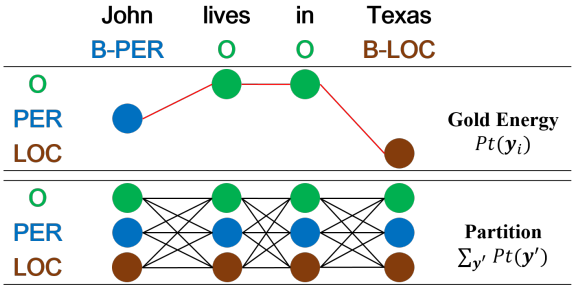
To tackle the problem of incomplete annotations, Carlson et al. (2009); Yang et al. (2018) explored bootstrap-based semi-supervised learning on unlabeled data, iteratively identifying new entities with the taggers and then re-training the taggers. Bellare and McCallum (2007); Li and Liu (2005); Fernandes and Brefeld (2011) explored an EM algorithm with semi-supervision.

For the *partial annotation* problem, most previous work has focused on building individual taggers for each dataset and using single-task learning (Liu et al., 2018) or multi-task learning (Crichton et al., 2017; Wang et al., 2018). In single-task learning, each model is trained separately on each dataset C_i, and makes local predictions on T_{C_i}. Based on the neural-CRF architecture, multi-task learning uses a different CRF layer for each dataset C_i (each task) to make local predictions on T_{C_i}, and shares the lower-level representation learning component across all tasks. Both single-task learning and multi-task learning make local

predictions and have to apply heuristics to combine the model predictions, resulting in the collision problem demonstrated in Figure 1.

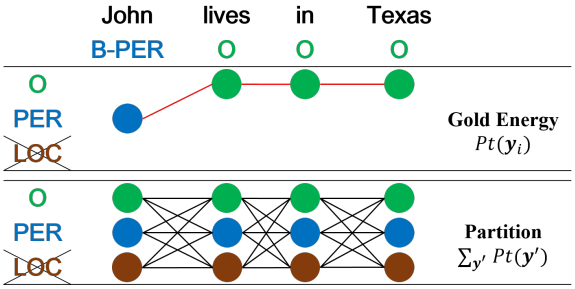
To the best of our knowledge, Greenberg et al. (2018) is the only prior work trying to build a unified model from multiple partially annotated corpora. We will show that their model, which is reminiscent of Tsuboi et al. (2008), is a special case of ours and that our other variations achieve better performance. In addition, they only evaluated the model on the training corpora while we conduct evaluations to test the model's ability to adapt to new corpora with different tag spaces.

4 Model



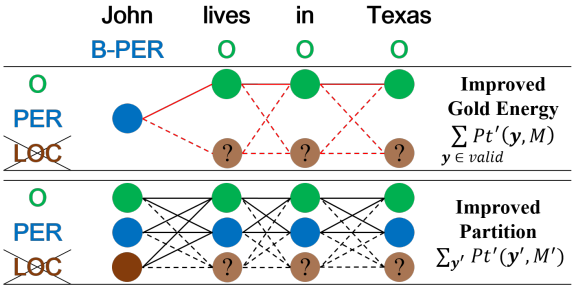
As mentioned above, we use a BiLSTM-CRF with character-level modeling as our base model. Our goal is to build a unified model to make global predictions. That is, our model will be jointly trained on multiple partially annotated datasets $\mathbb{C}$ and make predictions on the global tag space $T_{\mathbb{C}}$. Such a unified model will enjoy the benefit of learning robust representations from multiple datasets just like multi-task learning while maintaining a joint probability distribution of the global tag space to avoid possible conflicts from individual models.

4.1 Naive Approach



A simple solution to the problem is to merge all the datasets into one giant corpus. A single model can then be trained on this corpus to make global predictions. However, such a corpus will be missing many correct annotations, since each portion will be annotated with only a subset of the target entity types. Figure 2b shows an example: here, a location (*Texas*) exists but is labeled as a non-entity, because the original dataset from which this sentence is drawn does not annotate locations at all. As a result, this approach suffers from *false penalties* when applying the original likelihood function (Eq. 2-4) to train the model, meaning that it penalizes predictions that correctly identify entities with types that are not annotated for a particular sentence.

4.2 Improving the Gold Energy Function



One way to improve performance is to explicitly acknowledge the incompleteness of the existing "gold" annotations and to give the model credit for predicting any tag sequence that is consistent with

(a) **Original likelihood function** with *global annotation*

(b) **Original likelihood function** with *partial annotation*

(c) **Improved likelihood function** with *partial annotation*

Figure 2: Illustration of original (2a, 2b) and improved (2c) likelihood functions. Each figure has two parts upper and lower that illustrate the gold energy (numerator) and the partition (denominator) respectively. Solid lines represent tag sequences that are fully considered in the functions. Dashed lines represent tag sequences that are discounted. The sentences in 2b and 2c are not annotated with **LOC**.

the partial annotations. This can be done by modifying the CRF's gold energy function, illustrated in the upper part of Figure 2c. Specifically, in this example, *John* is labeled as *PER*, so *PER* is the only possible correct tag at that position. However, *lives*, *in*, and *Texas* are labeled as *O* (non-entity), which here means only that they may not be *PER*—but any of them could be *LOC*, since locations are not annotated for this sentence. Therefore, any sequence that assigns either *O* or *LOC* for any of these three positions is consistent with the gold labels. To account for this, we modify the gold energy function to credit all tag sequences

that are consistent with the gold annotations, encouraging the model to predict other consistent labels when the gold label is *O*. Tsuboi et al. (2008) propose a specific solution that applies this idea on incomplete annotations: instead of maximizing the likelihood of the gold tag sequence when optimizing the CRF model, they maximize the total likelihood of all possible tag sequences consistent with the gold labels. This approach is later used by Greenberg et al. (2018) to handle the problem of partial annotation. We will address a potential problem with their method and propose a generalized version in Section 4.4.

4.3 Improving the Partition Function

Modifying the gold energy function will give credit to a system for producing alternative entity labels for words tagged as *O* in the partially annotated training. A different solution is to simply *not penalize* predictions of such alternative labels. This can be done by modifying the partition function and keeping the gold energy function unchanged. The lower part of Figure 2c gives an illustration. As stated above, *LOC* is a consistent alternative entity label for *lives*, *in*, and *Texas*. We therefore exclude from our calculations any paths that include *LOC* at any of those positions. More generally, we exclude all such consistent but alternative tag sequences from the computation of the CRF's partition function. Section 4.4 gives formal definitions with equations. The improved partition function sets the model free to predict alternative labels without penalty (as long as they are consistent with the known gold annotations), but it does not give them any positive credit for doing so (as in the previous approach). We hypothesize that the improved partition function would work better than the improved gold energy function in our setting because it addresses the *false penalties* problem more precisely. We will verify this hypothesis in our experiments.

4.4 Discounting Alternative Sequences

There is a potential problem with naively applying the improved gold energy function: when the gold label is *O*, the model is encouraged to predict other consistent labels as strongly as it is encouraged to predict *O*. However, many *O* labels are confident annotations of *O*. As a result, naively training with the improved gold energy function tends to over-predict entities and not predict *O*s. To mitigate this problem, we discount the energy of tag sequences that go through alternative labels. This can be achieved by introducing a hyper-parameter $M(\text{mask}) \in [0, 1]$ as a discounting factor for the gold energy function. Formally, we modify Eq 3 to:

$$St'(\boldsymbol{y}, M) = \prod_{t=1}^{|\boldsymbol{y}|}(Score(\boldsymbol{y}[t], \boldsymbol{y}[t-1]) * mask(\boldsymbol{y}[t], M)),$$

where

$$mask(\boldsymbol{y}[t], M) = \begin{cases} M, & \text{if } \boldsymbol{y}[t] \in alternative \\ 1, & \text{Otherwise} \end{cases}.$$

where $alternative$ is the set of alternative labels. We thus have the improved gold energy function:

$$Improved\,Gold\,Energy = \sum_{\boldsymbol{y} \in valid} St'(\boldsymbol{y}, M), \quad (5)$$

where $valid$ is the set of all tag sequences that are consistent with the gold sequence, including the gold sequence itself.

Similarly, for the improved partition function, we can use the same strategy to discount the energy of alternative sequences rather than completely removing them. We thus introduce another $M' \in [0, 1]$ and the improved partition function becomes:

$$Improved\,Partition = \sum_{\boldsymbol{y}'} St'(\boldsymbol{y}', M'), \quad (6)$$

4.5 Combining Improved Functions

For generality, we combine the improved gold energy and the improved partition function to make a new likelihood function as our final model:

$$Improved\,LH = \frac{\sum_{\boldsymbol{y} \in valid} St'(\boldsymbol{y}, M)}{\sum_{\boldsymbol{y}'} St'(\boldsymbol{y}', M')} \quad (7)$$

To ensure Equation 7 is a valid likelihood function (the probabilities of all sequences sum to 1), we need a constraint that $M = M'$. Note that Equation 7 subsumes all models discussed in this section. Specifically, when $M = 0, M' = 1$, the model is the *Naive Model* discussed in Section 4.1; when $M = 1, M' = 1$, the model is the same as Greenberg et al. (2018) discussed in Section 4.2; when $M = 0, M' = 0$, the model

is the same as proposed in Section 4.3. We have a general perspective of all the models by simply treating M and M' as hyper-parameters.

Note that for the *Naive Model*, since $M! = M$, the Equation 7 is not always a valid likelihood function[3]. This may partially explain why the *Naive Model* performs so poorly under this setting. We posit that the model will work the best when $M = M'$.

5 Experimental Setup

5.1 Datasets

Our goal is to train a unified NER model on multiple partially annotated datasets. This model will make global predictions and can efficiently adapt to new corpora that contain tags from more than one training corpus. To fully test this capability, we would need a single test set annotated with all types of interest. However, the motivation behind this effort is that such a dataset typically does not exist. We therefore take two approaches to approximate such an evaluation.

In the first evaluation setting, we take advantage of the fact that although there may not be a *single* dataset annotated with all types of named entities of interest, there exist several datasets that cover types from more than one of the training corpora. Specifically, we are able to select test corpora that each cover types of interest from multiple training corpora. Table 1 shows the biomedical corpora we use and their entity types. For example, we use **BC5CDR** for global evaluation, because its entity types (*Chemical* and *Disease*) cover multiple training corpora (**BC4CHEM** for *Chemical* and **NCBI** for *Disease*).

In the second evaluation setting, we create synthetic datasets from the CoNLL 2003 NER dataset to simulate training and global evaluations. Specifically, the CoNLL 2003 dataset is annotated with four entity types: location, person, organization, and miscellaneous entities. We randomly split the training set into four portions, each containing only one entity type (all other types are removed). In this setting, the four portions of the training set are used for training and the original dataset with all entities annotated is used as a global corpus.

More details about all the datasets can be found in Appendix A.1.

[3]This may be confusing because when $M = 0, M' = 1$ it looks exactly the same as the original CRF likelihood function. But in the partial annotation setting, this means that the scores of alternative sequences will be zero in the numerator but non-zero in the denominator, which makes the total likelihood less than 1. It suggests that the original CRF likelihood function is not suitable for the partial annotation setting.

For Training		For Global Evaluations	
Corpus	**Entities**	**Corpus**	**Entities**
BC2GM	GP	BC5CDR	Chemical, Disease
BC4CHEM	Chemical		
NCBI	Disease	BioNLP13CG	GP, Disease, Chemical, others
JNLPBA	GP, DNA, Cell-type, Cell-line, RNA	BioNLP11ID	GP, Chemical, others
Linnaeus	Species		

Table 1: Details of the biomedical corpora. "others" denotes NE types that do not appear in the training corpora, and thus are not evaluated.

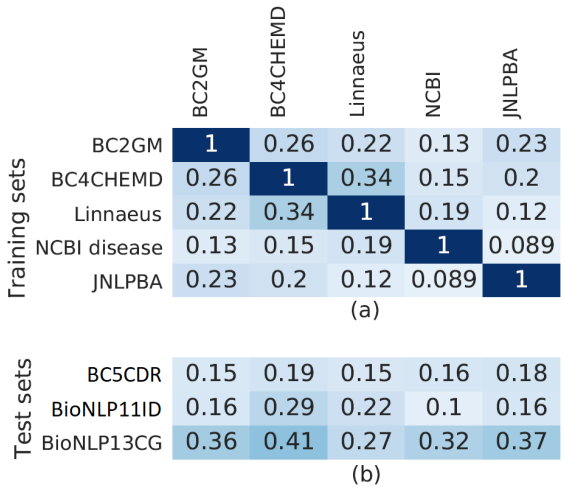


Figure 3: (a) The mention-level overlap among training sets. (b) The mention-level overlap between training datasets and evaluation datasets.

5.1.1 Biomedical Dataset Analysis

The motivation for this work rests on the assumption that even when a dataset is annotated for a certain set of entity types, it likely contains other types of entities that are unlabeled. To verify this assumption, we expand the annotations of each dataset using heuristics and compute the pairwise mention-level overlap between the datasets. Specifically, suppose we are comparing two datasets, A and B. We first construct A' and B', where A' contains all mentions in A but is augmented with new mentions found by taking all strings annotated in B and marking them as named entities in A (regardless of context; there may obviously be some errors). We do the same (in the

opposite direction) to construct B'. We then compute the pairwise overlap coefficient between A' and B' according to the following criterion:

$$\text{overlap}(A', B') = \frac{|A' \cap B'|}{\min(|A'|, |B'|)}.$$

Figure 3 shows the heat maps. For the training group, *BC2GM*, *BC4CHEMD*, and *Linnaeus* are considerably overlapped, although they are annotated with different entity types (GP, Chemical, and Species). This confirms our assumption that although the datasets are annotated for a subset of entity types, they contain other types that are unlabeled.[4]

5.2 Hyper-parameters.

We borrow most of the best hyper-parameters reported by Wang et al. (2018). The hidden sizes of the BiLSTMs are tuned, and the best value we found is 100 for the character-level BiLSTM, and 300 for the word-level BiLSTM. We also tuned both discounting factors M and M' in the range of [0,0.2,0.4,0.6,0.8,1.0]. It turns out that $M = 0, M' = 0$ (using improved partition function) and $M = 1, M' = 1$ (using improved gold energy function) make two local optimums. Therefore we report the performance of three special cases of our proposed framework, with $M, M' = [0, 0]$, $[1, 1]$, and $[0, 1]$ (the naive model), respectively.

5.3 Compared Models.

We compare different variations of our unified model and other models in different settings. We first train models on all training corpora, and then perform evaluations under two scenarios: (1) **no-supervision**: directly evaluating the trained models on each global corpora; (2) **limited-supervision**: fine-tuning the models on a small subset of the training portion of each global corpus before the evaluations.

Under both scenarios, we report performance of four different models:

- **MTM/MTM-vote**: Train a multi-task model (MTM) on training corpora, using a separate CRF for each corpus. (This is the current state-of-the-art structure (Wang et al., 2018) when evaluated on the training corpora.)
  - Under the no-supervision setting, we heuristically combine all existing CRF's predictions to make global predictions. Specifically, we apply two heuristics to resolve conflicts while preserving entity chunk-level consistency. First, where predictions from more than one model overlap, we expand each prediction's boundary to the outermost position. Second, we always favor the predictions of named entities over the predictions of non-entity.[5]
  - Under the limited-supervision setting, for each global corpus, we add a new CRF and train it along with the LSTMs.
- **Unified-01**: Use the naive training approach described in 4.1; this corresponds to our unified model with settings $M = 0, M' = 1$.
- **Unified-11**: Use the improved gold energy function described in 4.2; this corresponds to our unified model with settings $M = 1, M' = 1$ and is equivalent to the model proposed by Greenberg et al. (2018).
- **Unified-00**: Use the improved partition function proposed in 4.3; this corresponds to our unified model with settings $M = 0, M' = 0$.

Among the compared models, *Unified-01* (the naive model) and *MTM/MTM-Vote* are either simple or commonly used methods and thus are treated as baselines. *Unified-00* is a novel approach. Although Greenberg et al. (2018) used the approach of *Unified-11*, they only evaluated the model on training corpora/tasks while we apply it for task adaptation. Moreover, it is a special case of our proposed framework, thus we argue that people can simply tune M and M' to get good performance for adaptations to new tasks.

6 Results

As mentioned above, we compare the results of four different approaches in no-supervision and limited-supervision settings, both with real-world biomedical data and synthetic news data.

As a sanity check, we also evaluate the models on the test sets of the training corpora. The results can be found in Appendix A.2. It is shown that

[4] We further verified this conclusion by computing the heat maps on the original datasets. The overlaps between *BC2GM* and *BC4CHEMD*, and *BC2GM* and *Linnaeus* are nearly 0.

[5] A lower recall and f1 score was observed in the initial experiment without this heuristic.

Corpus	Trained on Other Biomedical Datasets									Traind on CoNLL		
	BC5CDR			BioNLP13CG			BioNLP11ID			CoNLL 2003

Table 2: Results for task adaptation in the no-supervision setting. The best f1 score in each column that is significantly better than the second best is bold-faced, while those are better but not significantly are underlined. All the significance tests are conducted using mention-level McNemar's Chi-square test, with p-value = 0.01.

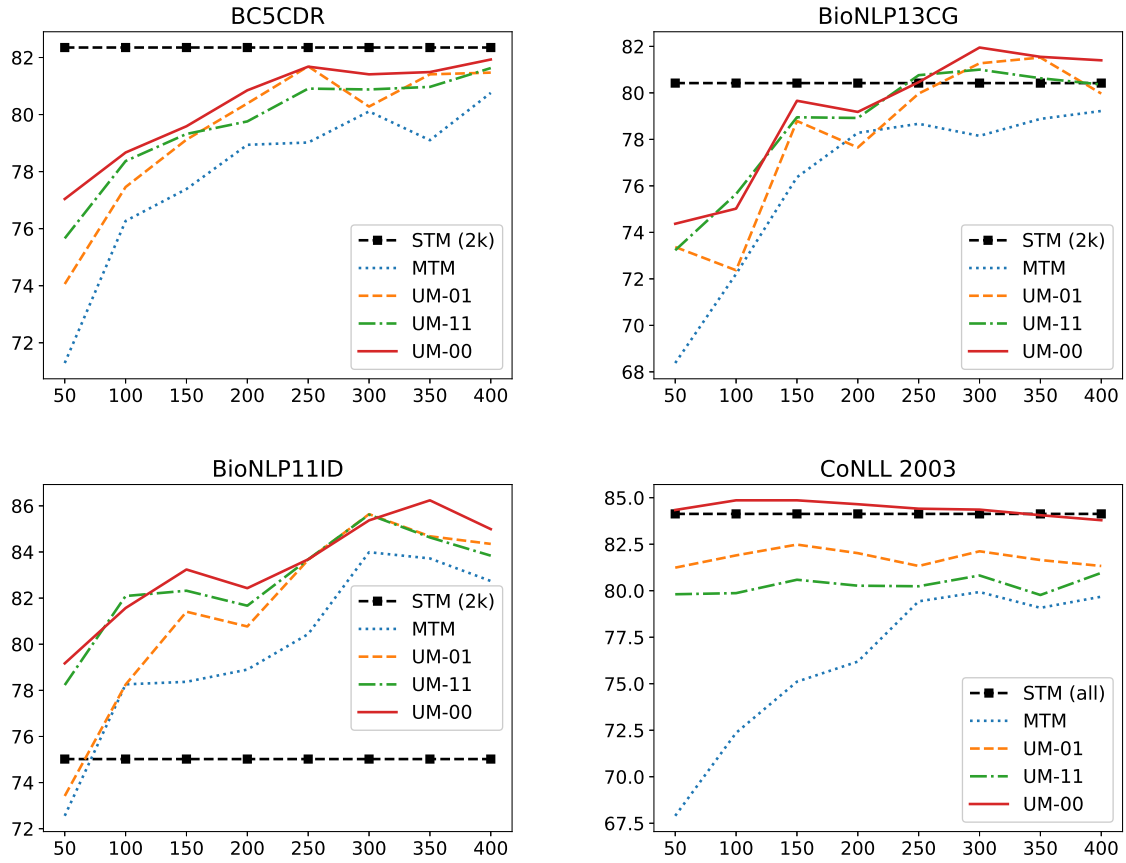

Figure 4: Plot of f1 scores for task adaptation in the limited-supervision setting. X-axis represents the number of sentences used for fine-tuning. *STM(2k)* is a STM trained on 2k sentences sampled from the global corpus, and *STM(all)* is trained on the entire training set of the corpus.

our MTM performs comparably with state-of-the-art systems evaluated on the training corpora, and thus is a strong baseline.

6.1 No-Supervision Setting

Table 2 demonstrates the results for task adaptation in the no-supervision setting. We report precision and recall in addition to f1 scores to better show the differences between the models.

Comparing on f1 scores, *Unified-00* (our new model) significantly outperforms all other models on three out of four datasets, demonstrating its effectiveness. *Unified-11* also achieves good results, with higher recall but lower precision than *Unified-00*. This aligns well with our hypothesis that it encourages predictions of entities. Conversely, *Unified-01* (the naive approach) achieves the highest precision but lowest recall, which is reasonable considering the problem of false penalties that discourages the model from predicting en-

tities. We also found that the model achieves better performance when $M = M'$, which supports our hypothesis in 4.5 that the model works better with a valid likelihood function.

6.2 Limited-Supervision Setting

To further demonstrate the models' ability to adapt to new datasets with a small amount of supervision, we sample a small subset of the training portion of each global evaluation corpus to fine-tune the trained models. We show the performance of the models fine-tuned with different amounts of sampled data. For each global corpus, we show a single-task model (STM) trained on it with a reasonable amount of data (two thousand sentences for the biomedical corpora). In the CoNLL 2003 setting, we train the STM on the entire training data for a fair comparison, because all other models are first trained on the four training portions, which essentially look through the entire training set (just partially annotated). The results of the STMs are used as benchmarks. Experimental results are presented in Figure 4.

Firstly, with much less training data, all the models achieve comparable or noticeably better performance than the STMs trained from scratch, demonstrating that training on the partially annotated corpora does help to boost performance on global evaluation corpora. Additionally, MTMs are worse than all the unified models, because they only share the LSTM layers, but lose all the knowledge in the CRFs when adapted to new corpora. The unified models have the advantage that they can reuse the robust CRFs learned from a large amount of data. This is more obvious in the CoNLL 2003 evaluation setting, where the unified models that reuse the pre-trained CRFs achieve good performance trained with only 50 sentences, but the MTM, which does not reuse the CRFs, needs a larger amount of training data to catch up.

In general, *Unified-00*, our novel approach proposed here, still performs the best on every dataset. We note that although *Unified-01* has an extremely low recall on the CoNLL 2003 dataset in the no-supervision setting, it works surprisingly well in the limited-supervision setting. On the other hand, *Unified-00* and *Unified-11* generally perform better than *Unified-01* on real-world biomedical datasets, especially when fine-tuned on less data. Again, since all the unified models are special cases of our proposed framework, we argue that, for adapting to new datasets, people can simply tune the discounting factors M and M' to get good results.

7 Conclusion and Future Work

In this paper, we propose a unified model that learns from multiple partially annotated datasets to make *joint* predictions on the union of entity types appearing in any training dataset. The model integrates learning signals from different datasets and avoids potential conflicts that would result from combining independent predictions from multiple models. Experiments show that the proposed unified model can efficiently adapt to new corpora that have more entity types than any of the training corpora, and performs better than the baseline approaches.

In future work, we plan to explore other algorithms (e.g. imitation learning) that allow the model the explore the unknown space during training, using delayed rewards to decide whether the model should trust its exploration. Analysis of the global evaluation results suggests that the unified model is under-predicting, meaning there is still room for improvement specifically on recall. We plan to explore further changes to the current objectives to encourage more entity predictions.

Finally, the approach proposed in this paper also does not handle entity types of varying granularities or tagsets with mismatched guidelines (e.g. one dataset annotates only for-profit companies as *ORG* and one annotates all formalized groups). Effectively modeling these complications is an interesting area for future work.

A Appendix

A.1 Datasets

Below we introduce the datasets in the biomedicine domain and the news domain.

A.1.1 Biomedicine domain: Local training group

The training group consists of five datasets: *BC2GM*, *BC4CHEM*, *NCBI-disease*, *JNLPBA*, and *Linnaeus*. The first two datasets are from different BioCreative shared tasks (Smith et al., 2008; Krallinger et al., 2015; Wei et al., 2015). *NCBI-disease* is created by Doğan et al. (2014) for disease name recognition and normalization. *JNLPBA* comes from the 2004 shared task from joint workshop on natural language processing in biomedicine and its applications (Kim et al., 2004), and *Linnaeus* is a species corpus composed by Gerner et al. (2010). More information about the datasets can be found in Table 3.

Below are detailed descriptions of the datasets:

BC2GM is a gene/protein corpus. The annotation is Gene. It's provided by the BioCreative II Shared Task for gene mention recognition.

BC4CHEM is a chemical corpus. The annotation is Chemical. It's provided by the BioCreative IV Shared Task for chemical mention recognition.

	Articles	Sentences	Tokens
Training set	946	14,987	203.621
Development set	216	3,466	51,362
Test set	231	3,684	46,435

Table 5: Statistics for the CoNLL 2003 NER dataset

NCBI-disease is a disease corpus. The annotation is Disease. It was introduced for disease name recognition and normalization.

JNLPBA consists of DNA, RNA, Gene/Protein, Cell line, Cell Type. The annotation is same as the NE names, except the Gene/Protein is annotated with Protein. It was provided by 2004 JNLPBA Shared Task for biomedical entity recognition.

Linnaeus is a species corpus. The annotation is Species. The original project was created for entity mention recognition.

A.1.2 Biomedicine domain: Global evaluation group

We reemphasize here that the purpose of the global evaluation is to test the model's ability to making global predictions and efficiently adapt to global corpora. While no corpus is globally annotated, we identify several existing corpora to *approximate* the global evaluation. Each test corpus is annotated with a *superset* of several training corpora to test the model's generalizability outside of the local tag spaces.

The global evaluation group contains three datasets: *BC5CDR*, *BioNLP13CG*, and *BioNLP11ID*. Each is annotated with multiple entity types. *BC5CDR* comes from the BioCreative shared tasks (Smith et al., 2008; Krallinger et al., 2015; Wei et al., 2015). *BioNLP13CG* and *BioNLP11ID* come from the BioNLP shared task (Kim et al., 2013). More information about the global evaluation datasets can be found in Table 4.

Below are detailed descriptions of the datasets:

BC5CDR is a chemical and disease corpus. The annotation is Chemical and Disease. It's provided by BioCreative V Shared Task for chemical and disease mention recognition.

BioNLP13CG consists of Gene/Protein and Related Product, Cancel, Chemical, Anatomy and Organism and others. **BioNLP11ID** consists of Gene/Protein, Chemical, and Organism. The annotation is same as the NE types but has a finer ontology scope.

Corpus	BC2GM	BC4CHM	NCBI	JNLPBA	Linnaeus
STM	79.9	88.6	84.1	72.7	87.3
MTM Crichton et al. (2017)	73.2	83.0	80.4	70.1	84.0
MTM Wang et al. (2018)	80.7	89.4	86.1	73.5	-
MTM (ours)	80.3	89.2	85.8	73.5	**88.5**
Unified-01	70.9	83.5	79.8	80.9	79.9
Unified-11	74.2	84.1	80.5	80.9	80.7
Unified-00	79.1	87.3	84.0	**83.8**	83.9

Table 6: Local evaluation (f1 scores). The best results that are significantly better than the second best are bold-faced, while those are best but not significantly better than the second best are underlined. All the significance tests are conducted using mention-level McNemar's Chi-square test, with p-value = 0.01.

There are inconsistencies between the entity type names in different datasets, mainly due to different granularities. To remove this unnecessary noise, we manually merged some entity types. For example, we unify Gene and Protein into Gene/Protein as they are commonly used interchangeably; we merge "Simple Chemical" to "Chemical" and leave the problem of entity type granularity for future work. The information in Table 3 and 4 reflects the merged types.

A.1.3 News domain: CoNLL 2003 NER dataset

We use the CoNLL 2003 NER dataset ((Sang and De Meulder, 2003)) to evaluate the models in news domain. More information about the dataset can be found in Table 5. We use synthetic data from the dataset to simulate local training and global evaluation. Specifically, the CoNLL 2003 NER dataset is annotated with four entity types: location, person, organization, and miscellaneous entities. We randomly split the training set into four portions, each contains only one entity type respectively, with other types changed to "O". The models are trained on the four training portions and we test on the original test set with all entity types annotated.

A.1.4 Data split

For the news domain, we use the default train, dev, test portion of the CoNLL 2003 NER dataset. For the biomedicine domain, we follow the data split in Crichton et al. (2017) for both the training and the evaluation groups. All datasets are divided into three portions: train, dev, and test. We train the model on the training set of the training group and tune the hyper-parameters on the corresponding development set. Global evaluations are performed on the test set of the evaluation group.

A.2 Local Evaluation

For a sanity check, we evaluate the models on the training corpora and compare the results with state-of-the-art systems. In this setting, all the models are trained on the training set of the training corpora (without fine-tuning on global evaluation corpora) and evaluated on their test set. The results are shown in Table 6. **STM** is the single-task models we implemented, following the settings in Wang et al. (2018). The SOTA is achieved by Wang et al. (2018) with multi-task model, which is shown in the table as **MTM Wang et al. (2018)**. They trained their model on *BC2GC*, *BC4CHM*, *NCBI*, *JNLPBA*, and *BC5CDR*. **MTM (ours)** is the multi-task model we trained on our five training corpora and used as a baseline in the global evaluations. It has the same architecture as Wang et al. (2018).

As we can see, **MTM Wang et al. (2018)** achieves the best results on 3 out of 4 datasets. And our MTM achieves very similar results, showing it is a strong model on training corpora. Our proposed models do not perform very well when evaluated on the training corpora. But in the global evaluation setting, they perform much better compared to our strong MTM. This demonstrates the superiority of our proposed models on task adaptation.

Learning Dense Representations for Entity Retrieval

Abstract

We show that it is feasible to perform entity linking by training a dual encoder (two-tower) model that encodes mentions and entities in the same dense vector space, where candidate entities are retrieved by approximate nearest neighbor search. Unlike prior work, this setup does not rely on an alias table followed by a re-ranker, and is thus the first fully learned entity retrieval model. We show that our dual encoder, trained using only anchor-text links in Wikipedia, outperforms discrete alias table and BM25 baselines, and is competitive with the best comparable results on the standard TACKBP-2010 dataset. In addition, it can retrieve candidates extremely fast, and generalizes well to a new dataset derived from Wikinews. On the modeling side, we demonstrate the dramatic value of an unsupervised negative mining algorithm for this task.

1 Introduction

A critical part of understanding natural language is connecting specific textual references to real world entities. In text processing systems, this is the task of *entity resolution*: given a document where certain spans of text have been recognized as *mentions* referring to entities, the goal is to link them to unique entries in a knowledge base (KB), making use of textual context around the mentions as well as information about the entities. (We use the term *mention* to refer to the target span along with its context in the document.)

Real world knowledge bases are large (e.g., English Wikipedia has 5.7M articles), so existing work in entity resolution follows a two-stage approach: a first component nominates candidate entities for a given mention and a second one selects the most likely entity among those candidates. This parallels typical *information retrieval* systems that consist of an index and a re-ranking model. In entity resolution, the index is a table mapping *aliases* (possible names) to entities. Such tables need to be built ahead of time and are typically subject to arbitrary, hard cutoffs, such as only including the thirty most popular entities associated with a particular mention. We show that this configuration can be replaced with a more robust model that represents both entities and mentions in the same vector space. Such a model allows candidate entities to be directly and efficiently retrieved for a mention, using nearest neighbor search.

To see why a retrieval approach is desirable, we need to consider how alias tables are employed in entity resolution systems. In the following example, *Costa* refers to footballer *Jorge Costa*, but the entities associated with that alias in existing Wikipedia text are *Costa Coffee*, *Paul Costa Jr*, *Costa Cruises*, and many others—while excluding the true entity.

> ***Costa** has not played since being struck by the AC Milan forward...*

The alias table could be expanded so that last-name aliases are added for all person entities, but it is impossible to come up with rules covering all scenarios. Consider this harder example:

> *...warned Franco Giordano, secretary of the **Refoundation Communists** following a coalition meeting late Wednesday...*

It takes more sophistication to connect the colloquial expression *Refoundation Communists* to the *Communist Refoundation Party*. Alias tables cannot capture all ways of referring to entities in general, which limits recall.

Alias tables also cannot make systematic use of context. In the *Costa* example, the context (e.g., *AC Milan forward, played*) is necessary to know that this mention does not refer to a company or a psychologist. An alias table is blind to this information and must rely only on prior probabilities of entities given mention spans to manage ambiguity. Even if the correct entity is retrieved, it might have such a low prior that the re-ranking model cannot recover it. A retrieval system with access to both the mention span and its context can significantly improve recall. Furthermore, by pushing the work of the alias table into the model, we avoid manual processing and heuristics required for matching mentions to entities, which are often quite different for each new domain.

This work includes the following contributions:

[*]Equal Contributions
[†]Work done during internship with Google

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 528–537
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

- We define a novel dual encoder architecture for learning entity and mention encodings suitable for retrieval. A key feature of the architecture is that it employs a modular hierarchy of sub-encoders that capture different aspects of mentions and entities.
- We describe a simple, fully unsupervised *hard negative mining* strategy that produces massive gains in retrieval performance, compared to using only random negatives.
- We show that approximate nearest neighbor search using the learned representations can yield high quality candidate entities very efficiently.
- Our model significantly outperforms discrete retrieval baselines like an alias table or BM25, and gives results competitive with the best reported accuracy on the standard TACKBP-2010 dataset.
- We provide a qualitative analysis showing that the model integrates contextual information and world knowledge even while simultaneously managing mention-to-title similarity.

We acknowledge that most of the components of our work are not novel in and of themselves. Dual encoder architectures have a long history (Bromley et al., 1994; Chopra et al., 2005; Yih et al., 2011), including for retrieval (Gillick et al., 2018). Negative sampling strategies have been employed for many models and applications, e.g. Shrivastava et al. (2016). Approximate nearest neighbor search is its own sub-field of study (Andoni and Indyk, 2008). Nevertheless, to our knowledge, our work is the first combination of these ideas for entity linking. As a result, we demonstrate the first accurate, robust, and highly efficient system that is actually a viable substitute for standard, more cumbersome two-stage retrieval and re-ranking systems. In contrast with existing literature, which reports multiple seconds to resolve a single mention, we can provide strong retrieval performance across all 5.7 million Wikipedia entities in around 3ms per mention.

2 Related work

Most recent work on entity resolution has focused on training neural network models for the candidate re-ranking stage (Francis-Landau et al., 2016; Eshel et al., 2017; Yamada et al., 2017a; Gupta et al., 2017; Sil et al., 2018). In general, this work explores useful context features and novel architectures for combining mention-side and entity-side features. Extensions include joint resolution over all entities in a document (Ratinov et al., 2011; Globerson et al., 2016; Ganea and Hofmann, 2017), joint modeling with related tasks like textual similarity (Yamada et al., 2017b; Barrena et al., 2018) and cross-lingual modeling (Sil et al., 2018), for example.

By contrast, since we are using a two-tower or dual encoder architecture (Gillick et al., 2018; Serban et al., 2018), our model cannot use any kind of attention over both mentions and entities at once, nor feature-wise comparisons as done by Francis-Landau et al. (2016). This is a fairly severe constraint – for example, we cannot directly compare the mention span to the entity title – but it permits retrieval with nearest neighbor search for the *entire* context against a single, all encompassing representation for each entity.

3 Data

As a whole, the entity linking research space is fairly fragmented, including many task variants that make fair comparisons difficult. Some tasks include named entity recognition (mention span prediction) as well as entity disambiguation, while others are concerned only with disambiguation (the former is often referred to as *end-to-end*. Some tasks include the problem of predicting a *NIL* label for mentions that do not correspond to any entity in the KB, while others ignore such cases. Still other tasks focus on *named* or proper noun mentions, while others include disambiguation of concepts. These variations and the resulting fragmentation of evaluation is discussed at length by Ling et al. (2015) and Hachey et al. (2013), and partially addressed by attempts to consolidate datasets (Cornolti et al., 2013) and metrics (Usbeck et al., 2015).

Since our primary goal is to demonstrate the viability of our unified modeling approach for entity retrieval, we choose to focus on just the disambiguation task, ignoring NIL mentions, where our set of entity candidates includes every entry in the English Wikipedia.

In addition, some tasks include relevant training data, which allows a model trained on Wikipedia (for example) to be tuned to the target domain. We save this fine-tuning for future work.

Training data Wikipedia is an ideal resource for training entity resolution systems because many mentions are resolved via internal hyperlinks (the mention span is the anchor text). We use the 2018-10-22 English Wikipedia dump, which includes 5.7M entities and 112.7M linked mentions (labeled examples). We partition this dataset into 99.9% for training and the remainder for model selection.

Since Wikipedia is a constantly growing an evolving resource, the particular version used can significantly impact entity linking results. For example, when the TACKBP-2010 evaluation dataset was published, Wikipedia included around 3M entities, so the number of retrieval candidates has increased by nearly two times. While this does mean new contexts are seen for many entities, it also means that retrieval gets more difficult over time. This is another factor that makes fair comparisons challenging.

Evaluation data There are a number of annotated datasets available for evaluating entity linking systems. Given the choices discussed above, the **TACKBP-2010**

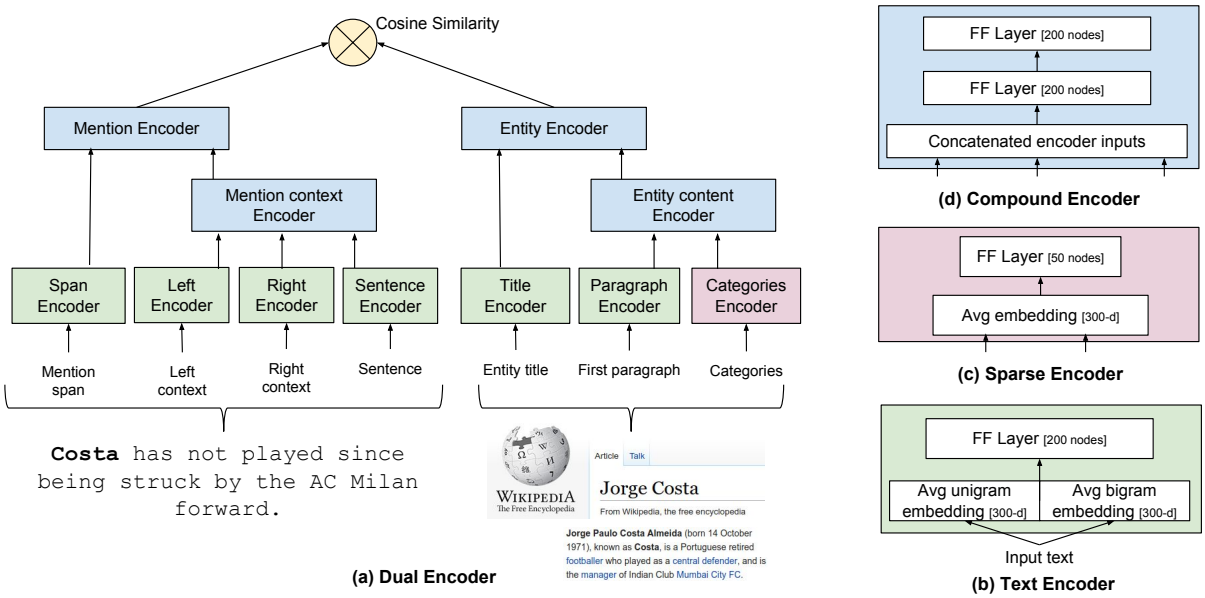

Figure 1: Architecture of the dual encoder model for retrieval (a). Common component architectures are shown for (b) text input, (c) sparse ID input, and (d) compound input joining multiple encoder outputs. Note that all text encoders share a common set of embeddings.

dataset[1] is the most widely used evaluation that matches our constraints and allows us to compare to a reasonable variety of prior work. It includes 1020 annotated mention/entity pairs derived from 1013 original news and web documents. While there is a related development set associated with this evaluation set, we do not use it for any fine-tuning, as explained above.

To further validate our results, we also include a new evaluation set called **Wikinews**, which includes news pages from Wikinews[2] in English for the year 2018. It includes 2263 annotated mention/entity pairs derived from 1801 original documents. Because we pulled these documents at the same time as the Wikipedia dump, the entity annotations are consistent with our training set and have not been subject to the kind of gradual rot that befalls older evaluation data as the updated KB diverges from the annotations. This data is available here: https://github.com/google-research/google-research/tree/master/dense_representations_for_entity_retrieval/.

4 Entity retrieval model

We use nearest neighbor search to retrieve entities based on a mention in context, after learning dense, fixed-length vector representations of each.

4.1 Dual Encoder model

The *dual encoder* is a two-tower architecture suitable for retrieval (Gillick et al., 2018). It has one network structure for encoding mentions (including their contexts), a second for encoding entities (including KB features), and a cosine function to compute similarity between representations (which must be the same dimension). A key property of this architecture is that there is no direct interaction between the encoders on each side. This enables efficient retrieval, but constrains the set of allowable network structures. The dual encoder learns a mention encoder ϕ and an entity encoder ψ, where the score of a mention-entity pair (m, e) defined as:

$$s(m, e) = \cos(\phi(m), \psi(e)) \quad (1)$$

Figure 1 shows the full model architecture and the feature inputs to each encoder. We use a *compound encoder* (Figure 1d) to add useful sub-structure to each tower. The mention-side encoder first combines the context features, and then combines the result with the mention span encoding. Similarly, the entity-side encoder first combines the entity paragraph and categories, and then combines the result with the entity title encoding.

The mention encoder uses four text features to capture both the span text and the textual context surrounding it. The context features include the five tokens immediately to the left and right of the span. In the sentence feature, the mention span is replaced by a special symbol.

The entity encoder uses the entity's title and the first paragraph of its Wikipedia page as text features. It additionally incorporates the unedited user-specified categories associated with the entity. We do not use the entity IDs as features so that the model generalizes more easily to new entities unseen at training time. In fact, more than 1M candidate entities available at retrieval time have no associated training examples, but this architecture allows these to be encoded using their feature representations.

[1] https://tac.nist.gov/
[2] https://en.wikinews.org

A shared embedding look-up is used for all text features (Figure 1b). Specifically, we embed all unigrams and bigrams to get 300-dimensional averaged unigram embeddings and 300-dimensional averaged bigram embeddings for each text feature. Unigram embeddings are initialized from GloVe vectors (Pennington et al., 2014), and we use 5M hash buckets for out-of-vocabulary unigrams and bigrams(Ganchev and Dredze, 2008). These averaged embeddings are concatenated and then passed through a feed-forward layer. For the category features, each entity category name is treated as a sparse input, and the embeddings for all categories for an entity are averaged to produce a 300-dimensional representation, which in turn is passed through a feed-forward layer (Figure 1c).

Our experiments show that this architecture is highly effective for both retrieval and resolution. Nevertheless, we expect that additional modeling ideas will further improve performance, especially for resolution. Recent work such as Durrett and Klein (2014) has shown improvements derived from better, longer-range, context features; similarly, there are many more potentially useful KB-derived features. More complex encoder architectures that use some form of attention over the input tokens and features could also be beneficial.

4.2 Training

Our training data is described in Section 3. The inputs to the entity encoder are constructed from the true entity referred by the landing page. The inputs to the mention encoder are constructed from the source page, using the mention span and surrounding context.

These pairs constitute only positive examples, so we use *in-batch random negatives* (Henderson et al., 2017; Gillick et al., 2018): for each mention-entity pair in a training batch, the other entities in the batch are used as negatives. Computationally, this amounts to building the all-pairs similarity matrix for all mentions and entities in a batch. We optimize softmax loss on each row of the matrix, so that the model is trained to maximize the score of the correct entity with respect to random entities. This is a version of the sampled softmax (Jozefowicz et al., 2016), which we use in place of the full softmax because the normalization term is intractable to compute over all 5.7M entities.

The softmax loss is not directly applied to the raw cosine similarities. Instead, a scalar multiplier a is learned to map the similarities (in the range $[-1, 1]$) to unbounded *logits*. For each training pair (m_i, e_i) in a batch of B pairs, the loss is computed as:

$$L(m_i, e_i) = -f(m_i, e_i) + \log \sum_{j=1}^{B} \exp(f(m_i, e_j)) \tag{2}$$

where

$$f(m_i, e_j) = a \cdot s(m_i, e_j) \tag{3}$$

We track in-batch recall@1 (accuracy) on the held out set during training. For each instance, the model gets a score of 1 if the correct entity is ranked above all in-batch random negatives, 0 otherwise. We stop training after the metric flattens out (about 40M steps).

For all experiments, we use a batch size of 100, standard SGD with Momentum of 0.9 and a fixed learning rate 0.01.

Our aim here is to demonstrate a pure retrieval system, so we train our models solely from Wikipedia and refrain from tuning them explicitly on in-domain documents from the evaluation tasks.

4.3 Hard negative mining

Random negatives alone are not enough to train an accurate entity resolution model because scoring the correct entity above random alternatives can typically be achieved just by comparing the mention text and entity title. More challenging negative examples must be introduced to force the model to exploit context. This strategy is somewhat akin to Importance Sampling (Bengio et al., 2003), for example.

After learning an initial model using random negatives, we identify hard negatives via the following steps:

1. Encode all mentions and entities found in training pairs using the current model.
2. For each mention, retrieve the most similar 10 entities (i.e., its nearest neighbors).
3. Select all entities that are ranked above the correct one for the mention as negative examples.

This yields new negative mention/entity pairs for which the model assigns a high score. It crucially relies on the fact that there is just one correct entity, unlike other tasks that consider general similarity or relatedness (and which are well served by random negatives). For example, negatives mined in this way for paraphrasing or image captioning tasks could actually turn out to be positives that were not explicitly labeled in the data. It is precisely because the distribution over candidate entities that match a contextualized mention tends to have such low entropy that makes negative mining such a good fit for this task.

After merging these with the original positive pairs to construct a classification task, we resume training the initial dual encoder model using logistic loss on this new set of pairs. To retain good performance on random negatives, the new task is mixed with the original softmax task in a multi-task learning setup in which the two loss functions are combined with equal weight and optimized together. For a pair (m, e) with label $y \in \{0, 1\}$, the hard negative loss is defined as:

$$\begin{aligned} L_h(m, e; y) = &- y \cdot \log f(m, e) \\ &- (1 - y) \cdot \log(1 - f(m, e)) \end{aligned} \tag{4}$$

where

$$f(m, e) = g(a_h \cdot s(m, e) + b_h) \tag{5}$$

Here, $g(x) = 1/(1 + e^{-x})$ is the logistic function, and a_h and b_h are learned scalar parameters to transform the cosine similarity into a logit.[3]

For the hard negatives task, we track *Area Under the ROC curve* (AUC) on a held out set of pairs. We stop training when the average of the evaluation metrics for the two tasks stabilizes (about 5M steps).

Finally, we iteratively apply this negative mining procedure. For each round, we mine negatives from the current model as described above and then append the new hard examples to the classification task. Thus each subsequent round of negative mining adds fewer and fewer new examples, which yields a stable and naturally convergent process. As we show in our experiments, iterative hard negative mining produces large performance gains.

4.4 Inference

Once the model is trained, we use the entity encoder to pre-compute encodings for all candidate entities (including those that do not occur in training). At prediction time, mentions are encoded by the mention encoder and entities are retrieved based on their cosine similarity. Since our focus is on model training, we use brute-force search in our evaluation. However, for online settings and larger knowledge bases, an approximate search algorithm is required. In Section 5.2 we show that, when using approximate search, the system retains its strong performance while obtaining a nearly 100x speedup on an already fast retrieval.

5 Experiments

5.1 Evaluation setup

We demonstrate our model performance as compared to a baseline alias table. As is standard, it is built by counting all (mention span, entity) pairs in the training data. The counts are used to estimate prior probabilities $P(e|m)$ of an entity given a mention span (alias); for each entity, the aliases are ordered according to these priors and limited to the top 100 candidates.

$$P(e|m) = \frac{count(e, m)}{\sum_{e' \in E} count(e', m)} \quad (6)$$

Here, $count(e, m)$ is the number of occurrences of mention m linked to entity e, and E is the set of all entities appearing in the data.

Since alias table construction is often extended with various heuristics, we also include a variant that includes unigrams and bigrams of the mention text as additional aliases. This can help when the entities (specifically person names) are referenced as last/first name at inference time.

Finally, since we are primarily concerned with demonstrating performance of a retrieval system (as opposed to a re-ranking system) or a combination of the two, we include results using the standard BM25 retrieval algorithm (the *Gensim* implementation[4]). We found that indexing each entity using its title gave much better results than indexing with the first paragraph text (or the full document text).

We measure recall@k (R@k), defined as the proportion of instances where the true entity is in the top k retrieved items. We report R@1 (accuracy of the top retrieved result), which is standard for TAC/KBP-2010, as well R@100, which better captures overall retrieval performance.

We refer to the models with these abbreviations:

- **AT-Prior**: The alias table ordered by $P(e|m)$.
- **AT-Ext**: The heuristically extended alias table.
- **BM25**: The BM25 retrieval algorithm, where each entity is indexed using its title.
- **DEER**: Our Dual Encoder for Entity Resolution, as described in section 4.

System	R@1	Entities
AT-Prior	71.9	5.7M
AT-Ext	73.3	5.7M
Chisholm and Hachey (2015)	80.7	800K
He et al. (2013)	81.0	1.5M
Sun et al. (2015)	83.9	818K
Yamada et al. (2016)	85.2	5.0M
Nie et al. (2018)	86.4	5.0M
Barrena et al. (2018)	87.3	523K
DEER (this work)	87.0	5.7M

Table 1: Comparison of relevant TACKBP-2010 results using Recall@1 (accuracy). While we cannot control the candidate entity set sizes, we attempt to approximate them here.

5.2 Results

Table 1 provides a comparison against the most relevant related work. While there are some reported improvements due to collective (*global*) resolution of all mentions in a document (Globerson et al. (2016) report 87.2% and Nie et al. (2018) report 89.1%), we limit comparisons to *local* resolution. We also limit comparisons to systems that ignore NIL mentions (referred to as *in-KB* accuracy), so all those reported in the table evaluate precisely the same set of mentions. As noted earlier, we cannot control the candidate sets used in each of these experiments, and we are at some disadvantage given our larger set of candidates.

Retrieval performance Table 2 provides the percent of mentions for which the correct entity is found in the top 100 retrieved results, using the different baselines

[3] The additive parameter is only needed for the logistic loss component, as the softmax function is invariant to translation.

and the DEER model. The learned representations deliver superior performance and do not require special handling for unigrams versus bigram lookups, counts for entity prominence, and so on.

Resolution performance To put DEER's architecture and performance in context, we compare it with prior work in some more detail here.

He et al. (2013) use a dual encoder setup to train a re-ranker, but start with unsupervised training to build representations of contexts and entities using Denoising Autoencoders. They use an alias table for candidate generation, and then train a ranking model using mention-specific batching to obtain hard in-batch negatives. Our results suggest that the autoencoder pretraining is not necessary and that our unsupervised negative mining can outperform heuristic selection of negatives.

Sun et al. (2015) also use a dual encoder that has similar structure to ours. Like He et al. (2013), they use it to score entries from an alias table rather than directly for retrieval. Their mention encoder is a considerably more complex combination of mention and context rather than the simple compounding strategy in our architecture. Their alias table method not only maps mentions to entities, but also uses additional filters to reduce the set of candidate entities based on words in the mention's context. They report that this method has a recall of 91.2% on TACKBP 2010, while our direct retrieval setup gives Recall@100 of 96.3% (see Table 2). They train their representations for each true mention-entity pair against a single random negative entity for the mention, whereas our method takes advantage of the entire batch of random negatives as well further refinement through hard negative mining.

Yamada et al. (2016) use an alias table derived from the December 2014 Wikipedia dump, restricted to the fifty most popular entities per mention. They tune their model on the TACKBP 2010 training set. Architecturally, they include features that capture the alias table priors and string similarities, both of which are not feasible in a dual encoder configuration that precludes direct comparison between mention- and entity-side features. DEER's better results indicate that learned representations of mentions and entities can be powerful enough for entity retrieval even without any cross-attention.

Nie et al. (2018) define a complex model that uses both entity type information and attention between the mention string and the entity description. To augment the small 1500 example training data in TACKBP, they also collected 55k mentions found in Wikipedia that were active in TACKBP 2010 to train this model. DEER is simply trained over all entities in Wikipedia and uses no cross-attention or explicit type information, yet delivers better resolution performance.

Most standard entity linking models build a single ranking model on top of the candidate set provided by an alias table. Barrena et al. (2018) instead train 523k mention-specific deep classifiers—effectively treating entity linking as a special form of word sense disambiguation. They do this by pre-training a single LSTM that predicts among 248k mentions, and then the parameters of this model are used to warm start each of the 523k mention-specific models. In doing so, they learn an effective context encoding, and can then fine-tune each mention model to discriminate among the small set of popular candidate entities for the mention (their alias table uses a cutoff of the thirty most popular entities for each mention). DEER in contrast, has a single mention encoder that is simple and fast, and performs nearly equivalently while retrieving from a much larger set of entities.

Approximate search Tables 1 and 2 report performance using brute force nearest-neighbor search. That is, we score each mention against all 5.7M entities to get the top k neighbors. However, a major motivation for using a single-stage retrieval model is that it can allow scaling to much larger knowledge bases by reducing retrieval time via approximate search.

To estimate performance in a real-world setting, we repeat the evaluation of DEER using the quantization-based approaches described by Guo et al. (2016). Table 3 shows the trade-off between search time and recall on Wikinews. Compared to brute force, search time can be reduced by an order of magnitude with a small loss in R@100, or by two orders of magnitude while losing less than 3 points. This is crucial for scaling the approach to even larger KBs and supporting the latency requirements of real-world applications.

Impact of hard negative mining Figure 2 shows the improvement in Recall@1 from each round of hard negative mining. The first iteration gives a large improvement over the initial round of training with only random negatives. Successive iterations yield further gains, eventually flattening out. Our strategy of append-

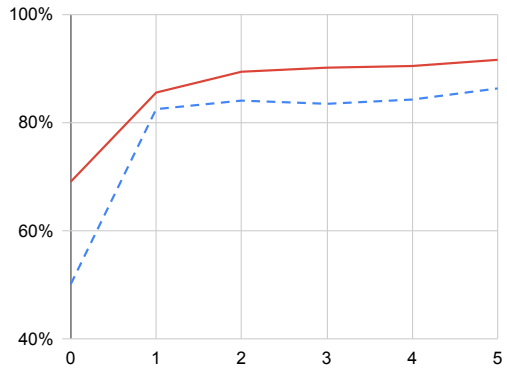

Figure 2: Recall@1 improvement for successive iterations of hard negative mining for Wikinews (solid) and TACKBP-2010 (dashed).

ing each new set of hard negatives to the previously mined ones means that each new set has proportionately less influence—this trades off some opportunity for improving the model in favor of stability.

5.3 Qualitative analysis

Here, we show a variety of examples to elucidate how DEER effectively models context, and to provide intuition for the learned entity representations.

First, we compare entities retrieved by DEER with those retrieved by the alias table baseline. Table 5 shows some instances where the alias table does not contain the correct entity for a given mention text (in the top 100 neighbors) or it fails to return any entity at all. In all of these cases, it is clear that context is essential. While a scoring stage is intended to leverage context, it is limited by the set of retrieved entities; our approach uses context directly.

For example, mentions like *Costa* and *Justin* are linked to the correct entities in the alias table, but with such low prior probability that we would need to retrieve far more than the top 100 entities to consider them. At the other extreme, mentions like *Refoundation Communists* and *European EADS* are missed by the baseline because they don't have direct string matches in the alias table. Additional extensions to our alias table allowing token re-ordering could help catch the former (though this might reduce precision too much), but it's unlikely that any alias table could connect *European EADS* with *Airbus* in the absence of an explicit anchor-text link. This example helps highlight how a fully learned retrieval model can generalize to new data.

Second, Table 6 shows more directly how modifying the context around a mention span changes the retrieved entities. For example, the model correctly differentiates between Phoenix the city, Phoenix the band, and Phoenix in mythology based on the sentence surrounding an identical mention span.

Third, since our model produces encodings for all 5.7M entities, we can retrieve nearest neighbors for any entity. Some examples are shown in Table 4. The model tends to prefer related entities of the same type, and often ones that share portions of their names, probably because entity titles are so important to linking with mentions. The nearest neighbors for *Jorge Costa*, our running example, include a variety of retired Portuguese football players, many of whom have *Costa* in their names.

Entity	Nearest neighbors
Jorge Costa	José Alberto Costa, Eduardo Costa, Peter Shilton, Rui Costa, Nuno Gomes, Ricardo Costa (Portuguese footballer), André Gomes, Bruno Ribeiro, Diego Costa
Costa Cruises	MSC Cruises, P&O Cruises, Princess Cruises, Island Cruises, AIDA Cruises, Silversea Cruises, Carnival Corporation & plc, Costa Concordia, Celebrity Cruises
Arctic sea ice decline	Arctic ice pack, Measurement of sea ice, Arctic geoengineering, Arctic sea ice ecology and history, Climate Change Science Program, Abrupt climate change, Sea ice thickness, Antarctic sea ice, Marine ice sheet instability
Pink Floyd	Led Zeppelin, The Who, Duran Duran, Syd Barrett, The Velvet Underground, Eddie Floyd, The Beatles, The Australian Pink Floyd Show, Roger Waters

Table 4: Nearest neighbors retrieved by DEER for a sample of entities.

Finally, Figure 3 is a t-SNE projection of the entity encodings for a selection of cities, bands, and people (nobel literature winners). The cities and bands were chosen to have high word overlap, e.g. *Montreal (city)* and *Of Montreal (band)*, to demonstrate how our entity embeddings differ from standard word embeddings. Note also the sub-clusters that form within each type cluster. Latin American authors cluster together, as do the Existentialists; the cities have some geographical proximity, though Brazil and Portugal are neighbors, presumably because of shared language and culture.

6 Conclusion

Our results with DEER show that a single-stage retrieval approach for entities from mentions is highly effective: without any domain-specific tuning, it performs at least as well as the best comparable two-stage systems. While our bag-of-ngrams encoders provided a strong proof of concept, we can almost certainly improve results with more sophisticated encoders, using a BERT architecture (Devlin et al., 2019), for example. Further, by virtue of approximate search techniques, it can be used for very

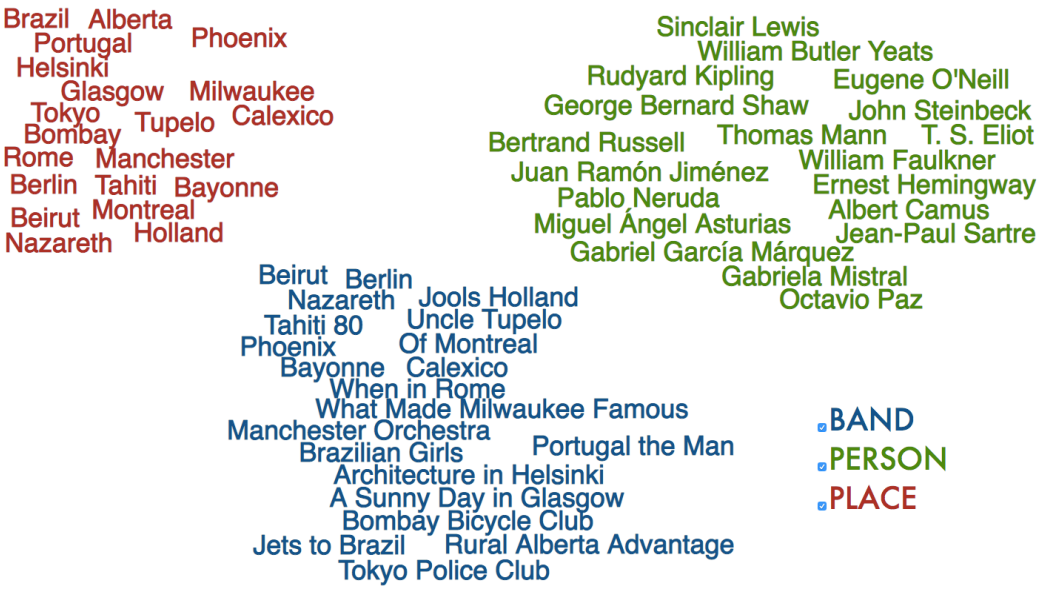

Figure 3: A 2D projection of cities, bands, and people embeddings (using t-SNE), color coded by their category.

fast retrieval, and is likely to scale reasonably to much larger knowledge bases.

We also note that the dual encoder approach allows for interesting extensions beyond traditional entity linking. For example, the context encodings provide a natural model for building entity expectations during text processing, such that entities relevant to the context can be retrieved and used for reference resolution as a document is processed incrementally. We expect this will be useful for collective entity resolution as well as modeling coherence.

Finally, while we focus on training with English Wikipedia, Sil et al. (2018) show that using cross-lingual datasets can help to refine the context information more effectively. Since English constitutes only a fraction of the total Wikipedia, and entity IDs are (mostly) language-independent, there is great opportunity to extend this work to far more training examples across far more languages.

Abstract

An interesting method of evaluating word representations is by how much they reflect the semantic representations in the human brain. However, most, if not all, previous works only focus on small datasets and a single modality. In this paper, we present the first multimodal framework for evaluating English word representations based on cognitive lexical semantics. Six types of word embeddings are evaluated by fitting them to 15 datasets of eye-tracking, EEG and fMRI signals recorded during language processing. To achieve a global score over all evaluation hypotheses, we apply statistical significance testing accounting for the multiple comparisons problem. This framework is easily extensible and available to include other intrinsic and extrinsic evaluation methods. We find strong correlations in the results between cognitive datasets, across recording modalities and to their performance on extrinsic NLP tasks.

1 Introduction

Word embeddings are the corner stones of state-of-the-art NLP models. Distributional representations which interpret words, phrases, and sentences as high-dimensional vectors in semantic space have become increasingly popular. These vectors are obtained by training language models on large corpora to encode contextual information. Each vector represents the meaning of a word.

Evaluating and comparing the quality of different word embeddings is a well-known, largely open challenge. Currently, word embeddings are evaluated with extrinsic or intrinsic methods. Extrinsic evaluation is the process of assessing the quality of the embeddings based on their performance on downstream NLP tasks, such as question answering or entity recognition. However, embeddings can be trained and fine-tuned for specific tasks, but this does not mean that they accurately reflect the meaning of words.

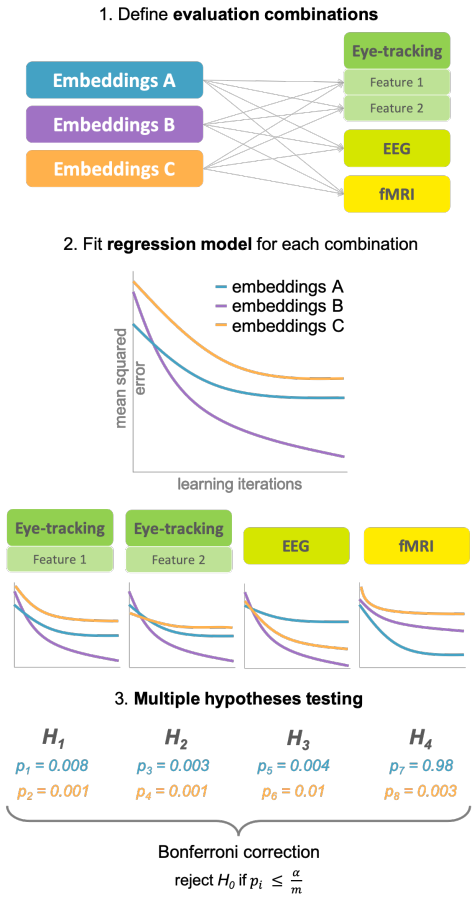

Figure 1: Overview of the cognitive word embedding evaluation process.

One the other hand, intrinsic evaluation methods, such as word similarity and word analogy tasks, merely test single linguistic aspects. These tasks are based on conscious human judgements. Conscious judgements can be biased by subjective factors and the tasks themselves might also be biased (Malvina Nissim, 2019). Additionally, the correlation between intrinsic and extrinsic metrics is not very clear, as intrinsic evaluation results fail

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 538–549
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

to predict extrinsic performance (Chiu et al., 2016; Gladkova and Drozd, 2016). Finally, both intrinsic and extrinsic evaluation types often lack statistical significance testing and do not provide a global quality score.

In this paper, we focus on the *intrinsic subconscious evaluation method* (Bakarov, 2018b), *which evaluates English word embeddings against the lexical representations of words in the human brain, recorded when passively understanding language*. Cognitive lexical semantics proposes that words are defined by how they are organized in the brain (Miller and Fellbaum, 1992). As a result, brain activity data recorded from humans processing language is arguably the most accurate mental lexical representation available (Søgaard, 2016). Recordings of brain activity play a central role in furthering our understanding of how human language works. To accurately encode the semantics of words, we believe that embeddings should reflect this mental lexical representation.

Evaluating word embeddings with cognitive language processing data has been proposed previously. However, the available datasets are not large enough for powerful machine learning models, the recording technologies produce noisy data, and most importantly, only few datasets are publicly available. Furthermore, since brain activity and eye-tracking data contain very noisy signals, correlating distances between representations does not provide sufficient statistical power to compare embedding types (Frank, 2017). For this reason we evaluate the embeddings by exploring how well they can predict human processing data. We build on Søgaard (2016)'s theory of evaluating embeddings with this task-independent approach based on cognitive lexical semantics and examine its effectiveness. The design of our framework follows three principles:

1. **Multi-modality**: Evaluate against various modalities of recording human signals to counteract the noisiness of the data.
2. **Diversity** within modalities: Evaluate against different datasets within one modality to make sure the number of samples is as large as possible.
3. **Correlation** of results should be evident across modalities and even between datasets of the same modality.

Contributions We present CogniVal, the first framework of cognitive word embedding evaluation to follow these principles and analyze the findings. We evaluate different embedding types against a combination of 15 cognitive data sources, acquired via three modalities: eye-tracking, electroencephalography (EEG) and functional magnetic resonance imaging (fMRI). The word representations are evaluated by assessing their ability of predicting cognitive language processing data. After fitting a neural regression model for each combination, we apply multiple hypotheses testing to measure the statistical significance of the results, taking into account multiple comparisons (see Figure 1). This contributes to the consistency of the results and to attain a global score of embedding quality. Our main findings when evaluating six state-of-the-art word embeddings with CogniVal show that the majority of embedding types significantly outperform a baseline of random embeddings when predicting a wide range of cognitive features. Additionally, the results show consistent correlations between between datasets of the same modality and across different modalities, validating the intuition of our approach. Finally, we present an exploratory but promising correlation analysis between the scores obtained using our intrinsic evaluation methods and the performance on extrinsic NLP tasks.

The code of this evaluation framework is openly available[1]. It can be used as is, or in combination with other intrinsic as well as extrinsic evaluation methods for word representations.

2 Related Work

Mitchell et al. (2008) pioneered the use of word embeddings to predict patterns of neural activation when subjects are exposed to isolated word stimuli. More recently, this dataset and other fMRI resources have been used to evaluate learned word representations.

For instance, Abnar et al. (2018) and Rodrigues et al. (2018) evaluate different embeddings by predicting the neuronal activity from the 60 nouns presented by Mitchell et al. (2008). Søgaard (2016) shows preliminary results in evaluating embeddings against continuous text stimuli in eye-tracking and fMRI data. Moreover, Beinborn et al. (2019) recently presented an extensive set of language–brain encoding experiments. Specifically, they evaluated the ability of an ELMo language model to predict brain responses of multiple

[1] https://github.com/DS3Lab/cognival

fMRI datasets.

EEG data has been used for similar purposes. Schwartz and Mitchell (2019) and Ettinger et al. (2016) show that components of event-related potentials can successfully be predicted with neural network models and word embeddings.

However, these approaches mostly focus on one modality of brain activity data from small individual cognitive datasets. The lack of data sources has been one reason why this type of evaluation has not been too popular until now (Bakarov, 2018a). Hence, in this work we collected a wide range of cognitive data sources ranging from eye-tracking to EEG and fMRI to ensure coverage of different features, and consequently of the cognitive processing taking place in the human brain during reading.

Evidence from cognitive neuroscience Murphy et al. (2018) review computational approaches to the study of language with neuroimaging data and show how different type of words activate neurons in different brain regions. Similarly, mapping fMRI data from subjects listening to stories to the activated brain regions, revealed semantic maps of how words are distributed across the human cerebral cortex (Huth et al., 2016).

Furthermore, word predictability and semantic similarity show distinct patterns of brain activity during language comprehension: semantic distances can have neurally distinguishable effects during language comprehension (Frank and Willems, 2017). These findings support the theory that brain activity data does reflect lexical semantics and is thus an appropriate foundation for evaluating the quality of word embeddings.

3 Word embeddings

Pre-trained word vectors are an essential component in state-of-the-art NLP systems. We chose six commonly used pre-trained embeddings to evaluate against the cognitive data sources. See Table 1 for an overview of the dimensions of each embedding type. We evaluate the following types of word embeddings:

- **Glove**: Pennington et al. (2014) provide embeddings of different dimensions trained on aggregated global word-word co-occurrence statistics over a corpus of 6 billion words.

embeddings	dim.	hidden layer units
Glove	50	[30, 26, 20, 5]
Glove	100	[50, 30]
Glove	200	[100, 50]
Glove	300	[150, 50]
Word2vec	300	[150, 50]
WordNet2vec	850	[400, 200]
FastText	300	[150, 50]
ELMo	1024	[600, 200]
BERT	768	[400, 200]
BERT	1024	[600, 200]

Table 1: Overview of word embeddings evaluated with CogniVal. The last column shows the search space of the grid search for the number of units in the hidden layer.

- **Word2vec**: Non-contextual embeddings trained on 100 billion words from a Google News dataset (Mikolov et al., 2013).

- **WordNet2Vec** (Saedi et al., 2018) These embeddings represent the conversion from semantic networks into semantic spaces. Trained on WordNet, a lexical ontology for English that comprises over 155,000 lemmas (but trained only on 60,000 words).

- **FastText** pre-trained embeddings use character n-grams to compose the vector of the full words (Mikolov et al., 2018). We evaluate the embeddings with and without subword information trained on 16 billion tokens of Wikipedia sentences as well as the ones trained on 600 billion tokens of Common Crawl.

- **ELMo** models both complex characteristics of word use (i.e. syntax and semantics), and how these uses vary across linguistic contexts (Peters et al., 2018). These word vectors are learned functions of the internal states of a deep bidirectional language model, which is pre-trained on a large text corpus. We take the first of the three output layers, containing the context insensitive word representations.

- **BERT** embeddings are contextual, bidirectional word representations, based on the idea that fine-tuning a pre-trained language model can help the model achieve better results in the downstream tasks (Devlin et al., 2019). We take the hidden states of the second to last

of 12 output layers as the representation for each token.

4 Cognitive data

In this paper, we consider three modalities of recording cognitive language processing signals: eye-tracking, electroencephalography (EEG), and functional magnetic resonance imaging (fMRI). All three methods are complementary in terms of temporal and spatial resolution as well as the directness in the measurement of neural activity (Mulert, 2013). For the word embedding evaluation we selected a wide range of datasets from these three modalities to ensure a more diverse and accurate representation of the brain activity during language processing.

Table 2 shows an overview of the cognitive data sources used, which are described in more detail below. Since the processing in the brain differs depending on whether the information is accessed via the visual or auditory system (Price, 2012), we include data of different stimuli, e.g. participants reading sentences or listening to audiobooks. Moreover, our collection of cognitive data sources contains datasets of both isolated (single words) and continuous (words in context, i.e. sentences or stories) stimuli. All datasets include English language stimuli and the participants were native speakers or highly proficient.

Eye-tracking Eye-tracking is an indirect measure of cognitive activity. Gaze patterns are highly correlated with the cognitive load associated with different stages of human text processing (Rayner, 1998). For instance, fixation duration is higher for long, infrequent and unfamiliar words (Just and Carpenter, 1980).

All eye-tracking datasets used in this work were recorded from natural, self-paced reading. Each dataset provides different eye-tracking features. The most common features, available in all 7 datasets are: first fixation duration, first pass duration, mean fixation duration, total fixation duration and number of fixations. For a complete list and description of the eye-tracking features available in each corpus see Appendix A.1.

Gaze vectors consist of specific features, which are extracted based on the reading times, fixations and regressions on each word. Feature values are aggregated on word type level and scaled between 0 and 1. The feature values were averaged over all subjects within a dataset. This preprocessing step is done separately for each data source before combining them. Hollenstein and Zhang (2019) show that combining gaze data from different sources can be helpful for NLP applications, even when they are recorded with different devices and filtering,

By using as many features as available from each dataset, including features characterizing basic, early and late word processing aspects, the goal is to cover the whole language understanding process on word level.

EEG Electroencephalography records electrical activity from the brain. It measures voltage fluctuations through the scalp with high temporal resolution.oh (Hauk and Pulvermüller, 2004) presents evidence for the modulation of early electrophysiological brain responses by word frequency. This is evidence that lexical access from written word stimuli is an early process that follows stimulus presentation by less than 200 ms.

The EEG datasets used in this work were either recorded from reading sentences or listening to natural speech. Word-level brain activity could be extracted by mapping to eye-tracking cues (ZuCo), by mapping to auditory triggers (Natural Speech), by recording only the last word in each sentence (N400), or through serial presentation of the words (UCL). Standard preprocessing steps for EEG data, including band-pass filtering and artifact removal, are performed in the same manner for all four data sources. See Appendix A.2 for details on EEG preprocessing.

The EEG data is aggregated over all available subjects and over all occurrences of a token. This yields an n-dimensional vector, where n is the number of electrodes, ranging from 32 to 130, depending on the EEG device used to record the data.

EEG data can be aggregated over all subjects within one dataset, because the number and locations of electrodes are identical. However, due to the differences in the number of electrodes between datasets, we cannot aggregate over all EEG datasets.

fMRI Functional magnetic resonance imaging is a technique for measuring and mapping brain activity by detecting changes associated with blood flow. fMRI has a temporal resolution of two seconds, which means that with continuous stimuli such as natural reading or story listening, one scan covers multiple words. We use datasets of

Table 2: Cognitive data sources used in this work. Coverage is the percentage of vocabulary in data source occurs in British National Corpus list of most frequent English words[2].

isolated stimuli (e.g the NOUNS dataset) as well as continuous stimuli (e.g. HARRY POTTER). While it is easier to extract word-level signals from isolated stimuli, continuous stimuli allow extracting signals in context over a wider vocabulary.

Where multiple trials were available, the brain activation for each word is calculated by taking the mean over the scans. Moreover, if the stimulus is continuous (HARRY POTTER and ALICE datasets), the data is aligned with an offset of four seconds to account for hemodynamic delay[3].

fMRI data contains representations of neural activity of millimeter-sized cubes called voxels. Standard fMRI preprocessing methods such as motion correction, slice timing correction and co-registration had already been applied before. To select the voxels to be predicted we use the pipeline provided by Beinborn et al. (2019). This pipeline consists of extracting corresponding scan(s) for each word, and randomly selecting 100, 500 and 1000 voxels (for the HARRY POTTER, PEREIRA and NOUNS datasets). The published version of the ALICE dataset provided the preprocessed signal averaged for six regions of interest, hence for this particular dataset we predict the activation for these regions only. Appendix A.3 contains the details of the preprocessing steps. Finally, the fMRI data is converted to n-dimensional vectors, where n is the number of randomly selected voxels (100, 500 or 1000) or regions (6).

5 Embedding evaluation method

In order to evaluate the word embeddings against human lexical representations, we fit the embeddings to a wide range cognitive features, i.e. eye-tracking features and activation levels of EEG and fMRI. This section describes how these models were trained and evaluated. After evaluating each combination separately, we test for statistical significance taking into account the multiple comparisons problem. See Figure 1 for an overview of the evaluation process.

5.1 Models

We fit neural regression models to map word embeddings to cognitive data sources. Predicting multiple features from different sources and modalities allows us to evaluate different aspects of capturing the semantics of a word. Hence, separate models are trained for all combinations. For instance, fitting FastText embeddings to EEG vectors from ZUCO, or fitting ELMo embeddings to

[2] https://www.kilgarriff.co.uk/bnc-readme.html

[3] The fMRI signal measures a brain response to a stimulus with a delay of a few seconds, and it decays slowly over a duration of several seconds (Miezin et al., 2000). For continuous stimuli, this means that the response to previous stimuli will have an influence on the current signal. Thus, context of the previous words is taken into account

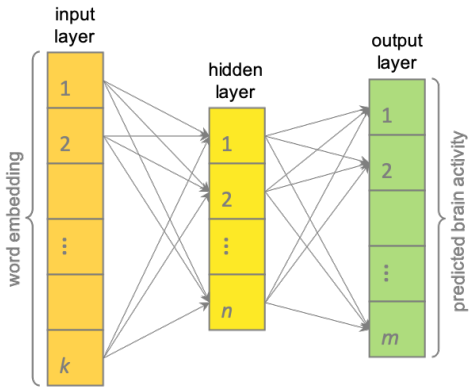

Figure 2: Neural architecture of regression models.

first fixation durations of the DUNDEE corpus.

For the regression models, we train neural networks with k input dimensions, one dense hidden layer of n nodes using ReLU activation and an output layer of m nodes using linear activation. The model is a multiple regression with layers of dimension k-n-m, where k is the number of dimensions of the word embeddings and m changes depending on the cognitive data source to be predicted. For predicting single eye-tracking features m equals 1, whereas for predicting EEG of fMRI vectors m is the dimension of the cognitive data vector, or more specifically, the number of electrodes in the EEG data or the number of voxels in the fMRI data. Figure 2 shows this neural architecture. The loss function optimizes the mean squared error (MSE) and uses an Adam optimizer with a learning rate of 0.001.

5-fold cross validation is performed for each model (80% training data and 20% test data). The optimal number of nodes n in the hidden layer is selected individually for each combination of cognitive data source and embedding type. To this end, a grid search is performed before training, which is evaluated on a validation set consisting of 20% of the training data with 3-fold cross validation (see Table 1 for details on the search space). The best model is then saved and used to predict the cognitive feature for each word in the test set. Finally, the results are measured with the mean squared error, averaged over all predicted words.

CogniVal allows for evaluation against another word embedding type as well as evaluation against a random baseline. To generate a fair baseline we create random vectors for each word of n dimensions, corresponding to the same number of dimensions of the embeddings to be evaluated.

5.2 Multiple hypotheses testing

With the purpose of achieving consistency and going towards a global quality metric that can be combined with other evaluation methods, we perform statistical significance testing on each hypothesis. A hypothesis consists of comparing the combination of an embedding type and a cognitive data source to the random baseline.

Since the distribution of our test data is unknown and the datasets are small, we perform a Wilcoxon signed-rank test for each hypothesis (Dror et al., 2018). Additionally, to counteract the multiple hypotheses problem, we apply the conservative Bonferroni correction, where the global null hypothesis is rejected if $p < \alpha/N$, where N is the number of hypotheses (Dror et al., 2017). In our setting, $\alpha = 0.01$ and $N = 4$ for EEG (one hypothesis per EEG data source), $N = 59$ for for fMRI (one hypothesis per participant of each fMRI data source), and $N = 42$ for eye-tracking (one hypothesis per feature per eye-tracking corpus).

This approach of significance testing can easily be used in combination with other intrinsic and extrinsic evaluation methods. The significance ratios

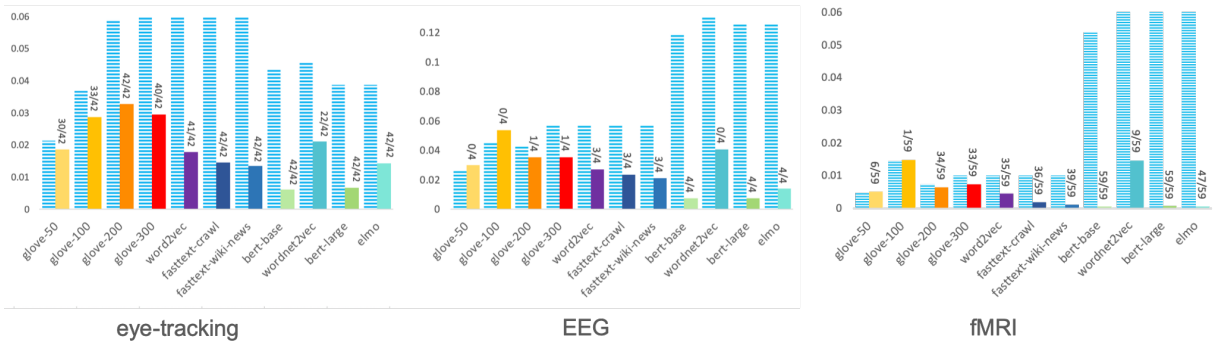

Figure 3: Results for each modality: Aggregated results for all embeddings predicting cognitive features for all datasets of a modality (sorted by dimension of embeddings in increasing order from left to right). The striped blued bars represent random baseline. The labels on the embedding bars show the ration of significant results under the Bonferroni correction to the total number of hypotheses.

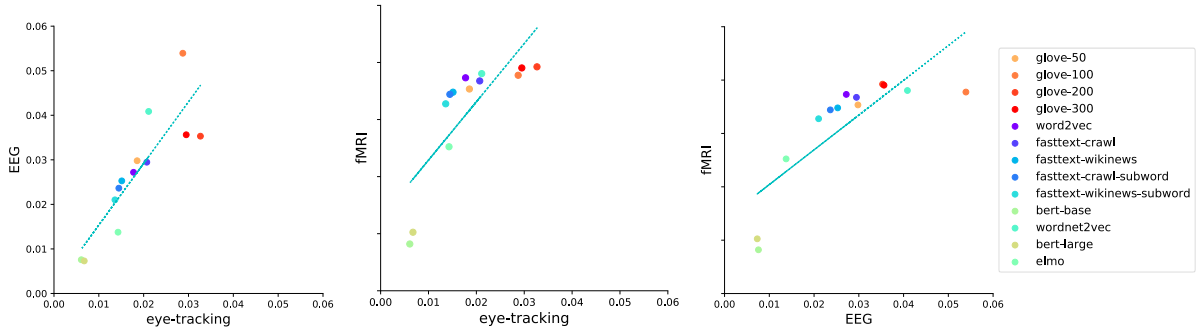

Figure 4: Correlation plots between all three modalities of cognitive signals.

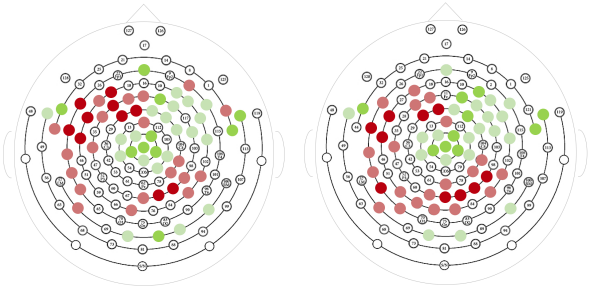
are shown in Figure 3.

6 Results & Discussion



Prediction results First, we show in Figure 3 how well each word embedding type is able to predict eye-tracking features, EEG and fMRI vectors. As can be seen the majority of results are significantly better than the random baselines. BERT, ELMo and FastText embeddings achieve the best prediction results. All exact numbers can be found in Appendix B. While a random baseline can be considered a rather naive choice, this setting also allows us compare the performance between word embedding types.

When predicting single eye-tracking features, the performance varies greatly. For instance, Table 4 shows that the prediction error on number of fixations and total reading time from the ZuCo dataset is much lower than for first fixation duration. This suggest that more general eye-tracking features covering the complete reading process of a word are easier to predict.

In the case of predicting voxel vectors of fMRI data, the results improve when choosing a larger number of voxels (see Table 3). Hence, in the remainder of this work we present only the results for 1000 voxels.

We also examined the EEG results in more depth by analyzing which electrodes are predicted more accurately and which electrodes values are very difficult to predict. This is exemplified by Figure 5, which shows the 20 best and worst predicted electrodes of the ZuCo data for the BERT embeddings of 1024 dimensions as well as aggregated over all cognitive data sources. The middle central electrodes are predicted more accurately. The middle central electrodes are known to register the activity of the Perisylvian cortex, which is relevant for language related processing (Catani et al., 2005). Moreover it can be speculated that there is a frontal asymmetry between the electrodes on the left and right hemispheres.

Cognitive data implications The diversity of cognitive data sources chosen for this work allows us to analyze and compare results on several levels and between several cognitive metrics. In order to conduct this evaluation on a collection of 15

(a) (b)

Figure 5: EEG electrode analysis, (a) for BERT (large) and (b) aggregated over all embedding types. Red = worst predicted electrodes, green = best predicted electrodes.

datasets from three modalities, many crucial decisions were taken about preprocessing, feature extraction and evaluation type. Since there are different methods on how to process different types of cognitive language understanding signal, it is important to make these decisions transparent and reproducible.

Moreover, it is a challenge to segment brain activity data correctly and meaningfully into word-level signal from naturalistic, continuous language stimulus (Hamilton and Huth, 2018). This makes consistent preprocessing across data sources even more important.

Another challenge is to consolidate the cognitive features to be predicted. For instance, we chose a wide selection of eye-tracking features that cover early and late word processing. However, choosing only general eye-tracking features such as total reading time would also be a viable strategy. On the other hand, the EEG evaluation could be more coarse-grained, one could also try to predict known ERP effects (e.g. Ettinger et al. (2016)) or features selected based on frequency bands. Moreover, the voxel selection in the fMRI preprocessing could be improved by either predicting all voxels or applying information-driven voxel selection methods (Beinborn et al., 2019).

Correlations between modalities Next, we analyze the correlation between the predictions of the three modalities (Figure 4). There is a strong correlation between the results of predicting eye-tracking, EEG and fMRI features. This implies that word embeddings are actually predicting brain activity signals and not merely preprocessing artifacts of each modality. Moreover, the

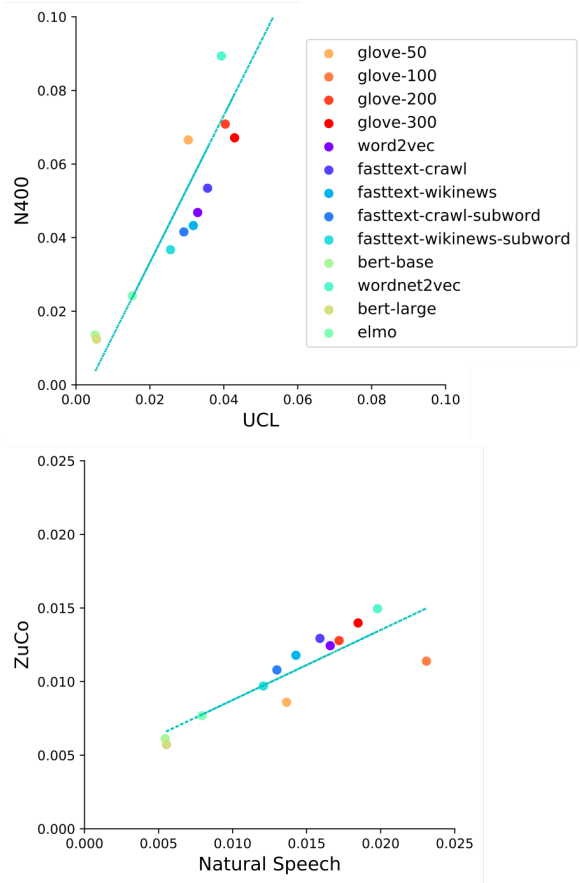


Figure 6: Correlation between results on EEG datasets.

same correlation is also evident between individual datasets within the same modality. As an example, Figure 6 (bottom) shows the correlation of the results predicted for the Natural Speech and ZuCo EEG datasets, where the first had speech stimuli and the latter text. Figure 6 (top) reveals the same positive correlation for two EEG datasets that were preprocessed differently and were recorded with a different number of electrodes. Moreover, the UCL dataset contains word-by-word reading and the N400 contains natural reading of full sentences.

Correlation with extrinsic evaluation results We performed a simple comparison between the results of word embeddings predicting cognitive language processing signals and the performance of the same embedding types in downstream tasks. We collected results for two NLP tasks: on the SQuAD 1.1 dataset for question answering (Rajpurkar et al., 2016) and on the CoNLL-2003 test split for named entity recognition (Tjong Kim Sang and De Meulder, 2003).

The SQuAD results are taken from Devlin et al.

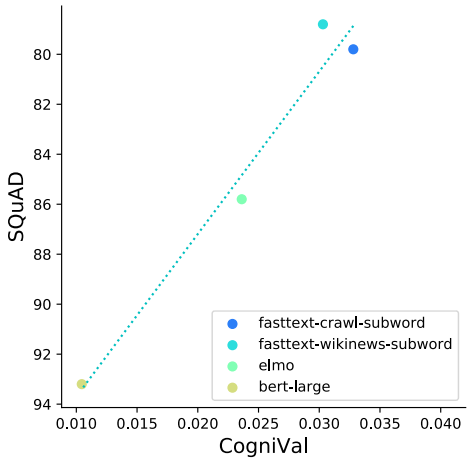

Figure 7: Correlation between the SQuAD 1.1 task and the CogniVal results.

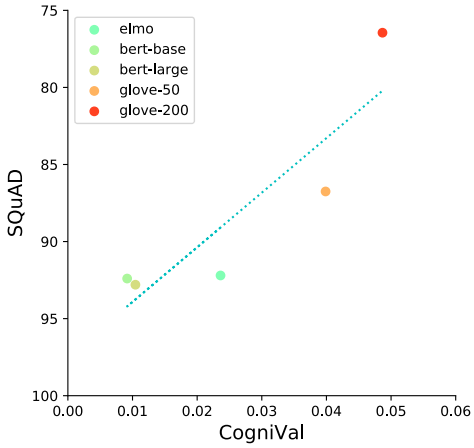

Figure 8: Correlation between NER on CoNLL-2003 and the CogniVal results.

(2019) for BERT, from Mikolov et al. (2018) for FastText, and from Peters et al. (2018) for ELMo. The NER results are from the same source for ELMo and BERT, for Glove-50 from Pennington et al. (2014) and for Glove-200 from Ghannay et al. (2016). We correlated these results to the prediction results over all cognitive data sources. Figures 7 and 8 show the correlation plots between the CogniVal results and the two downstream tasks.

While this is merely an exploratory analysis, it shows interesting findings: If the cognitive embedding evaluation correlates with the performance of the embeddings in extrinsic evaluation tasks, it might be used not only for evaluation but also as a predictive framework for word embedding model selection. This is especially noteworthy, since it does not seem to be the case for other intrinsic methods (Chiu et al., 2016).

7 Conclusion

We presented CogniVal, the first multi-modal large-scale cognitive word embedding evaluation framework. The vectorized word representations are evaluated by using them to predict eye-tracking or brain activity data recorded while participants were understanding natural language. We find that the results of eye-tracking, EEG and fMRI data are strongly correlated not only across these modalities but even between datasets within the same modality. Intriguingly, we also find a correlation between our cognitive evaluation and two extrinsic NLP tasks, which opens the question whether CogniVal can also be used for predicting downstream performance and hence, choosing the best embeddings for specific tasks.

We plan to expand the collection of cognitive data sources as more of them become available, including data from other languages such as the Narrative Brain Dataset (Dutch, fMRI, Lopopolo et al. (2018)) or the Russian Sentence Corpus (eye-tracking, Laurinavichyute et al. (2017)). Thanks to naturalistic recording of longer text spans, CogniVal can also be extended to evaluate sentence embeddings or even paragraph embeddings.

CogniVal can become even more effective by combining the results with other intrinsic or extrinsic embedding evaluation frameworks (Nayak et al., 2016; Rogers et al., 2018) and building on the multiple hypotheses testing.

8 Acknowledgements

We thank Lisa Beinborn, Stefan Frank and Thomas Lemmin for their valuable input on preprocessing EEG and fMRI data.

Abstract

Story understanding requires developing expectations of what events come next in text. Prior knowledge – both statistical and declarative – is essential in guiding such expectations. While existing semantic language models (SemLM) capture event co-occurrence information by modeling event sequences as semantic frames, entities, and other semantic units, this paper aims at augmenting them with causal knowledge (i.e., one event is likely to lead to another). Such knowledge is modeled at the frame and entity level, and can be obtained either statistically from text or stated declaratively. The proposed method, KnowSemLM[1], infuses this knowledge into a semantic LM by joint training and inference, and is shown to be effective on both the event cloze test and story/referent prediction tasks.

1 Introduction

Natural language understanding requires a coherent understanding of a series of events or actions in a story. In story comprehension, we need to understand not only what events have appeared in text, but also what is likely to happen *next*. While event extraction has been well studied (Ji and Grishman, 2008; Huang and Riloff, 2012; Li et al., 2013; Peng et al., 2016; Nguyen et al., 2016; Nguyen and Grishman, 2016), the task of predicting future events (Radinsky et al., 2012; Radinsky and Horvitz, 2013) has received less attention.

One perspective is to utilize the co-occurrence information between past and future events learned from a large corpus, which has been studied in *script learning* works (Chambers and Jurafsky, 2008; Pichotta and Mooney, 2014, 2016a; Peng and Roth, 2016; Peng et al., 2017). However, only considering co-occurrence information is not sufficient for modeling event sequences in natural language. Human decisions on the likelihood of a specific event depend on both *local context* – what has happened earlier in text – and *global context* – knowledge gained from human experience. This paper leverages both the *local* and *global* context information to model event sequences, and shows that it can lead to more accurate predictions of future events. For example, the following text snippet describes a scenario of someone taking a flight:

... I checked in at the counter, took my luggage to the security area, got cleared ten minutes in advance, and waited for my plane ...

This example consists of a series of events, i.e., "check in (a flight)", "be cleared (at the security)", "wait for (the plane)", etc., which humans who have traveled by plane are very familiar with. However, this event sequence appears infrequently in text.[2] Consequently, only relying on event co-occurrence in text is not sufficient – there is also a need to model some "common sense" information.

The local and global contexts in this example are illustrated in Figure 1. The existing event sequence is "(sub)check_in[flight]", "(sub)clear[security]" and "(sub)wait_for[plane]" (denoted by blue dots), where "sub" means subject. Language models (LM) for statistical co-occurrences of events can capture this local context and generate a distribution over all possible events, e.g., "(sub)purchase[food]" and "(sub)go_to[work]", as in the blue circle.

More importantly, global context is the knowledge of event causality learned from human experience in the form of "cause-effect" event pairs (i.e., one event leads to another). One such pair is represented as "(sub)wait_for[plane] ⇒

[1]Related resources refer to https://cogcomp.seas.upenn.edu/page/publication_view/886.

[2]The events "check in" and "be cleared" only co-occur twice in a same document in the 20-year New York Times corpus (1987-2007); we count with frame and entity level abstractions (see Section 2.1 for details).

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 550–562
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

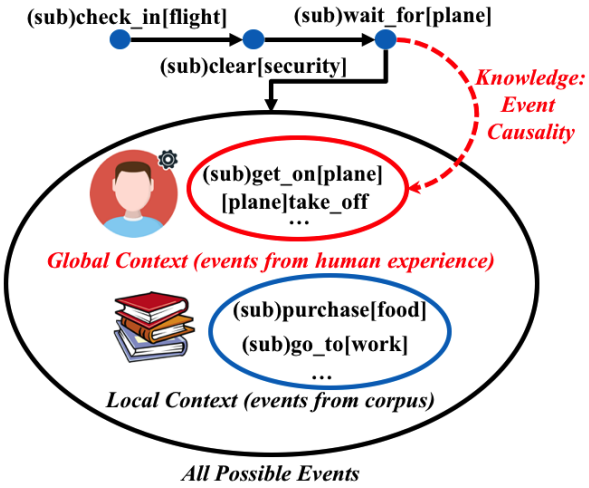

Figure 1: **Local and global context information when modeling event sequences.** The blue dots are events that are already described in text. The blue circle indicates local context, i.e., event sequences inferred from a large corpus via semantic LMs; the red circle represents global context, i.e., events learned from human experience via knowledge of event causality (which may overlap with local context). For event representations, we abstract over the surface forms of semantic frames and entities, where "sub" represents the shared common subject. The proposed KnowSemLM leverages both information to better predict future events.

(sub)get_on[plane]", which means that one has to wait for a plane before getting on it (red dashed arrow in Figure 1). Global context, as a result, helps generate a distribution over a focused set of expected events, as in the red circle. Note that the causality links have directions, and one event might lead to multiple possible events, e.g., one has to wait for the plane before it takes off "(sub)wait_for[plane] ⇒ [plane]take_off". Such connections can be viewed as temporal relations. Here, we consider causality to include temporal orderings of events which align with common sense. More discussions are provided in Sec. 6.

Thus, we propose KnowSemLM, a knowledge infused semantic language model. It combines knowledge from external sources (in the form of event causality) with the basic semantic LM (Peng et al., 2017) trained on a given text corpus. Our model is a generative model of events, where each event is either generated based on a piece of knowledge or generated from the semantic LM. When predicting future events at inference time, we generate two distributions over events: one from the given knowledge, and the other from the semantic LM. We also learn a binary variable that selects the distribution from which we take the next event. In this way, the proposed KnowSemLM has the ability to generate event sequences based on both local and global context, and better imitate the story generation process.

This knowledge infused semantic LM operates on abstractions over the surface form – semantic frames and entities. We associate each semantic unit (frames and entities) with an embedding and construct a joint embedding space for each event. We train KnowSemLM on a large corpus and use the same embedding setting for events involved in the knowledge. The event causality knowledge is mined either statistically from the training corpus or declaratively for constrained domains (both in the form of event pairs). In the statistical way, we utilize a set of discourse connectives to identify "cause-effect" event pairs and filter them based on their counts; if provided with event templates for specific domains, we also manually write down such pairs based on human experience. In both ways, we further enrich the knowledge base by considering transitivity among event pairs.

We evaluate KnowSemLM on two tasks – event cloze test and story/referent predictions. In both cases, we model text as a sequence of events and apply trained KnowSemLM to calculate conditional probabilities of future events given text and knowledge. We show that KnowSemLM can outperform competitive results from models with no such knowledge. In addition, we demonstrate the language modeling ability of KnowSemLM through quantitative and qualitative analysis.

The main contributions can be summarized as follows: 1) formulation of knowledge used in story generation as event causality; 2) proposal of KnowSemLM to integrate such event causality knowledge into semantic language models; 3) demonstration of the effectiveness of KnowSemLM via multiple benchmark tests.

The rest of the paper is organized as follows. We define how we model events and event causality knowledge in Sec. 2, followed by the description of the knowledge infused KnowSemLM (Sec. 3). The training procedure of KnowSemLM is detailed in Sec. 4, followed by our experimental results and analysis (Sec. 5) and related work (Sec. 6). We conclude in Sec. 7.

2 Event and Knowledge Modeling

To better understand the proposed KnowSemLM, here we first introduce the event representation and

event causality model used in this paper.

2.1 Event Representation

To preserve the full semantic meaning of events, we need to consider multiple semantic aspects: semantic frames, entities, and sentiments. We adopt the event representation proposed in Peng et al. (2017), which is built upon abstractions of three basic semantic units: (disambiguated) semantic frames, subjects & objects in such semantic frames, and sentiments of the frame text.

In a nutshell, the event representation is a combination of the above three semantic elements.

... Steven Avery committed murder. He was arrested, charged and tried ...

For example, the event representations of the above text would be (four separate events):

PER[new]-commit.01-ARG[new](NEG)
ARG[new]-arrest.01-PER[old](NEU)
ARG[new]-charge.05-PER[old](NEU)
ARG[new]-try.01-PER[old](NEG)

Here, "commit.01", "arrest.01" and so on represent disambiguated predicates ("01" and "05" refer to the disambiguated senses in VerbNet). The arguments (subject and object) of a predicate are denoted with NER types ("PER, LOC, ORG, MISC") or "ARG" if unknown, along with a "[new/old]" label indicating if it is the first appearance in the sequence. Additionally, the sentiment of a frame is represented as positive (POS), neural (NEU), or negative (NEG).

We formally define such an explicit and abstracted event as e. Computationally, the vector representation of an event e^{vec} is built in a joint semantic space:

$$e^{\text{vec}} = W_f r_f + W_e r_e + W_s r_s.$$

During language model training, we learn frame embeddings W_f (r_f, r_e, r_s are one-hot vectors for each unique frame, entity and sentiment abstraction, respectively) as well as the transforming matrices W_e and W_s.

2.2 Knowledge: Causality between Events

We model the knowledge gained from human experience as pre-determined relationship between events. Since we are modeling event sequences, the knowledge of one event leads to another is very important, hence event causality. We formally define a piece of event knowledge as

$$e_x \Rightarrow e_y,$$

meaning that the *outcome* event e_y is a possible result of the *causal* event e_x. Note that event causality here is directional, and one event may lead to multiple different outcomes. We group all event knowledge pairs with the same causal event, thus event e_x can lead to a set of events:

$$e_x \Rightarrow \{e_{y_1}, e_{y_2}, e_{y_3}, \cdots, e_{y_m}\}.$$

We store all such event causality structures in a knowledge base KB_{EC}.

3 Knowledge Infused SemLM

With a proper modeling of events and event causality above, this section explains the proposed `KnowSemLM`, a method to inject causality knowledge into a semantic LM. Specifically, `KnowSemLM` is based on FES-RNNLM (*Frame-Entity-Sentiment infused Recurrent Neural Net Language Model*) proposed in Peng et al. (2017). We briefly review FES-RNNLM and describe how `KnowSemLM` adds knowledge on top of it.

3.1 FES-RNNLM

To model semantic sequences and train the joint event representations in Sec. 2.1, we build neural language models over such sequences. Peng et al. (2017) uses Log-Bilinear Language model (Mnih and Hinton, 2007), but since we require the use of event causality knowledge to be based on past events, we choose to implement an RNN language model (RNNLM) where the generation of future events is only dependent on past events.

For ease of explanation, we denote a semantic sequence of joint event representations as $[e_1, e_2, \cdots, e_t]$, with e_t being the t_{th} event in the sequence. Thus, we model the conditional probability of an event e_t given its context as

$$\begin{aligned} & p_{\text{lm}}(e_t | e_1, \cdots, e_{t-1}) \\ &= \text{softmax}(W_s h_t + b_s) \\ &= \frac{\exp(e_t^{\text{vec}}(W_s h_t + b_s))}{\sum_{e \in \mathcal{V}} \exp(e^{\text{vec}}(W_s h_t + b_s))}. \end{aligned}$$

Note that the softmax operation is carried out over the event vocabulary $\mathcal{V}$, i.e., all possible events in the language model. Moreover, the hidden layer h_t in RNN is computed as: $h_t = \phi(e_t^{\text{vec}} W_i + h_{t-1} W_h + b_h)$, where ϕ is the activation function. For language model training, we learn parameters W_s, b_s, W_i, W_h, and b_h, and maximize the sequence probability $\prod_{t=1}^{k} p_{\text{lm}}(e_t | e_1, e_2, \cdots, e_{t-1})$.

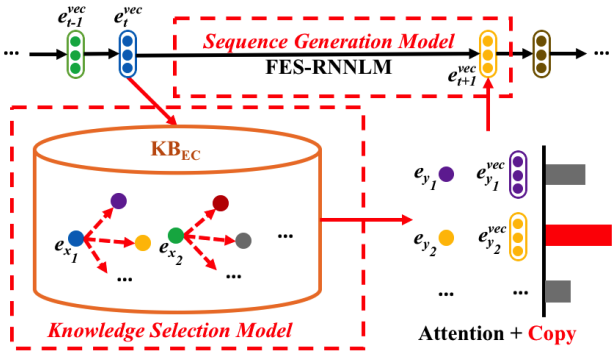

Figure 2: **Overview of the computational workflow for the proposed KnowSemLM.** There are two key components: 1) a knowledge selection model, which activates the use of knowledge based on probabilistically matching causal event and produce a distribution over outcome events via attention; 2) a sequence generation model, which takes input from both the knowledge selection model and the base semantic language model (FES-RNNLM) to generate future events via a copying mechanism. Note that the single dots indicate explicit event representations while three consecutive dots stand for event vectors.

3.2 KnowSemLM

In Figure 2, we show the computational workflow of the proposed KnowSemLM. There are two key components: 1) a knowledge selection model, which activates the use of knowledge based on probabilistically matching causal events and produces a distribution over outcome events; 2) a sequence generation model, which takes input from both the knowledge selection model and the base semantic language model (FES-RNNLM) to generate future events via a copying mechanism.[3]

Knowledge Selection Model

For an event in the sequence e_t, we first match it with possible causal events $\{e_x\}$ in the knowledge base KB_{EC} based on the bi-focal attention of previous events. Thus, from the knowledge base, we get a list of outcome events $\mathcal{V}_y \triangleq \{e_{y_1}, e_{y_2}, \cdots\}$.

Computationally, we model the conditional probability of matching with causal event e_x and outcome event e_y from knowledge base given the context of $e_1, e_2, \cdots, e_t$ as

$$p_{\text{kn}}(e_x \Rightarrow e_y | e_1, e_2, \cdots, e_t) = \frac{\exp(e_x^{\text{vec}} W_a h_t) \exp(e_y^{\text{vec}} W_b h_t)}{\sum_{e \in \mathcal{V}_x, e' \in \mathcal{V}_y} \exp(e^{\text{vec}} W_a h_t) \exp(e'^{\text{vec}} W_b h_t)}.$$

[3]The proposed computational framework of KnowSemLM is similar to DynoNet proposed in He et al. (2017). Compared to DynoNet, the knowledge base utilized here operates on event level representations rather than on tokens.

Here, we use the bi-focal attention mechanism (Nema et al., 2018) via attention parameters W_a, W_b, and apply it on the hidden layer h_t, which embeds information from all previous events in the sequence. Therefore, we produce a distribution over the set of possible outcome events $\mathcal{V}_y$.

Sequence Generation Model

The base semantic LM produces a distribution over events from the language model vocabulary, which represents *local* context, while the knowledge selection model generates a set of outcome events with a probability distribution, which represents *global* context of event causality knowledge. The sequence generation model then combines the local and global context for generating future events. Therefore, we model the conditional probability of event e_{t+1} given context $p(e_{t+1}|\text{Context}) = p(e_{t+1}|e_1, e_2, \cdots, e_t, \text{KB}_{\text{EC}})$. This overall distribution is computed via a copying mechanism (Jia and Liang, 2016), i.e., we either generate the next event (e_i) from the language model vocabulary ($\mathcal{V}$) or copy from the outcome event set (e_y) based on the following probabilities:

$$\begin{cases} p(e_{t+1} = e_i \in \mathcal{V} | \text{Context}) & = (1-\lambda) p_{\text{lm}}(e_i) \\ p(e_{t+1} = e_y \in \mathcal{V}_y | \text{Context}) & = \lambda p_{\text{kn}}(e_y). \end{cases}$$

Here, λ is a learned scaling parameter to choose between events from LM vocabulary $\mathcal{V}$ and events from event causality knowledge base KB_{EC}.

4 Construction of KnowSemLM

4.1 Dataset and Preprocessing

Dataset: We use the New York Times (NYT) Corpus[4] (from year 1987 to 2007) as the training corpus. It contains over 1.8M documents in total.

Preprocessing: We preprocess all training documents with Semantic Role Labeling and Part-of-Speech tagging. We also implement the explicit discourse connective identification module of a shallow discourse parser (Song et al., 2015). Additionally, we utilize within-document entity co-reference (Peng et al., 2015a) to produce co-reference chains and get the anaphoricity information. To obtain all annotations, we use the Illinois NLP tools (Khashabi et al., 2018).[5] Further, we obtain event representations from text with frame, entity and sentiment level abstractions by following procedures described in Peng et al. (2017).

[4]https://catalog.ldc.upenn.edu/LDC2008T19

[5]http://cogcomp.org/page/software/

4.2 Knowledge Mining

Statistical Way: Part of the human knowledge can be mined from text itself. Since discourse connectives are important for relating different text spans, we carefully select discourse connectives which can indicate a "cause-effect" situation. For example, "The police arrested Jack *because* he killed someone." In this sentence, readers can gain the knowledge of "the person who kills shall be arrested", which can be represented as "PER[*]-kill.01-*[*](*) ⇒ *[*]-arrest.01-PER[old](*)" according to the abstractions specified in Sec. 2.

In practice, we choose 22 "cause-effect" connectives/phrases (such as "because", "due to", "in order to"). We then extract all event pairs connected by such connectives from the NYT training data, and abstract over their surface forms to get the event level representations. Finally, we filter cases where the direction of the event causality pairs is unclear from a statistical standpoint. Specifically, we calculate the ratio of counts of one direction over another, i.e. $\theta = \frac{\#(e_x \Rightarrow e_y)}{\#(e_y \Rightarrow e_x)}$. If $\theta > 2$, then we store $e_x \Rightarrow e_y$ as knowledge; while $\theta < 0.5$, we only keep $e_y \Rightarrow e_x$. In the case of $0.5 < \theta < 2$, we filter both event causality pairs since we are unsure of the knowledge statistically.

After the above filtering procedures, we automatically get 8,293 different pairs of event pairs (without human efforts). According to Sec. 2, we merge them if they have the same causal event, i.e. $e_x \Rightarrow e_y$ and $e_x \Rightarrow e_z$ becomes $e_x \Rightarrow \{e_y, e_x\}$. Thus, we get a total of 2,037 causal events (trees); and on average, each causal event has 4 possible outcome events. Furthermore, those event pairs of knowledge defined in this work are transitive, e.g., if $e_1 \Rightarrow e_2$ and $e_2 \Rightarrow e_3$, then we can have $e_1 \Rightarrow e_3$. Considering this *transitivity*, we iterate over all pairs twice, and derive more event causality pairs, achieving a total number of 9,022.[6]

Declarative Way: Besides mining knowledge automatically from text corpus, we also take full advantage of human input in some practical situations. For the InScript Corpus (Modi et al., 2017), it specifies 10 everyday scenarios, e.g., "Bath", "Flight", "Haircut". In each scenario, the corpus also provides event templates and the corresponding event template annotations for the text. Examples of such generated event causality knowledge can be referred back to Sec. 1, e.g., "(sub)wait_for[plane] ⇒ (sub)get_on[plane]". In total, we manually generate 875 event causality pairs and group them with 121 causal events. Here, since during the manual generation process, we try to cover all event causality knowledge that makes sense; we do not further apply the transitive property and expand.

[6]We do not further carry out the transitivity expansion process, since empirically the noise it introduces outweighs the benefits it brings (see Sec. 5.4 for details).

Method	Accuracy
Granroth-Wilding and Clark (2016)	49.57%
Wang et al. (2017)	55.12%
KnowSemLM w/o knowledge	39.23%
KnowSemLM w/o transit. & fine-tuning	43.56%
KnowSemLM w/o fine-tuning	45.28%
KnowSemLM	**56.27%**

Table 1: **Accuracy results for the event cloze task.** KnowSemLM outperforms previously reported results and we show the ablation study results for model without the use of knowledge (w/o knowledge), without the use of knowledge transitivity as described in Sec 4.2 (w/o transit.) and without fine-tuning on the dev data (w/o fine-tuning), resepctively.

4.3 Model Training

Based on the formulation in Sec. 3, we apply the overall sequence probability as the objective: $\prod_{t=1}^{k} p(e_t|e_1, e_2, \cdots, e_{t-1}, \text{KB}_{\text{EC}})$. where k is the sequence length. For the sequence generation model, we implement the Long Short-Term Memory (LSTM) network with a layer of 64 hidden units while the dimension of the input event vector representation is 200. Because we carry out the same event-level abstractions as in Peng et al. (2017), the event vocabulary is the same, with the size of ∼4M different events.[7]

5 Experiments

We show that KnowSemLM can achieve better performance for the event cloze test and story/referent prediction tasks compared to models without the use of knowledge. We also evaluate the language modeling ability of KnowSemLM through quantitative and qualitative analysis.

5.1 Application for Event Cloze Test

Task Description and Setting: We utilize the MCNC task and dataset proposed in Granroth-Wilding and Clark (2016) as the benchmark evaluation. For each test instance, the goal is to recover the event (defined as predicate with associated entities) from an event chain given multiple choices.

[7]Please see Table 2 in Peng et al. (2017) for details.

Since the event definition in this task is compatible with our representation defined in Sec 2.1[8], we can directly convert event chains into our semantic event sequences. In this application task, we train KnowSemLM on the NYT portion of the Gigaword[9] corpus, and also fine-tune on the development set specified in this task[10].

Application of KnowSemLM: For each test case (i.e., an event chain inside a document), we first construct the event level representation as described in Sec. 2 for each event in the chain. We then apply KnowSemLM to obtain the overall sequence probability by replacing the missing event with each candidate choice. The final decision is made by choosing the event with the highest probability. Note that the event causality knowledge here for both training and testing is generated automatically from NYT corpus specified in Sec. 4.2 (the Statistical Way). To efficiently calculate the sequence probability, we limit the context window size surrounding the missing event to be 10.

Results: The accuracy results are shown in Table 1. We compare KnowSemLM with previous reported results on this event cloze test (Granroth-Wilding and Clark, 2016; Wang et al., 2017). KnowSemLM outperforms both baselines and we further carry out the ablation study to measure the impact of knowledge, transitivity of knowledge, and fine-tuning. We can see that it is important for the semantic LM to consider knowledge and also learn the process of applying such knowledge in event sequences, i.e., the fine-tuning step.

5.2 Application for Story Prediction

Task Description and Setting: We use the benchmark ROCStories dataset (Mostafazadeh et al., 2017), and follow the test setting in Peng et al. (2017). For each instance, we are given a four-sentence story and the system needs to predict the correct fifth sentence from two choices; with the incorrect ending being semantically unreasonable, or un-related. Instead of treating the task as a supervised binary classification problem with a development set to tune, we evaluate KnowSemLM in an unsupervised fashion where we directly evaluate on the test set. In such a way, we can directly compare with the FES-LM model proposed in Peng et al. (2017), which is base model of KnowSemLM without the use of knowledge. Similar to the training of FES-LM, we fine tune KnowSemLM on the in-domain short story training data, with the model trained on NYT corpus as initialization.[11]

Baselines	Accuracy	
Seq2Seq	58.0%	
Mostafazadeh et al. (2016)	58.5%	
Seq2Seq with attention	59.1%	
Model w/o Knowledge	S.	M.V.
FES-LM (Peng et al., 2017)	62.3%	61.6%
Knowledge Model	S.	M.V.
KnowSemLM	**66.5%**	63.1%

Table 2: **Accuracy results for story cloze test in the unsupervised setting.** "S." represents the inference method with the single most informative feature while "M.V." means majority voting.

Application of KnowSemLM: For each test story, we generate a set of conditional probability features from KnowSemLM. We first construct the event level representation as described in Sec. 2. We then utilize the conditional probability of the fifth sentence given previous context sentences and the knowledge base KB_{EC} as features. Here KB_{EC} is generated automatically from NYT corpus specified in Sec. 4.2 without human efforts. We get multiple features depending on how long we go back in the context in terms of events. In practice, we get at most 12 events as context since one sentence can contain multiple events. Thus, for each story, we generate at most 12 pairs of conditional probability features from two given choices. Every pair of such features can yield a decision on which ending is more probable. Here, we test two different inference methods: a single most informative feature (where we go with the decision made by the pair of features which have the highest ratio) or majority voting based on the decision made jointly by all feature pairs.

Results: The accuracy results are shown in Table 2. We compare KnowSemLM with Seq2Seq baselines (Sutskever et al., 2014) and Seq2Seq with attention mechanism (Bahdanau et al., 2014). We also include the DSSM system

[8] Our event representation is abstracted on a higher level. Thus, we process the original NYT documents, where event chains come from, for abstraction purposes; and then match it to the event chains in the test data.

[9] https://catalog.ldc.upenn.edu/LDC2011T07

[10] https://mark.granroth-wilding.co.uk/papers/what_happens_next/

[11] We iterate over the NYT corpus until it converges on the perplexity metric for the development set, and then the model is further trained on ROC-Stories training set for 5 epochs.

Method	Accuracy
Base (Modi et al., 2017)	62.65%
EntityNLM (Ji et al., 2017)	74.23%
Base*	60.58%
Base* w/ FES-RNNLM	63.79%
Base* w/ KnowSemLM	**76.15%**

Table 3: **Accuracy results for the referent prediction task on InScript Corpus.** We re-implement the base model (Modi et al., 2017) as "Base*", and apply KnowSemLM to add additional features. "Base* w/ FES-RNNLM" is the ablation study where no event causality knowledge is used. Even though "Base*" model performs not as good as the original base model, we achieve the best performance with added KnowSemLM features.

Perplexity	
FES-RNNLM	121.8
KnowSemLM w/o transitivity	120.7
KnowSemLM	120.4
Narrative Cloze Test (Recall@30)	
FES-RNNLM	47.9
KnowSemLM w/o transitivity	49.3
KnowSemLM	49.6

Table 4: **Results for perplexity and narrative cloze test.** Both studies are conducted on the NYT hold-out data. "FES-RNNLM" represents the semantic LM without the use of knowledge. The numbers show that KnowSemLM has lower perplexity and higher recall on narrative cloze test, which demonstrates the contribution of the infused knowledge.

	Match/Event	Activation/Event	λ
NYT	0.13	0.03	0.36
InScript	0.82	0.28	0.46

Table 5: **Statistics for the use of event causality knowledge in KnowSemLM.** We gather the statistics for both NYT and InScript Corpus. "Match/Event" represents average number of times a causal event match is found in the event causality knowledge base per event; while "Activation/Event" stands for the average number of times we actually generate event predictions from the outcome events of the knowledge base. In addition, we believe the ratio of "Activation/Event" over "Match/Event" co-relates with the scaling parameter λ.

from Mostafazadeh et al. (2016) as the original reported result. KnowSemLM outperforms both baselines and the base model without the use of knowledge, i.e., FES-LM. The best performance achieved by KnowSemLM uses single most informative feature, with the feature being the conditional probability depending on only the nearest preceding event and event causality knowledge).

5.3 Application for Referent Prediction

Task Description and Setting: For referent prediction task, we follow the setting in Modi et al. (2017), where the system predicts the referent of an entity (or a new entity) given the preceding text. The task is evaluated on the InScript Corpus, which contains a group of documents where events are manually annotated according to predefined event templates. Each document contains one entity which needs to be resolved. The InScript Corpus can be divided into 10 situations and is split into standard training, development, and testing sets. We fine-tune KnowSemLM on the InScript Corpus training set, with the model trained on NYT corpus as initialization.

Application of KnowSemLM: For each test case (i.e., an entity inside a document), each candidate choice will be represented as a different event representation. Note that the event representation here comes from the event templates defined in the InScript Corpus. In the meantime, we can extract the event sequence from the preceding context. Thus, we can apply KnowSemLM to compute the conditional probability of the candidate event e_{t+1} given the event sequence and the event causality knowledge: $p_k(e_{t+1}|e_{t-k}, e_{t-k+1}, \cdots, e_t, \text{KB}_{\text{EC}})$. Here, knowledge in KB_{EC} is generated manually from event templates specified in Sec. 4.2. Moreover, index k decides how far back we consider the preceding event sequence. We then add this set of conditional probabilities as additional features in a base model (re-implementation of the linear model proposed in Modi et al. (2017), namely "Base*") to train a classifier to predict the right referent.

Results: The accuracy results are shown in Table 3. We compare with the original base model as well as the EntityNLM proposed in Ji et al. (2017) as baselines. Our re-implemented base model ("Re-base") does not perform as good as the original model. However, with the help of additional features from FES-RNNLM, we outperform the base model. More importantly, with additional features from KnowSemLM, we achieve the best performance and beat the EntityNLM system. This demonstrates the importance of the manually added event causality knowledge, and the ability of KnowSemLM to successfully capture it.

5.4 Analysis of KnowSemLM

First, to evaluate the language modeling ability of KnowSemLM, we report perplexity and narrative cloze test results. We employ the same experimental setting as detailed in Peng and Roth (2016) on the NYT hold-out data. Results are shown in Table 4. Here, "FES-RNNLM" serves as the semantic LM without the use of knowledge for the ablation study. The numbers shows that KnowSemLM has lower perplexity and higher recall on narrative cloze test; which demonstrates the contribution of the infused event causality knowledge. The results w.r.t. the transitivity evaluation shows that the expansion through knowledge transitivity improves the model quality.

We also gather the statistics to analyze the usage of event causality knowledge in KnowSemLM. We compute two key values: 1) average number of times a causal event match is found in the event causality knowledge base per event (so that we can potentially use the outcome events to predict), i.e. "Match/Event"; 2) average number of times we actually generate event predictions from the outcome events of the knowledge base (result of the final probability distribution), i.e. "Activation/Event". We get the statistics on both NYT and InScript Corpus, and associate the numbers with the scaling parameter λ in Table 5. The frequency of event matches and event activations from knowledge are both much lower in NYT than in InScript. Moreover, we can compute the chance of an outcome event being used as the prediction when it participates in the probability distribution. On NYT, it is $0.03/0.13 = 23\%$; while on InScript, it is $0.28/0.82 = 34\%$. We believe such chance co-relates with the scaling parameter λ.

For qualitative analysis, we provide a comparative example between KnowSemLM and FES-RNNLM in practice. The system is fed into the following input:

... Jane wanted to buy a new car. She had to borrow some money from her father. ...

So, on an event level, we abstract the text as "PER[new]-want.01-buy.01-ARG[new](NEU), PER[old]-have.04-borrow.01-ARG[new](NEU)". For FES-RNNLM, the system predicts the next event as "PER[old]-sell.01-ARG[new](NEU)" since in training data, there are many co-occurrences between the "borrow" event and "sell" event (coming from financial news articles in NYT). In contrast, for KnowSemLM, since we have the knowledge "PER[*]-borrow.01-ARG[*](*) $\Rightarrow$ PER[old]-return.01-ARG[old](*)", meaning that something borrowed by someone is likely to be returned, the predicted event would be "PER[old]-return.01-ARG[old](NEU)". This is closer to the real text semantically: ... *She promised to return the money once she got a job* ... Such an example shows that KnowSemLM works in situations where 1) the required knowledge is stored in the event causality knowledge base, and 2) the training data contains scenarios where required knowledge is put into use.

6 Related Work

Our work is built upon the previous works for semantic language models (Peng and Roth, 2016; Peng et al., 2017; Chaturvedi et al., 2017). This line of work is in general inspired by script learning. Early works (Schank and Abelson, 1977; Mooney and DeJong, 1985) tried to learn scripts via construction of knowledge bases from text. More recently, researchers focused on utilizing statistical models to extract high-quality scripts from large amounts of data (Chambers and Jurafsky, 2008; Bejan, 2008; Jans et al., 2012; Pichotta and Mooney, 2014; Granroth-Wilding and Clark, 2016; Rudinger et al., 2015; Pichotta and Mooney, 2016a,b). Other works aimed at learning a collection of structured events (Chambers, 2013; Cheung et al., 2013; Balasubramanian et al., 2013; Bamman and Smith, 2014; Nguyen et al., 2015; Inoue et al., 2016). In particular, Ferraro and Durme (2016) presented a unified probabilistic model of syntactic and semantic frames while also demonstrating improved coherence. Several works have employed neural embeddings (Modi and Titov, 2014a,b; Frermann et al., 2014; Titov and Khoddam, 2015). Some prior works have used scripts-related ideas to help improve NLP tasks (Irwin et al., 2011; Rahman and Ng, 2011; Peng et al., 2015b).

Several recent works focus on narrative/story telling (Rishes et al., 2013), as well as studying event structures (Brown et al., 2017). Most recently, Mostafazadeh et al. (2016, 2017) proposed story cloze test as a standard way to test a system's ability to model semantics. They released ROCStories dataset, and organized a shared task for LSDSem'17; which yields many interesting works on this task. Cai et al. (2017) developed a model that uses hierarchical recurrent networks with at-

tention to encode sentences and produced a strong baseline. Lee and Goldwasser (2019) considered the problem of learning relation aware event embeddings for commonsense inference, which can account for different relations between events, beyond simple event similarity. We differ from them because the basic semantic unit we model is event level abstractions instead of word tokens.

The definition of event causality knowledge in this work includes temporal ordering relationships. Much progress has been made in identifying and modeling such relations. In early works (Mani et al., 2006; Chambers et al., 2007; Bethard et al., 2007; Verhagen and Pustejovsky, 2008), the problem was formulated as a classification problem for determining the pair-wise event temporal relations; while recent works (Do et al., 2012; Mirza and Tonelli, 2016; Ning et al., 2017, 2018) took advantage of utilizing structural constraints such as transitive properties of temporal relationships via ILP to achieve better results. Comparatively, the concept of event causality knowledge here is broader and more flexible. Any event causality relation gained from human experience could be represented and utilized in KnowSemLM; as shown in Sec. 4.2 that such knowledge can be both mined from corpus and written down declaratively.

Since we formulate the semantic sequence modeling problem as a language modeling issue, we also review recent neural language modeling literature. Bengio et al. (2003) introduced a model that learns word vector representations as part of a simple neural network architecture for language modeling. Collobert and Weston (2008) decoupled the word vector training from the downstream training objectives, which paved the way for Collobert et al. (2011) to use the full context of a word for learning the word representations. The skip-gram and continuous bag-of-words (CBOW) models of Mikolov et al. (2013) propose a simple single-layer architecture based on the inner product between two word vectors. Mnih and Kavukcuoglu (2013) also proposed closely-related vector log-bilinear models, vLBL and ivLBL, and Levy and Goldberg (2014) proposed explicit word embeddings based on a PPMI metric. Additionally, researcher have been attempting to infuse knowledge into the language modeling process (Ahn et al., 2016; Yang et al., 2016; Ji et al., 2017; He et al., 2017; Clark et al., 2018).

Most recently, pre-trained language models such as BERT (Devlin et al., 2019), GPT (Radford et al., 2018), and XLNET (Yang et al., 2019) have achieved much success for language modeling and generation tasks. Our proposed knowledge infused semantic language model can not be directly applied upon such word-level pre-trained language models. However, as future works, we are interested in exploring the possibility of pre-training a semantic language model with frame and entity abstractions on a large corpus with event causality knowledge, and fine-tune it on application tasks.

7 Conclusion

This paper proposes KnowSemLM, a knowledge infused semantic LM. It utilizes both local context (i.e., what has been described in text) and global context (i.e., causality knowledge about events) to predict future events. We show that such event causality knowledge can be obtained statistically from a corpus or declaratively in specific scenarios. Similar to previous works, KnowSemLM takes advantage of event-level abstractions to achieve generalization. Evaluations demonstrate that the knowledge awareness of the proposed KnowSemLM helps improve results on tasks such as the event cloze test and story/referent prediction.

Abstract

This study proposes a *Neural Attentive Bag-of-Entities* model, which is a neural network model that performs text classification using entities in a knowledge base. Entities provide unambiguous and relevant semantic signals that are beneficial for capturing semantics in texts. We combine simple high-recall entity detection based on a dictionary, to detect entities in a document, with a novel neural attention mechanism that enables the model to focus on a small number of unambiguous and relevant entities. We tested the effectiveness of our model using two standard text classification datasets (i.e., the 20 Newsgroups and R8 datasets) and a popular factoid question answering dataset based on a trivia quiz game. As a result, our model achieved state-of-the-art results on all datasets. The source code of the proposed model is available online at https://github.com/wikipedia2vec/wikipedia2vec.

1 Introduction

Text classification is an important task, and its applications span a wide range of activities such as topic classification, spam detection, and sentiment classification. Recent studies showed that models based on neural networks can outperform conventional models (e.g., naïve Bayes) on text classification tasks (Kim, 2014; Iyyer et al., 2015; Tang et al., 2015; Dai and Le, 2015; Jin et al., 2016; Joulin et al., 2017; Shen et al., 2018). Typical neural network-based text classification models are based on words. They typically use words in the target documents as inputs, map words into continuous vectors (embeddings), and capture the semantics in documents by using compositional functions over word embeddings such as averaging or summation of word embeddings, convolutional neural networks (CNN), and recurrent neural networks (RNN).

Apart from the aforementioned approaches, past studies attempted to use entities in a knowledge base (KB) (e.g., Wikipedia) to capture the semantics in documents. These models typically represent a document by using a set of entities (or *bag of entities*) relevant to the document (Gabrilovich and Markovitch, 2006, 2007; Xiong et al., 2016). The main benefit of using entities instead of words is that unlike words, entities provide unambiguous semantic signals because they are uniquely identified in a KB. One key issue here is to determine the way in which to associate a document with its relevant entities. An existing straightforward approach (Peng et al., 2016; Xiong et al., 2016) involves creating a set of relevant entities using an entity linking system to detect and disambiguate the names of entities in a document. However, this approach is problematic because (1) entity linking systems produce disambiguation errors (Cornolti et al., 2013), and (2) entities appearing in a document are not necessarily relevant to the given document (Gamon et al., 2013; Dunietz and Gillick, 2014).

This study proposes the *Neural Attentive Bag-of-Entities* (NABoE) model, which is a neural network model that addresses the text classification problem by modeling the semantics in the target documents using entities in the KB. For each entity name in a document (e.g., *"Apple"*), our model first detects entities that may be referred to by this name (e.g., *Apple Inc.*, *Apple (food)*), and then represents the document using the weighted average of the embeddings of these entities. The weights are computed using a novel neural attention mechanism that enables the model to focus on a small subset of the entities that are less ambiguous in meaning and more relevant to the document. In other words, the attention mechanism is designed to compute weights by jointly addressing entity linking and entity salience detection (Ga-

Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

mon et al., 2013; Dunietz and Gillick, 2014) tasks. Furthermore, the attention mechanism improves the interpretability of the model because it enables us to inspect the small number of entities that strongly affect the classification decisions.

We validate the effectiveness of our proposed model by addressing two important natural language tasks: a text classification task using two standard datasets (i.e., the 20 Newsgroups and R8 datasets), and a factoid question answering task based on a popular dataset derived from the *quiz bowl* trivia quiz game. As a result, our model achieved state-of-the-art results on both tasks. The source code of the proposed model is available online at https://github.com/wikipedia2vec/wikipedia2vec.

2 Our Approach

Given a document, our model addresses the text classification task by using the following two steps: it first detects entities from the document, and then classifies the document using the proposed model with the detected entities as inputs.

2.1 Entity Detection

In this step, we detect entities that may be relevant to the document. Here, we use a simple method based on an *entity dictionary* that maps an entity name (e.g., "Washington") to a set of possible referent entities (e.g., *Washington, D.C.* and *George Washington*). In particular, we first take all words and phrases in a document, treat them as entity names if they exist in the dictionary, and detect all possible referent entities for each detected entity name. Following past work (Hasibi et al., 2016; Xiong et al., 2016), the boundary overlaps of the names are resolved by detecting only those that are the earliest and the longest.

We use Wikipedia as the target KB, and the entity dictionary is built by using the names and their referent entities of all internal anchor links in Wikipedia (Guo et al., 2013). We also collect two statistics from Wikipedia, namely *link probability* and *commonness* (Mihalcea and Csomai, 2007; Milne and Witten, 2008). The former is the probability of a name being used as an anchor link in Wikipedia, whereas the latter is the probability of a name referring to an entity in Wikipedia.

We generate a list of entities by concatenating all possible referent entities contained in the dictionary for each detected entity name, and feed it to the model presented in the next section. Note that we do not disambiguate entity names here, but detect all possible referent entities of the entity names.

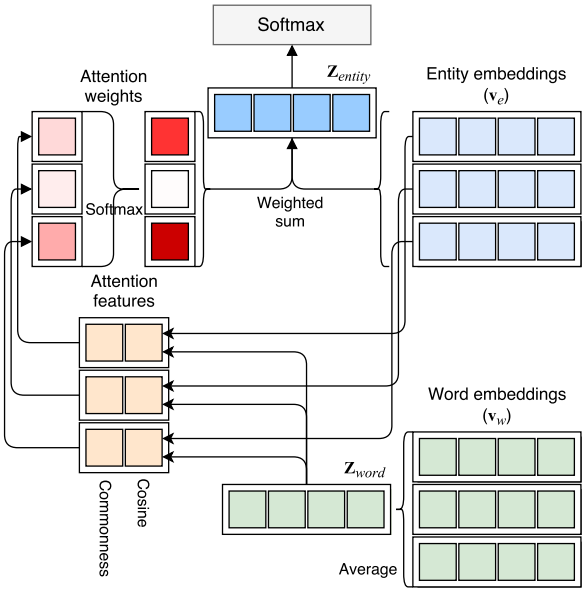

Figure 1: Architecture of the NABoE-entity model.

2.2 Model

Figure 1 shows the architecture of our model. Given words $w_1, ..., w_N$, and entities $e_1, ..., e_K$ detected from target document D, we first compute the word-based representation of D:

$$\mathbf{z}_{word} = \frac{1}{N} \sum_{i=1}^{N} \mathbf{v}_{w_i}, \quad (1)$$

where $\mathbf{v}_w \in \mathbb{R}^d$ is the embedding of word w. We then derive the entity-based representation of D as a weighted average of the embeddings of the entities:

$$\mathbf{z}_{entity} = \sum_{i=1}^{K} a_{e_i} \mathbf{v}_{e_i}, \quad (2)$$

where $\mathbf{v}_e \in \mathbb{R}^d$ is the embedding of entity e and a_e the normalized attention weight corresponding to e computed using the following softmax-based attention function:

$$a_e = \frac{\exp(\mathbf{w}_a^\top \Phi(e, D) + b_a)}{\sum_{i=1}^{K} \exp(\mathbf{w}_a^\top \Phi(e_i, D) + b_a)}, \quad (3)$$

where $\mathbf{w}_a \in \mathbb{R}^l$ is a weight vector, $b_a \in \mathbb{R}$ is the bias, and $\Phi(e, D)$ is a function that generates an l-dimensional vector consisting of the features of the attention function.

We use the following two features in the attention function:

- **Cosine**: the cosine similarity between the embedding of the entity $\mathbf{v}_e$ and the word-based representation of the document $\mathbf{z}_{word}$.
- **Commonness**: the probability that the entity name refers to the entity in KB.

Here, our aim is to capture the relevance and the unambiguity of entity e in document D using the attention function. Thus, the problem is related to the tasks of entity salience detection (Gamon et al., 2013; Dunietz and Gillick, 2014), which aims to detect entities relevant (or salient) to the document, and entity linking, which aims to resolve the ambiguity of entities. The key assumption relating to these two tasks in the literature is that if an entity is semantically related to the given document, it is relevant to the document (Dunietz and Gillick, 2014), and it is likely to appear in the document (Milne and Witten, 2008; Ratinov et al., 2011). With this in mind and following past work (Yamada et al., 2016), we use the cosine similarity between $\mathbf{v}_e$ and $\mathbf{z}_{word}$ as a feature. Further, as in past entity linking studies, we also use the commonness of the name referring to the entity.

Moreover, we derive a representation based both on entities and words by simply adding $\mathbf{z}_{entity}$ and $\mathbf{z}_{word}$[1]:

$$\mathbf{z}_{full} = \mathbf{z}_{entity} + \mathbf{z}_{word}. \quad (4)$$

We then solve the task using a multiclass logistic regression classifier with the computed representation (i.e., with $\mathbf{z}_{entity}$ or $\mathbf{z}_{full}$) as features. In the remainder of this paper, we denote our models based on $\mathbf{z}_{entity}$ and $\mathbf{z}_{full}$ by **NABoE-entity** and **NABoE-full**, respectively.

3 Experimental Setup

In this section, we describe our experimental setup used both in the text classification and the factoid question answering experiments presented below.

3.1 Entity Detection

As the target KB, we used the September 2018 version of Wikipedia, which contains a total of 7,333,679 entities.[2] Regarding the entity dictionary described in Section 2.1, we excluded an entity name if its link probability was lower than 1% and a referent entity if its commonness given the entity name was lower than 3% for computational efficiency. Entity names were treated as case-insensitive. As a result, the dictionary contained 18,785,550 entity names, and each name had 1.14 referent entities on average.

Furthermore, to detect entities from a document, we also tested two publicly available entity linking systems, **Wikifier** (Ratinov et al., 2011; Cheng and Roth, 2013) and **TAGME** (Ferragina and Scaiella, 2012), instead of using dictionary-based entity detection.[3] We selected these systems because they are capable of detecting non-named entities (e.g., technical terms) that are useful for addressing the text classification task.[4] Here, we used the entities detected and disambiguated by these systems as inputs to our neural network model.

3.2 Pretrained Embeddings

We initialized the embeddings of words ($\mathbf{v}_w$) and entities ($\mathbf{v}_e$) using pretrained embeddings trained on KB. To learn embeddings from the KB, we used the method adopted in the open source Wikipedia2Vec tool (Yamada et al., 2016, 2018a). In particular, we generated an entity-annotated corpus from Wikipedia by treating entity links in Wikipedia articles as entity annotations, and trained skip-gram embeddings (Mikolov et al., 2013a,b) of 300 dimensions with negative sampling using the generated corpus as inputs. The learned embeddings place similar words and entities close to one another in a unified vector space. Here, we used the same version of Wikipedia described in Section 3.1.

4 Text Classification

To evaluate the effectiveness of our proposed model, we first conducted the text classification

[1] We also tested concatenating $\mathbf{z}_{entity}$ and $\mathbf{z}_{word}$ to derive $\mathbf{z}_{full}$; however, adding them generally achieved enhanced performance in our experiments presented below.

[2] We downloaded the Wikipedia dump from Wikimedia Downloads: https://dumps.wikimedia.org/

[3] In our experiments, we simply used all entities detected by the entity linking systems.

[4] In our preliminary experiments, we also tested three other state-of-the-art entity linking systems: AIDA (Hoffart et al., 2011), WAT (Piccinno and Ferragina, 2014), and the commercial Entity Analysis API in Google's Cloud Language service. However, these systems achieved lower overall performance compared to Wikifier and TAGME because they tended to ignore non-named entities.

task on two standard datasets, namely the 20 Newsgroups (20NG) (Lang, 1995) and R8 datasets (Debole and Sebastiani, 2005).

4.1 Setup

Our experimental setup described in this section follows that in past work (Liu et al., 2015; Jin et al., 2016; Yamada et al., 2018b). In particular, we used the 20NG and R8 datasets to train and test the proposed model. The 20NG dataset was created using the documents obtained from 20 Newsgroups and contained 11,314 training documents and 7,532 test documents.[5] The R8 dataset consisted of news documents from the eight most popular classes of the Reuters-21578 corpus (Lewis, 1992) and comprised 5,485 training documents and 2,189 test documents. We created the development set for each dataset by selecting 5% of the documents for training. Note that the class distribution of the R8 dataset is highly imbalanced. For example, the number of documents in the largest and smallest classes is 3,923 documents and 51 documents, respectively.

We report the accuracy and macro-average F1 scores. The model was trained using mini-batch stochastic gradient descent (SGD) with its batch size set to 32 and its learning rate controlled by Adam (Kingma and Ba, 2014). We used words and entities that were detected three times or more in the dataset and ignored the other words and entities. The size of the embeddings of words and entities was set to $d = 300$. We used early stopping based on the accuracy of the development set of each dataset to avoid overfitting of the model.

4.2 Baselines

We used the following models as our baselines:

- **BoW-SVM** (Jin et al., 2016): This model is based on a conventional linear support vector machine (SVM) with bag of words (BoW) features. It outperformed the conventional naïve Bayes-based model.

- **BoE** (Jin et al., 2016): This model extends the skip-gram model; It learns different word embeddings per target class from the dataset, and a linear model based on learned word embeddings is used to classify the documents. The performance of this model was superior to that of many state-of-the-art models, including those based on the skip-gram and CBOW models (Mikolov et al., 2013b), and the paragraph vector model (Le and Mikolov, 2014).

- **SWEM-concat** (Shen et al., 2018): This model is based on a neural network model with simple pooling operations (i.e., average and max pooling) over pretrained word embeddings.[6] Despite its simplicity, it outperformed many neural network-based models such as the word-based CNN model (Kim, 2014) and RNN model with LSTM units (Shen et al., 2018).

- **TextEnt** (Yamada et al., 2018b): This model learns entity-aware document embeddings from Wikipedia, and uses a neural network model with the learned embeddings as pretrained parameters to address text classification.

As described in Section 2.1, we also tested the variants of our NABoE-entity and NABoE-full models for which **Wikifier** and **TAGME** were used as the entity detection methods.

4.3 Results

Table 1 shows the results of our models and those of our baselines. Here, *w/o att.* and *w/o emb.* signify the model without the neural attention mechanism (all attention weights a_e are set to $\frac{1}{K}$, where K is the number of entities in the document) and the model without the pretrained embeddings (the embeddings are initialized randomly), respectively.

Relative to the baselines, our models yielded enhanced overall performance on both datasets. The NABoE-full model outperformed all baseline models in terms of both measures on both datasets. Furthermore, the NABoE-entity model outperformed all the baseline models in terms of both measures on the 20NG dataset, and the F1 score on the R8 dataset. Moreover, our attention mechanism consistently improved the performance. These results clearly highlighted the effectiveness of our approach, which addresses text

[5] We used the by-date version downloaded from the author's web site: http://qwone.com/~jason/20Newsgroups/.

[6] We also tested all four models proposed in Shen et al. (2018) (i.e., SWEM-aver, SWEM-max, SWEM-concat, and SWEM-hier). These models generally delivered comparable performance, with SWEM-concat slightly outperforming the other models on average.

classification by using a small number of unambiguous and relevant entities detected by the proposed attention mechanism. Moreover, the pretrained embeddings improved the performance on both datasets.

Further, the models based on the dictionary-based entity detection (see Section 2.1) generally outperformed the models based on the entity linking systems (i.e., Wikifier and TAGME). We consider that this is because these entity linking systems failed to detect or disambiguate entity names that were useful to address the text classification task. Moreover, our attention mechanism consistently improved the performance for Wikifier- and TAGME-based models because the attention mechanism enabled the model to focus on entities that were relevant to the document.

4.4 Analysis

In this section, we provide a detailed analysis of the performance of our model in terms of conducting the text classification task. We first provide a comparison of the SWEM-concat, NABoE-entity, and NABoE-full models using class-level F1 scores on both of the datasets (see Table 2). Here, we aim to compare the detailed performance of the word-based model (SWEM-concat), entity-based model (NABoE-entity), and the model based on both words and entities (NABoE-full). Compared with the SWEM-concat model, the NABoE-full and NABoE-entity models performed more accurately in 23 out of 28 and 17 out of 28 classes, respectively. This result clearly demonstrates the ability of the model to successfully capture strong semantic signals that can only be obtained from entities. Moreover, we observed that the NABoE-entity model achieved weaker performance especially for the *misc.forsale* class in the 20NG dataset and several classes in the R8 dataset. Regarding the *misc.forsale* class, because documents in this class contain a wider variety of entities (i.e., objects users want to sell) than other classes, the model failed to capture the effective semantic signals from the entities. Further, as described in the error analysis provided below, it often appeared to be difficult to distinguish pairs of

Table 4: Top five influential entities for each class of the NABoE-entity model in the 20NG and R8 datasets.

similar classes in the R8 dataset based only on entities.

Next, we conducted a feature study of the attention mechanism by excluding one feature at a time from the NABoE-entity model (Table 3). We found both of the features to make an important contribution to the performance.

Furthermore, to investigate the attention mechanism in more detail, we computed the top influential entities in the attention mechanism for each class on the 20NG and R8 datasets. In particular, we calculated the number of times each entity obtained the highest attention weight in the test documents in each class and selected the five most frequent ones. Table 4 presents the results. Overall, our attention mechanism successfully selected entities that were highly relevant to each class. For example, *Cryptography*, *Algorithm*, *Escrow*, *Considered harmful*, and *Encryption* were selected for the *sci.crypt* class. Furthermore, although we did not explicitly perform entity disambiguation, the model successfully overcame the ambiguity issues in the entity names and attended to the entities that were relevant to the classes.

Subsequently, we conducted an error analysis by selecting 50 random test documents for which the NABoE-entity model made wrong predictions. Most of the errors were caused by two pairs of classes: 22 errors were caused by misclassifying documents of *acq* (corporate acquisitions) and those of *earn* (corporate earnings), and 13 errors were caused by misclassifying documents of *interest* and those of *money-fx*. Furthermore, the model tended to perform poorly if a document contained entities that strongly indicate an incorrect class. For example, a *money-fx* document containing the entity *interest rate* multiple times was classified into the *interest* class, and a document in the *acq* class reporting news related to oil companies (i.e., ExxonMobil and ZENEX) was classified into the *crude* class.

5 Factoid Question Answering

In this section, we address factoid question answering based on a dataset consisting of questions of the *quiz bowl* trivia quiz game. Factoid ques-

tion answering is one of the common settings of question answering that aims to predict an entity (e.g., events, authors, and books) that is described in a given question. The players of quiz bowl solve questions consisting of sentences that describe an entity. Quiz bowl questions have frequently been used for evaluating neural network-based models in recent studies (Iyyer et al., 2014, 2015; Yamada et al., 2017).

This task has a significantly larger number of target classes compared to the task addressed in the previous experiment. Our main aim here is to evaluate the effectiveness of using entities to capture the finer-grained semantics required to perform the task of factoid question answering effectively.

5.1 Setup

Our experimental setup described in this section follows that in past work (Xu and Li, 2016; Yamada et al., 2017). We address this task as a text classification problem that selects the most relevant answer from the possible answers observed in the dataset. We obtained the dataset proposed in Iyyer et al. (2014)[7]. We only used questions in the history and literature categories. Furthermore, we excluded questions of which the answers appear fewer than six times in the dataset. As a result, the number of candidate answers was 303 and 424 in the history and literature categories, respectively. We used 20% of questions each for the development set and test sets, and the remaining 60% for the training set. As a result, the training, development, and test sets consisted of 1,535, 511, and 511 questions for the history category, and 2,524, 840, and 840 questions for the literature category.

The settings we used to train the model were the same as those in the previous experiment (see Section 4.1). The model was trained using mini-batch SGD with its learning rate controlled by Adam (Kingma and Ba, 2014) and its mini-batch size set to 32. We used words and entities that were detected three times or more in the dataset, and ignored the other words and entities. The size of the embeddings of words and entities was set to $d = 300$. As in past work, we report the accuracy score, and the score on the development set was used for early stopping.

[7]This dataset was downloaded from the authors' web page: https://cs.umd.edu/~miyyer/qblearn/.

Name	History	Literature
NABoE-full	**.949**	**.985**
NABoE-entity	.941	.979
NABoE-entity w/o att.	.845	.943

Wikifier (NABoE-full)	.935	.967
Wikifier (NABoE-entity)	.930	.952
Wikifier (NABoE-entity w/o att.)	.924	.941
Wikifier (NABoE-entity w/o emb.)	.934	.949
TAGME (NABoE-full)	.941	.977
TAGME (NABoE-entity)	.930	.963
TAGME (NABoE-entity w/o att.)	.922	.961
TAGME (NABoE-entity w/o emb.)	.932	.962
BoW	.508	.462
FTS-BRNN	.881	.931
NTEE	.947	.951
SWEM-concat	.900	.966

Table 5: Accuracy of the proposed and baseline methods for the factoid QA task.

5.2 Baselines

We used the following baseline models:

- **BoW** (Xu and Li, 2016) This model is based on a logistic regression classifier with conventional binary BoW features.
- **FTS-BRNN** (Xu and Li, 2016) This model is based on a bidirectional RNN with gated recurrent units (GRU). It uses the logistic regression classifier with the features derived by the RNN.
- **NTEE** (Yamada et al., 2017) This model is a state-of-the-art model that uses a multi-layer perceptron classifier with the features computed using the embeddings of words and entities trained on Wikipedia using the neural network model proposed in their paper.

Similar to our previous experiment, we also add **SWEM-concat**, and the variants of our NABoE-entity and NABoE-full models based on **Wikifier** and **TAGME** (see Section 4.2). Note that all the baselines address the task as a text classification problem.

5.3 Results and Analysis

Table 5 provides the results of our models and those of our baselines. Overall, our models achieved enhanced performance on this task. In particular, the NABoE-full model successfully outperformed all the baseline models, and the NABoE-entity model achieved competitive performance and outperformed all the baseline models in the literature category. These results clearly

highlighted the effectiveness of our model for this task.

Furthermore, similar to the previous text classification experiment, the attention mechanism and the pretrained embeddings consistently improved the performance. Moreover, the models based on dictionary-based entity detection outperformed the models based on the entity linking systems.

We also conducted an error analysis using the NABoE-entity model and the test questions in the history category. We found nearly 70% of the errors to be caused by questions of which the answers were country names. This is because these questions tended to provide indirect clues (e.g., describing a notable person born in the country) and most entities used in these clues do not directly indicate the answer (i.e., country names). Furthermore, our model failed in difficult cases such as predicting *Tokugawa shogunate* instead of *Tokugawa Ieyasu*.

6 Related Work

KB entities have been conventionally used to model the semantics in texts. A representative example is Explicit Semantic Analysis (ESA) (Gabrilovich and Markovitch, 2006, 2007), which represents a document using a bag of entities, namely a sparse vector of which each dimension corresponds to the relevance score of the text to each entity. This simple method is shown to be effective for various NLP tasks including text classification (Gabrilovich and Markovitch, 2006; Gupta and Ratinov, 2008; Negi and Rosner, 2013) and information retrieval (Egozi et al., 2011; Xiong et al., 2016),

Several neural network models that use KB entities to capture the semantics in texts have been proposed. These models typically depend on an additional preprocessing step that extracts the relevant entities from the target texts. For example, Wang et al. (2017) used the Probase conceptualization API for short text classification by retrieving the Probase entities that were relevant to the target text and used them in a model based on CNN. Pilehvar et al. (2017) also extracted entities using a graph-based linking algorithm and used these entities in a neural network model. A similar approach was adopted in Yamada et al. (2018b,c); they extracted entities from the target text using an entity linking system and simply used the detected entities in a neural network model. However, unlike these models, our proposed model addresses the task in an *end-to-end* manner; i.e., entities that are relevant to the target text are automatically selected using our neural attention mechanism. Furthermore, we also used the model proposed by Yamada et al. (2018b) as a baseline in our text classification experiments.

Additionally, our work is also related to studies on entity linking. Entity linking models can be roughly classified into two groups: *local* models, which resolve entity names independently using the contextual relevance of the entity given a document, and *global* models, in which all the entity names in a document are resolved simultaneously to select a topically coherent set of results (Ratinov et al., 2011). Recent state-of-the-art models typically combine both of these models (Yamada et al., 2016; Ganea and Hofmann, 2017; Cao et al., 2018; Kolitsas et al., 2018). However, several studies also showed that the local model alone can achieve results competitive to those of the global and combined models (Eshel et al., 2017; Ganea and Hofmann, 2017; Yamada et al., 2017; Cao et al., 2018; Kolitsas et al., 2018). In this study, we adopt a simple but effective local model, which uses cosine similarity between the embedding of the target entity and the word-based representation of the document to capture the relevance of an entity given a document.

7 Conclusions

This study proposed NABoE, which is a neural network model that performs text classification using entities in Wikipedia. We combined simple dictionary-based entity detection with a neural attention mechanism to enable the model to focus on a small number of unambiguous and relevant entities in a document. We achieved state-of-the-art results on two important NLP tasks, namely text classification and factoid question answering, which clearly verified the effectiveness of our approach. As a future task, we intend to more extensively analyze our model and explore its effectiveness for other NLP tasks. Furthermore, we would also like to test more expressive neural network models for example by integrating global entity coherence information into our neural attention mechanism.

Abstract

The official voting records of United States congresspeople are preserved as roll call votes. Prediction of voting behavior of politicians for whom no voting record exists, such as individuals running for office, is important for forecasting key political decisions. Prior work has relied on past votes cast to predict future votes, and thus fails to predict voting patterns for politicians without voting records. We address this by augmenting a prior state of the art model with multiple sources of external knowledge so as to enable prediction on unseen politicians. The sources of knowledge we use are news text and Freebase, a manually curated knowledge base. We propose augmentations based on unigram features for news text, and a knowledge base embedding method followed by a neural network composition for relations from Freebase. Empirical evaluation of these approaches indicate that the proposed models outperform the prior system for politicians with complete historical voting records by 1.0% point of accuracy (8.7% error reduction) and for politicians without voting records by 33.4% points of accuracy (66.7% error reduction). We also show that the knowledge base augmented approach outperforms the news text augmented approach by 4.2% points of accuracy.

1 Introduction

Roll call votes are official records of how politicians vote on bills (potential laws) in the United States House of Representatives and Senate. Reliable prediction of these votes, using historical voting records and the text of bills, can be used to forecast political decisions on key issues, which can be informative for the electorate and other political stakeholders. Prior work has used politicians' voting records as a means to study their ideological stances (Poole and Rosenthal, 1985; Clinton et al., 2004), as well as roll call votes combined with the text of the corresponding bills to predict votes on newly drafted bills (Gerrish and Blei, 2012; Kraft et al., 2016; Kornilova et al., 2018). However, these approaches fail to make good predictions for the votes of politicians whose records are not established, such as new candidates for office – a time when this information can be most useful for the electorate. We hypothesize that additional sources of knowledge about new politicians can predict their future votes.

In this work we explore two sources of additional knowledge about politicians to better predict roll call votes: news article text about the politicians, and Freebase (Bollacker et al., 2008), which is a manually curated knowledge base (KB). Relevant news articles may contain words that are indicative of a politician's stance with respect to specific issues. A KB such as Freebase is likely to contain rich information such as events a congressperson attends, people they are related to, and personal details such as schools they were educated at; this information may be correlated with a politician's stance on specific issues (Sunshine Hillygus, 2005; Duckitt and Sibley, 2010; Kraut and Lewis, 1975). Information in a KB is likely to be more restricted, but more reliable, than information extracted from news articles.

We integrate these sources of information into the embedding based prediction model proposed in Kraft et al. (2016). We experiment with two representations for news articles: as the mean of the embeddings of the words in the article, and as a bag of words. To represent information in KBs, we first capture the KB relations using Universal Schema (US) (Riedel et al., 2013), and then construct relation embeddings using a neural network.

We evaluate the proposed approaches on multiple sessions of Congress under two settings: (1) with only politicians that are observed at train-

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 574–581
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

ing time, which is similar to the setting of prior work (Kraft et al., 2016; Kornilova et al., 2018) and (2) where a subset of politicians' voting patterns are never observed at training time, representing the new candidate for office setting. We establish a new state-of-the-art under the evaluation framework used by most prior work (Setting 1). We also show that our approach outperforms a state-of-the-art model in our evaluation framework (Setting 2). Compared to the previous state-of-the-art model for roll call prediction, in Setting (1) our best approach gives an improvement in accuracy of 1.0% (an error reduction of 8.7%), and in Setting (2) our best approach gives an improvement in accuracy of 33.4% (an error reduction of 66.7%). Additionally, in Setting (2), augmentation via KB gives 4.2% more accurate predictions than augmentation from news text.

Code to reproduce our experiments can be found here: https://github.com/ronakzala/universal-schema-bloomberg/.

2 Models

All the models we explore take as input the voting record (denoted $\mathcal{V}$) for a politician p, the text of a bill b, and (optional) knowledge about the politician (denoted $\mathcal{K}$), and output a probability $\mathrm{P}(y = \texttt{Yea}|b, \mathcal{V}, \mathcal{K})$ that politician p will vote Yea on bill b. In this discussion, all features (voting record and knowledge augmentation) as well as labels (vote predictions) are specific to p, but for ease of reading we don't subscript to p.

We start with a baseline model that does not use any additional knowledge. We augment this model with knowledge from news articles mentioning p (denoted $\mathcal{N}$) and from parts of the Freebase KB relevant to p (denoted $\mathcal{F}$) (i.e. $\mathcal{N} \subset \mathcal{K}$ and $\mathcal{F} \subset \mathcal{K}$). In our augmented models, vector representations of this additional knowledge are denoted as $\mathbf{v}_\mathcal{N}$ and $\mathbf{v}_\mathcal{F}$. These vectors can be read as complementary representations of politician p, derived from how the politician appears in news articles and in curated sources of world knowledge, rather than by prior voting behavior. These vectors are used in conjunction with the politician's representation in terms of their historical voting record, denoted as $\mathbf{v}_\mathcal{V}$, which is learned as a model parameter. Now, we describe the forms of the baseline and augmented models.

2.1 Baseline Model

Our baseline is the model proposed by Kraft et al. (2016). This model represents a politician p by a vector $\mathbf{v}_\mathcal{V}$ and a bill b using a bag of words of the 1,000 most frequent unigrams across all bills, after excluding stopwords and single-character tokens. The model is defined as follows:

$$\mathbf{v}_b = \sum_{w \in b} \mathbf{e}_w / |b|$$
$$\mathbf{Z}_b = \mathbf{W}_{bill} \cdot \mathbf{v}_b + \mathbf{d}_{bill}$$
$$\mathrm{P}(y = \texttt{yea}|b, \mathcal{V}) = \sigma(\mathbf{Z}_b \cdot \mathbf{v}_\mathcal{V})$$

Here, $e_w \in \mathbb{R}^{d_{word}}$ is initialized to pre-trained GloVe word embeddings[1] and finetuned as a model parameter. $\mathbf{v}_\mathcal{V} \in \mathbb{R}^{d_{emb}}$ is the embedding for politician p and is initialized uniformly at random in $[-10^{-2}, 10^{-2}]$. Bill b is represented as $\mathbf{v}_b$, the average of word embeddings $\mathbf{e}_w$, and then transformed into the same space as $\mathbf{v}_\mathcal{V}$ via weight matrix $W_{bill} \in \mathbb{R}^{d_{emb} \times d_{word}}$ and bias vector $d_{bill} \in \mathbb{R}^{d_{emb}}$, i.e. $\mathbf{Z}_b \in \mathbb{R}^{d_{emb}}$.

2.2 News Text Augmented Model

We incorporate knowledge about politician p from relevant news articles in the form of unigram features extracted from the set of news articles that mention p, denoted $\mathcal{N}$. This model represents each article $a_j \in \mathcal{N}$ as a bag of words of the most frequent 2,000 unigrams across all articles for all politicians, after excluding stopwords and single-character tokens. The news augmented model is formulated as:

$$\mathbf{v}_b = \sum_{w \in b} \mathbf{e}_w / |b|$$
$$\mathbf{Z}_b = \mathbf{W}_{bill} \cdot \mathbf{v}_b + \mathbf{d}_{bill}$$
$$\mathbf{Z}_\mathcal{N} = \mathbf{W}_{news} \cdot \mathbf{v}_\mathcal{N} + \mathbf{d}_{news}$$
$$\mathrm{P}(y = \texttt{yea}|b, \mathcal{V}, \mathcal{N}) = \sigma(\mathbf{Z}_b \cdot [\mathbf{v}_\mathcal{V} + \mathbf{Z}_\mathcal{N}])$$

Most of the notation above is same as the one for the baseline model in §2.1. Here, $\mathbf{v}_\mathcal{N}$ is a vector representing the knowledge about p contained in N. $\mathbf{Z}_\mathcal{N} \in \mathbb{R}^{d_{emb}}$ represents $\mathbf{v}_\mathcal{N}$ transformed into the space of $\mathbf{v}_\mathcal{V}$ via weight matrix $\mathbf{W}_{news}$ and bias vector d_{news}. We experiment with two variations for computing $\mathbf{v}_\mathcal{N}$. First we compute $\mathbf{v}_\mathcal{N}$ as the mean GloVe vectors of all unigrams in $\mathcal{N}$

[1] http://nlp.stanford.edu/data/glove.6B.zip

(model denoted by NWGL):

$$\mathbf{v}_{\mathcal{N}}^{\text{GloVe}} = \frac{1}{\sum_{a \in \mathcal{N}} |a|} \sum_{a \in \mathcal{N}} \sum_{w \in a} \mathbf{e}_w$$

where $\mathbf{e}_w$ represents the GloVe vector for word w in article a. We also consider a variant where each article $a \in \mathcal{N}$ is represented as a vector of relative frequencies of the words in a (model denoted by NWFR):

$$\mathbf{v}_{\mathcal{N}}^{\text{FREQ}} = \sum_{a \in \mathcal{N}} \mathbf{f}_a$$

where $\mathbf{f}_a$ is a vector of unigram relative frequencies in article $a \in \mathcal{N}$.

2.3 Knowledge Base Augmented Model

Building on the baseline model, the knowledge base augmented model (denoted by KBUS) represents the contextual information for politician p as a vector $\mathbf{v}_{\mathcal{F}}$. The KB augmented model is formulated as:

$$\mathbf{v}_b = \sum_{w \in b} \mathbf{e}_w / |b|$$
$$\mathbf{Z}_b = \mathbf{W}_{bill} \cdot \mathbf{v}_b + \mathbf{d}_{bill}$$
$$\text{P}(y = \texttt{yea} | b, \mathcal{V}, \mathcal{F}) = \sigma(\mathbf{Z}_b \cdot [\mathbf{v}_{\mathcal{V}} + \mathbf{Z}_{\mathcal{F}}])$$

Most of the notation above remains the same as the baseline model in §2.1. $\mathbf{Z}_{\mathcal{F}}$ is created from an embedded subgraph of the Freebase KB. Freebase consists of relation triples of the form (e_1, r, e_2), where e_1, and e_2 denote entities (e.g., `Barack Obama`, `Columbia University`) and r denotes a relation (e.g., `graduate_of`). These relation triples are embedded in a vector space by Universal Schema (Riedel et al., 2013), giving vector representations $\mathbf{v}_{e_1}$, $\mathbf{v}_{e_2}$, and $\mathbf{v}_r$ for the elements of the triple, e_1, e_2, and r. Universal Schema embeddings for entities and relations are trained for the KB completion task, to maximize the probability of triples existing in the KB parameterized by $\text{P}(r, e_1, e_2) = \sigma(\mathbf{v}_r^T [\mathbf{v}_{e_1}; \mathbf{v}_{e_2}])$.

The KB knowledge vector $\mathbf{Z}_{\mathcal{F}}$ is derived from the Universal Schema entity embeddings. For each politician p, we consider the subset of relations in which the politician is either e_1 or e_2, denoted $\mathcal{F}$. We link p to a KB entity in Freebase by exact textual match on p's name. Let r_i be a relation in a triple in $\mathcal{F}$ and o_i be the entity that is *not* politician p in that triple; we compute $\mathbf{Z}_{\mathcal{F}}$ as:

$$\mathbf{Z}_{\mathcal{F}} = \sum_{i \in \mathcal{F}} \mathbf{t}_i \cdot \text{P}(r_i, o_i, p)$$
$$\mathbf{t}_i = \text{FFN}([\mathbf{v}_{r_i}; \mathbf{v}_{o_i}])$$

Here $[;]$ denotes concatenation, v_{r_i} the Universal Schema embedding for relation r_i, and v_{o_i} the Universal Schema embedding for o_i. $\mathbf{t}_i$ is the embedding of the ith triple and is computed by passing v_{r_i} and v_{o_i} through a shallow feed forward network (FFN) of the form: $tanh(\mathbf{W}\mathbf{x} + \mathbf{b})$. The parameters of this FFN are learned in the course of model training, and the dimensionality of $\mathbf{t}_i$ is a hyperparameter. The final representation for the contextual knowledge from the KB for politician p is therefore a sum of the Freebase triple Universal Schema embeddings weighted by the probability that p would participate in each triple.

3 Experiment Description

We evaluate the proposed knowledge augmented models under two evaluation protocols (§3.3): one where all politicians' voting records are observed in the training data (Setting 1) and another in which some politicians are unobserved at training time, representing the new candidate for office setting (Setting 2). We also evaluate the performance of simple baseline methods and previous state-of-the-art methods (§3.2) in both settings. Finally, we perform a close comparison of baseline methods against the proposed methods and highlight individual politicians for which the knowledge augmented models better predict voting behavior than the baselines (§4.0.4).

3.1 Datasets

Our data comes from three sources: roll call voting records from Congress Sessions 106-109, news articles from the Concretely Annotated New York Times Corpus (Ferraro et al., 2014), and the KB from Freebase. Here we briefly describe each source and major preprocessing decisions.

3.1.1 Roll Call Votes

The roll call votes dataset was compiled to resemble the one used by Kraft et al. (2016). The dataset covers the 106th-109th Congress (1999-2006), where each session spans 2 years, and was created by querying GovTrack[2] using pub-

[2]Online Roll Call Votes: `https://www.govtrack.us/`

licly available tools[3]. Bill texts, bill metadata, and lists of roll call votes were all queried separately and matched using bill IDs. The resulting dataset contains voting records for 709 unique politicians across sessions and almost 1 million politician-bill-vote examples. In order to facilitate future research on this data we make our tools and raw data available to the community, a component absent from prior work[4].

3.1.2 New York Times Corpus

We use the The Concretely Annotated NYT Corpus (Ferraro et al., 2014) as a source of knowledge contained in news articles. This corpus contains approximately 1.8 million articles for the period 1987-2007, which includes the sessions of Congress for which we report experimental results. The corpus is automatically annotated using the CoreNLP package with a host of annotations such as part of speech and named entity tags.

To obtain the set of politician-relevant articles for the news article augmented model (§2.2), we first construct a list of politician names from our roll call vote data and Wikipedia aliases for these names. We identify candidate names in each article by extracting all spans in the article annotated with the `Person` entity type tag. We then look for exact string matches to the list of politician names in the candidate names extracted from each article. By this means, we identify a total of 50,800 relevant articles. Each article is represented as a bag of words from the 2,000 most frequent words across all articles after dropping stop words and single character words. When training and evaluating our models, we conservatively include only the subset of relevant articles published before the congressional session from which the bill comes; this way, information from news text necessarily predates the congressional votes and does not inform about the model about voting outcomes.

3.1.3 Freebase

We use Freebase as a source of KB knowledge. Freebase is a large, structured knowledge base that consists of relation triples created by human contributors. It contains about 46 million unique entities and 332 million relation triples.

In extracting relations relevant to politicians in our roll call vote data, we first filter to only relations that mention a politician explicitly as one of the entities. We add to this set relations one hop away from the politicians in the knowledge base (the politicians do not directly participate in this set of one hop away relations). The combination of direct and one hop away relations gives about 800,000 relation triples. This subset of Freebase is embedded with Universal Schema, following which only the direct politician relations, along with the scores learned by Universal Schema for these relations, are used in our KB augmented model (§2.3). Although Freebase relations are not temporally marked, Freebase does not contain politicians' voting records, so vote information cannot "bleed into" our models from Freebase.

3.2 Baselines

We compare the performance of the proposed models against several baseline and previous state-of-the-art models. These are:

KJR16: The model from Kraft et al. (2016). The numbers we report for KJR16 are based on our re-implementation of the original model. We also apply slightly different preprocessing decisions to the text of bills. For example, we drop stop words and single-character tokens, unlike the original paper.

MAJ: This baseline model predicts the majority class (`Yea`) for all votes on all bills.

PARTYM: This baseline predicts that a congressperson will vote for a bill in the direction of their party's majority vote for that bill. A congressperson can have a party affiliation of Republican, Democrat, or Independent. A politician's party is generally a very strong predictor of their voting behavior. We compare against this baseline specifically to measure how much gain contextual knowledge about a politician can bring over just predicting that a congressperson will toe the party line. This baseline operates in a slightly unrealistic setting, since the party majority vote is determined *after* all the votes have been cast for a given bill.

3.3 Experimental Setup

For all experiments, our models are trained and evaluated on each Congress session separately. This setup resembles that of most prior work. One exception is Kornilova et al. (2018), who evaluate

[3]Tools to query online congressional data sources: https://github.com/unitedstates/congress

[4]https://github.com/ronakzala/universal-schema-bloomberg/

Session	Majority Class	Accuracy (%)		Precision (%)		Recall (%)		F1 (%)	
		KJR16	BP	KJR16	BP	KJR16	BP	KJR16	BP
106	83.03	85.90	**86.49**	**90.46**	89.14	92.78	**95.32**	91.60	**92.13**
107	85.86	91.10	**91.63**	91.65	**92.57**	98.06	**98.51**	95.06	**95.44**
108	87.10	90.64	**91.68**	91.88	**93.64**	**97.27**	97.15	94.38	**95.36**
109	83.48	86.24	**88.07**	91.85	**92.28**	91.26	**93.05**	91.05	**92.66**
Average	84.87	88.47	**89.47**	91.46	**91.91**	94.84	**96.00**	93.02	**93.89**

Table 1: Performance of KJR16 (our reimplementation of Kraft et al. (2016)) compared to our Best Proposed (BP) model (News augmented-Glove, NWGL), in evaluation Setting (1).

on the next Congress session; even in this case, they restricted their evaluation sets to only those politicians that were observed at training time.

We use a train/dev/test split of $60\%/20\%/20\%$; every session of Congress contains about 250,000 politician-bill-vote examples given that each congress contains between 500-650 bills, and approximately 550 politicians. All of the reported numbers are averaged over four random restarts of the models.

As noted earlier, we evaluate the models under two settings: (Setting 1) in this setting all politicians are present in both training and test data (this is the setting used in all prior work); and (Setting 2) in this setting, votes from 5% of the politicians, chosen at random for each session of Congress, are removed from the training set[5], resulting in a reduction of around 7,000 politician-bill-vote examples from each session of Congress. All of these politicians are still present in the test set.

3.4 Model Hyperparameters and Training

All the models we train (KJR16, NWGL, NWFR, KBUS) use a bill embedding ($\mathbf{v}_b$) of size 50, and a per-politician embedding $\mathbf{v}_\mathcal{V}$ of size 10. The NWGL model additionally uses a mean GloVe vector ($\mathbf{v}_\mathcal{N}^{\text{GloVe}}$) of size 50, whereas the NWFR model uses a word frequency vector ($\mathbf{v}_\mathcal{N}^{\text{FREQ}}$) of size 2,000. The KBUS model has an entity embedding ($\mathbf{v}_o$) of size 25, and relation embedding ($\mathbf{v}_r$) of size 25, resulting in a KB knowledge vector ($\mathbf{Z}_\mathcal{F}$) of size 10 using the FFN architecture: $\{50, 10\}$. These settings were chosen without exploration; further hyperparameter tuning may result in different model performance.

All models were trained using vanilla SGD with a learning rate of 0.1 for up to 20 epochs[6]. We trained with early stopping based on the accuracy on the development set of politician-bill pairs.

For all models, we report accuracy, precision, recall, and F averaging over all vote predictions (i.e. we micro-average).

4 Results and Analysis

Our experiments attempt to answer several questions: (1) Setting 1: Does politician-related knowledge augmentation improve predictive performance when voting records of all politicians are observed (§4.0.1)? (2) Setting 2: Does politician-related knowledge augmentation improve performance when voting records of some politicians are not observed (§4.0.2)? (3) Does knowledge augmentation from a manually curated KB improve model performance compared to knowledge augmentation using unstructured text (§4.0.3)? (4) Finally, for which politicians are our knowledge augmented models more effective than predicting a party majority (PARTYM) vote (§4.0.4)?

4.0.1 Setting 1: All Voting Records Observed

Tables 1 and 2a display the performance of our proposed models when the voting patterns of all politicians are observed. Our best proposed model NWGL outperforms KJR16 in all sessions of Congress according to most metrics (Table 1). NWGL outperforms KJR16 by 1% point of accuracy on average, an error reduction of 8.7%. Knowledge augmentation in any form (NWGL, NWFR and KBUS) gives small improvements in roll call vote prediction over KJR16 (Table 2a).

4.0.2 Setting 2: Some Voting Records Absent

Table 2b displays results in the setting where some politicians' voting data was removed from the training set, representing the new candidate for office setting. For this setting, KJR16 makes random predictions. By contrast, all our models are able to

[5]On average, 2-10% of politicians are newcomers during every session, making our removal of 5% politicians realistic.

[6]No momentum or minibatching was used.

Model	Accuracy (%)	F1
MAJ	*83.82*	*91.19*
PARTYM	*83.56*	*90.54*
KJR16	88.47	93.17
NWGL	**89.47**	**93.89**
NWFR	89.33	93.78
KBUS	89.19	93.68

(a) Setting 1: All politicians in the test set are present in the training set.

	All		Absent from train		Present in train	
Model	Accuracy (%)	F1 (%)	Accuracy (%)	F1 (%)	Accuracy (%)	F1 (%)
MAJ	*83.82*	*91.19*	*83.65*	*91.07*	*83.82*	*91.19*
PARTYM	*83.56*	*90.54*	*84.59*	*91.07*	*83.53*	*90.52*
KJR16	84.31	90.73	49.96	62.37	85.51	91.48
NWGL	85.24	91.23	78.40	86.79	85.48	91.38
NWFR	83.65	90.54	79.13	87.66	83.80	90.64
KBUS	**85.98**	**91.96**	**83.36**	**90.52**	**86.07**	**92.01**

(b) Setting 2: An arbitrary 5% of politicians in every session of Congress are absent from the training set.

Table 2: Performance of our proposed models: News augmented-Glove (NWGL), News augmented-Word Frequency (NWFR) and KB Augmented-US (KBUS). These are compared to baselines Majority Class (MAJ) and Majority Party (PARTYM), and to the model from Kraft et al. (2016) (KJR16) for both evaluation settings. Here we report performance averaged across all four sessions of Congress, and highlight the best model excluding MAJ and PARTYM, which are unrealistic solutions.

successfully predict many of the votes of unseen politicians. The KB augmented model, KBUS, outperforms KJR16 by 33.4% points of accuracy, an error reduction of 66.7%.

MAJ and PARTYM outperform the proposed models in Setting 2. However, PARTYM is based on knowledge of the future and so is impractical, and MAJ has no discriminative power for individual politicians.

4.0.3 Comparison of Augmented Models

The KB augmented model KBUS relies on structured contextual information present in relation triples while the news text augmented models NWGL and NWFR rely on unstructured representations of contextual information (average of unigram embeddings). Also, the KB is manually curated while the news augmented models rely on noisier automatically selected and processed sources of information.

In Setting 1 (the setting in which all politicians are present in the training data) all three augmented models perform similarly, with NWGL and KBUS slightly outperforming NWFR (Table 2a). However, in Setting 2 (where some politicians are unseen in the training data) KBUS clearly outperforms NWGL and NWFR, both overall (85.98% accuracy) and specifically on the unseen politicians (83.36% accuracy). We conclude that the structured nature of the additional knowledge provided to this model might allow for more effective use of contextual knowledge. This also suggests that the news text augmented model can be improved by improving the quality of news text features or learning a more clever weighting of unigram embeddings, for example by the CNN embedding approach used in Kornilova et al. (2018).

4.0.4 Comparison with PARTYM

Here we present a deeper analysis of specific politicians to highlight cases where rich contextual information aids prediction as compared to a model only relying on party affiliation.

We examine results for the 108th Congress, where our KB augmented model KBUS achieves an accuracy of 91.39%, while the PARTYM baseline has accuracy of only 85.26%. The congressperson embeddings learned by KBUS also appear to capture party affiliation (as demonstrated by the near-linear separability of parties evident in Figure 1), but they strictly outperform PARTYM for this session. The embeddings learned by

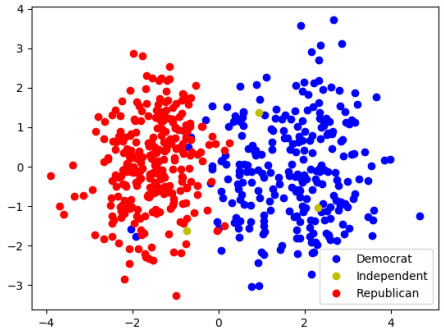

Figure 1: 2-dimensional PCA projected congressperson embeddings by the KBUS model for the 108th congress. Points are colored by party affiliation.

PARTYM primarily err under two circumstances: politicians who do not always vote the party line, and those who identify themselves as Independent. We examine a handful of individual politicians to highlight cases where the proposed models outperform the PARTYM baseline:

Politicians straying party lines : Joe Baca was a congressman from California (D-CA) who was a Democrat during the 108th Congress, but has since changed party twice, due to his Republican-leaning ideology. For Congressman Baca KBUS's accuracy is 90.9%, compared to PARTYM's accuracy of 79.09%. As another example, Jeff Flake (R-AZ) was at that time a congressman recognized as a traditional conservative, but voted with Democrats on issues such as immigration and employment non-discrimination. For Congresssman Flake, KBUS's accuracy is 83.92% while PARTYM's accuracy is 76.78%.

Independent candidates : Joseph Lieberman was an Independent senator from Connecticut (I-CT). For Senator Lieberman, KBUS's accuracy is 91.67% while PARTYM's accuracy is 83.33%. Votes cast by Independents cannot be reliably predicted by considering how other Independents would vote on the same bill.

These results further highlight the importance of a model that is able to combine voting history with rich contextual knowledge in order to accurately predict votes.

5 Related Work

Prior work on predicting roll call votes on bills is primarily focused on using Ideal Point Models, which assume that a politician's ideology and the ideology reflected in a bill lie along a single dimension. In Clinton et al. (2004), an Ideal Point model was trained over both politicians and bills/issues, and at inference time the similarity between politician and bill was used to determine how likely the politician was to vote for the bill. However, most politicians have distinct views on different issues, meaning that the views of one politician cannot be captured in a single dimension. Recent work has taken this into account. For example, Gerrish and Blei (2012) created a model in which each politician's ideal point is adjusted per issue, based on the bill text.

Kraft et al. (2016) used an embedding based model which jointly learns bill and politician embeddings, and can predict how a politician will vote on a bill. As demonstrated in this paper, this model works well when a politician's voting track record has already been established. However, it fails for politicians not in the training data, such as those who have never been elected to office or voted on bills relevant to the issues in the target bill. Although we did not implement any Ideal Point Models, they obviously share this weakness.

There have also been approaches that incorporate additional knowledge about politicians and bills to yield extra insight into politicians' voting patterns. Kornilova et al. (2018) enhanced the embeddings learned by their model by providing bill sponsorship information along with a CNN architecture for learning bill embeddings, while Nguyen et al. (2015) supplemented their model by taking into consideration the type of language legislators use. However, these models share the inability of earlier models to predict voting behavior for new politicians or political candidates. In fact, Kornilova et al. (2018) explicitly note that their model cannot handle unobserved politicians: they say, "During testing, we only include legislators present in the training data". The contributions of Kornilova et al. (2018), among them the CNN-based bill representation and the incorporation of bill metadata, are orthogonal to those in this paper. We leave the exploration of how to combine these two approaches to future work.

Our work builds on the idea of using additional knowledge about politicians to enhance vote pre-

diction performance. The model described by Kraft et al. (2016) serves as our baseline model, and our proposed augmented models build on this baseline by supplementing it with additional knowledge about the politicians. Unlike Kornilova et al. (2018), the additional knowledge we inject is about politicians rather than bills. This allows our proposed models to generalize to politicians unseen at training time.

6 Conclusion and Future Work

In this paper we proposed methods for augmenting a state of the art model (Kraft et al., 2016) for roll call vote prediction with rich sources of additional knowledge to facilitate prediction in cases where the voting record for a politician is unavailable at training time. This is typically the case for new candidates for office or newly elected politicians. We demonstrate that our proposed models outperform a previous state-of-the-art model both when the voting record for all politicians in the test set is known and when the voting record of some politicians is not available at training time.

We propose several avenues for future research. First, researchers could explore richer representations for text, both bill text and news text - for example, CNNs or contextual language models like BERT (Devlin et al., 2019). Second, researchers could explore methods for knowledge augmentation using open information extraction or other ways of automatically constructing KBs, to reduce reliance on manually curated knowledge sources which are subject to bias and quickly become out of date. And third, models could be explored that can take into account interactions between politicians (e.g. changes in majority party, changes in politicians' affiliation, party movement leftward or rightward), between bills (e.g. bill combination or revision), and between politicians and bills across sessions of Congress (e.g. bill revision).

Abstract

We propose BeamSeg, a joint model for segmentation and topic identification of documents from the same domain. The model assumes that lexical cohesion can be observed across documents, meaning that segments describing the same topic use a similar lexical distribution over the vocabulary. The model implements lexical cohesion in an unsupervised Bayesian setting by drawing from the same language model segments with the same topic. Contrary to previous approaches, we assume that language models are not independent, since the vocabulary changes in consecutive segments are expected to be smooth and not abrupt. We achieve this by using a dynamic Dirichlet prior that takes into account data contributions from other topics. BeamSeg also models segment length properties of documents based on modality (textbooks, slides, *etc.*). The evaluation is carried out in three datasets. In two of them, improvements of up to 4.8% and 7.3% are obtained in the segmentation and topic identifications tasks, indicating that both tasks should be jointly modeled.

1 Introduction

Documents exhibit a content organization that aggregates related text passages in topically coherent segments. Understanding the document structure at the segment level enables efficient content navigation. This has become more relevant with the number of available documents on the Web. The current information landscape allows access to documents describing the same subject, providing alternative views or complementary information. This is advantageous in a variety of scenarios. For example, students have at their disposal several learning materials and might need to find a particular topic segment that best suits their learning needs. Finding such documents is an easy task since search engines are capable of returning documents conveying related information. However, if search engines are effective in retrieving these documents, the task of putting them into a coherent picture remains a challenge (Shahaf et al., 2012). Automatically finding document segments – text segmentation – and identifying which ones discuss the same topic – topic identification – addresses this issue (Jeong and Titov, 2010).

Text segmentation and topic identification have been used as intermediate steps in a variety of natural language processing tasks, including summarization (Radev et al., 2004), opinion mining (Murakami et al., 2009), semantic and information retrieval (Purver, 2011; Amoualian et al., 2017). The improvements they brought spurred research in text segmentation. Invariably, all works resort to the lexical cohesion theory (Halliday and Hasan, 1976), which postulates that discourse structure is correlated to the use of cohesive vocabulary. Thus, segments can be identified by detecting vocabulary changes. Most approaches either consider segmentation and identification separately and/or do not take into account all documents in the dataset (single-document approach). Recently, some works studied these phenomena in collections of related documents (Jeong and Titov, 2010; Mota et al., 2016). These multi-document models assume that documents describing the same topic have similar lexical cohesion properties; an example of this phenomenon with similar segments but in different documents is depicted in Figure 1. Thus, better likelihood estimations can be obtained if all documents are taken into account (Mota et al., 2016). In this work, we expand the multi-document lexical cohesion idea by hypothesizing that vocabulary relationships between different segments exist. For example, if a word is heavily used in one segment, it is likely that it continues to appear in the following one, though less frequently. Modeling such interactions can lever-

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 582–592
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

age topic segmentation algorithms. We also explore the role of modality in the multi-document scenario. Previous approaches treat all documents equally, but it is plausible that we can improve segmentation by making assumptions about the expected segment length on a document modality basis. For example, segments in slide presentations are expected to be shorter than in video lectures.

We propose BeamSeg, a Bayesian unsupervised topic modeling approach to breaking documents in coherent segments while identifying similar topics. The generative process assumes that segments can share the same topic and, consequently, are generated from the same lexical distribution. Lexical cohesion is achieved by having higher segmentation likelihoods when the probability mass is concentrated in a narrow subset of words. This is in the same spirit as topic modeling approaches such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003), but here the inherent topics are constrained to the linear discourse structure. To model interactions between lexical distributions, we use a dynamic prior, which assumes that the word probabilities change smoothly across topics. To model segment length characteristics, we assign prior variables conditioned on document modality.

The linear segmentation constraint has been used to make inference tractable by exhaustively exploring the segmentation space to obtain the exact maximum-likelihood estimation (Eisenstein and Barzilay, 2008). Given a multi-document setting, this is not feasible, as segments can share topics. We address this issue using a beam search algorithm, which allows the inference procedure to recover from early mistakes. In our experiments, we show that BeamSeg is able to perform well when segmenting learning materials, where previously single-document models obtained better results (Mota et al., 2018). We also observe that topic identification is more accurately determined in a joint model, as opposed to a pipeline approach (performing the tasks sequentially), indicating that both problems should be modeled simultaneously.

We summarize our contributions as follows:

- A novel joint model for topic segmentation and identification with a dynamic prior.
- An inference procedure based on a beam search algorithm.
- A study on how different modality-based segment length priors influence segmentation.

The source code is available in the following repository: `github.com/pjdrm/BeamSeg`.

2 Related Work

Following the lexical cohesion theory, segmentation algorithms identify spans of text with prominent vocabulary changes. The main difference between algorithms is how lexical cohesion is implemented: some resort to lexical similarity; the remaining follow a probabilistic approach.

Lexical approaches rely on a similarity metric between sentences, usually the cosine. A classic method is TextTiling (Hearst, 1997), which assumes that topic boundaries are found in consecutive sentences with a low similarity value; several other works built on this idea (Galley et al., 2003; Balagopalan et al., 2012). C99 (Choi, 2000) is another lexical approach, and uses a similarity matrix in a divisive clustering to obtain segments. MinCut (Malioutov and Barzilay, 2006) casts segmentation in a minimum cut graph partitioning problem. The graph has a node for each sentence; edges are weighted using lexical similarity. Long-distance textual relationships are modeled by connecting all sentences. Affinity Propagation Segmentation (Kazantseva and Szpakowicz, 2011) also models such relationships but uses affinity propagation clustering (Frey and Dueck, 2007). The algorithm creates a factor graph and maximizes the segment similarity sum function. Alemi and Ginsparg (2015) proposed the Content Vector Segmentation (CVS) sentence vector representation based on segment word embeddings. Using this representation in C99 improves bag-of-words results.

In another line of research, Wang et al. (2017) combined learning to rank and a convolutional neural network to learn a coherence function between text pairs; higher-ranked pairs are likely to be segments. Despite a promising approach, state-of-the-art results were not achieved. Also following an approach using neural networks, is the SECTOR algorithm (Arnold et al., 2019), which uses a topic embedding trained based on utterance topic classification. Following the network architecture from (Koshorek et al., 2018), two stacked LSTM layers are used to decode word embedding representation of utterances. To recover segmentation, a TextTiling approach is applied to the topic embedding layer. The evaluation results show that SECTOR is able to improve a C99 baseline.

Just as we introduced average **velocity** we will now describe **average acceleration**. Notice when **velocity** changes ... over **time**. And ... introduce an **average acceleration** ... The **average acceleration** between **time** t2 ... And the dimension ... secs per **time** squared.	**Acceleration** We say ... changing **velocity** are "accelerating" **Acceleration** is the "Rate of change of **velocity**" You hit the accelerator to speed up ... it's true you also hit ... friction is slowing ... **Average acceleration** Unit of **acceleration**: (m/s)/s=m/s2	The **acceleration** of a particle ... rate of change of **velocity** ... **time**. Average acceleration ... is v2 - v1 t2 - t1 ... **Acceleration** may be positive, negative or zero. Zero **acceleration** means we have constant **velocity**. Note that the direction and **acceleration** need not coincide.

Figure 1: Examples of segment excerpts from video, slide presentation, and PDF documents describing the acceleration topic. Words in bold depict shared vocabulary across segments.

Probabilistic approaches to segmentation follow a setup similar to the LDA model: words are assigned to topics such that probability mass is distributed on a small set of topically relevant words. In order to adapt this idea to segmentation, the model needs to be able to determine if sentences belong to the same topic (or mixture of topics). An example of such adaptation is the single-document segmentation model PLDA (Purver et al., 2006), where topic proportions are shared by sentences within the same segment. Segmentation is then determined through a binary topic shift sentence variable. Models such as TopicTiling (Riedl and Biemann, 2012), Structured Topic Model (STM) (Du et al., 2013), and NTSeg (Jameel and Lam, 2013) extend this LDA-based approach to segmentation. In all these approaches, topic identification is not possible since all segments are a mixture of topics.

In this paper, we adopt a probabilistic multi-document view on segmentation. Only two other models follow this approach: MultiSeg (Jeong and Titov, 2010) and Bayesseg-MD (Mota et al., 2016). MultiSeg uses a two-level LDA model where documents are generated using local and global topics. Local topics are specific to a document; global topics are shared between documents. Documents are mixtures of topics, but each segment is generated by a single topic, lending itself to a joint model of segmentation and topic identification. The multi-document aspect of the model stems from topic proportions being inferred from the whole dataset. In the experiments, this joint modeling outperforms a pipeline strategy that performs these tasks sequentially.

The other multi-document model, Bayesseg-MD, is an extension of Bayesseg (Eisenstein and Barzilay, 2008). In Bayesseg, sentences from the same segment are assigned the same topic. The inference procedure affords an exact maximum-likelihood estimation by exploring the segmentation space with a dynamic programming algorithm. This approach cannot be applied to multi-document segmentation since the hidden topic variables are integrated out; other single-document models following this approach also have this problem (Eisenstein, 2009; Malmasi et al., 2017). Bayesseg-MD sidesteps this problem by using lexically similar sentences from other documents. The word counts of such sentences are added to the segment likelihood estimation to reduce data sparseness. Despite using all documents for segment likelihood estimations, topic identification is not available. In this paper, we address these issues by designing an inference algorithm that explicitly tracks segment topic assignments.

3 BeamSeg Model

We implement lexical cohesion in a Bayesian setting in a generative process where segments with the same topic are drawn from the same multinomial language model. Thus, all u utterances with a topic k have their bag-of-words representation $\mathbf{x}_u$ drawn from language model ϕ_{z_u}; z_u is the hidden topic variable of u. We constrain the model to yield linear segmentations by having topics occurring at most once per document. This induces higher likelihood segmentations to have language models concentrating probability mass on a small subset of the vocabulary. Conversely, low likelihood segmentations spread the probability mass on a broad set of words. This modeling behavior is attuned to the lexical cohesion theory. Multi-document segmentation emerges by assuming that topics are shared across documents.

During inference, we want to find the hidden

set of language models Φ and the topic vector assignment $\mathbf{z}$ that maximize the likelihood of the joint distribution of the model. Since we only care about segmentation, this process can be simplified by analytically marginalizing out the hidden language models Φ. This enables search to be carried out only in the segmentation space. Therefore, inference amounts to finding the segmentation $\hat{\mathbf{z}} = \text{argmax}_{\mathbf{z}}\, p(\mathbf{X}|\mathbf{z})p(\mathbf{z})$. Using the marginalized joint likelihood, an approximation of $\hat{\mathbf{z}}$ is obtained using a beam search algorithm.

3.1 Language Models

Using the previous setup, we define the joint likelihood as follows:

$$p(\mathbf{X}|\mathbf{z}, \Phi) = \prod_{k}^{K} p(\phi_k|\beta) \prod_{u}^{U} p(\mathbf{x}_u|\phi_{z_u}), \quad (1)$$

where $\mathbf{X}$ is the set of all U utterances in the dataset; K is the number language models; and β are the Dirichlet prior parameters from which Φ is drawn.

The marginalization process is performed by appealing to the conjugacy between multinomial language models and the Dirichlet prior. This allows the conjugate Dirichlet distribution to integrate to one, leaving the marginalized joint likelihood expression with the normalizing constants:

$$\begin{aligned} p(\mathbf{X}|\mathbf{z}) &= \int p(\mathbf{X}|\mathbf{z}, \Phi)p(\Phi|\beta)d\Phi \quad (2) \\ &= \Big(\frac{\Gamma(W\beta)}{\Gamma(\beta)^W}\Big)^K \prod_{k=1}^{K} \frac{\prod_{w=1}^{W} \Gamma(n_{U,w}^k + \beta)}{\Gamma(n_U^k + \beta)}, \end{aligned}$$

where W is the vocabulary set; $n_{U,w}^k$ is number of times word w is assigned topic k in all U utterances of the document collection; n_U^k is number of times topic k appears in U; and the symbol Γ refers to the Gamma function. The resulting expression in Equation 2 corresponds to the product of the individual topic likelihoods, comprised of segments from different documents.

3.2 Segment Length Prior

The $\hat{\mathbf{z}} = \text{argmax}_{\mathbf{z}}\, p(\mathbf{X}|\mathbf{z})p(\mathbf{z})$ expression we want to maximize to obtain the most likely segmentation puts a prior, $p(\mathbf{z})$, on the segment length of documents. Given the approach of searching the segmentation space only during inference, we do not require the mathematical conveniences of conjugacy for the segment length prior. In this perspective, we can plug in different distributions to see how they behave during the segmentation task. One of such distribution is the Beta-Bernoulli, which has been used before in a probabilistic approach to segmentation (Purver et al., 2006):

$$p(\mathbf{z}) = \left(\frac{\Gamma(2\gamma)}{\Gamma(\gamma)^2}\right)^D \prod_{d=1}^{D} \frac{\Gamma(n_1^d + \gamma)\Gamma(n_0^d + \gamma)}{\Gamma(U_d + 2\gamma)}, \quad (3)$$

where D is the number of document in the dataset, U_d is the total number of utterances in document d, n_1^d is the number of segments in d, n_0^d the number of non-segment boundary utterances in d, and γ the hyperparameter of the Beta distribution.

We also propose a Gamma-Poisson distributed segment length prior. In this setup, we assume that the document topic shift probabilities are drawn from a Gamma prior parameterized by α and β:

$$p(\mathbf{z}) = \left(\frac{\beta^\alpha}{\Gamma(\alpha)}\right)^D \prod_{d=1}^{D} \frac{\Gamma(n_1^d + \alpha)}{(U_d + \beta)^{n_1^d + \alpha}} \quad (4)$$

Applying priors based on document modality can be done by assuming they are known *a priori*, which is the approach we take. It is only necessary to have dedicated hyperparameters for each modality and apply them accordingly when computing segmentation likelihood. This means we are encoding in the model our prior beliefs about the segment length of each modality. Nonetheless, if the lexical cohesion in a hypothesized segment is strong enough, the model will identify it even if the length is not inline with the prior.

3.3 Dynamic Language Model Prior

The previous priors assume that language model's draws are independent of each other, and, thus cannot encode relationships between them. This is not a reasonable assumption in datasets with documents following an overarching subject. We hypothesize that in these cases, language models change smoothly across topics by establishing a dynamic between the previous and the current prior parameters. This time series modeling of topics can be found in other works (Blei and Lafferty, 2006b,a; Du et al., 2013; Jahnichen et al., 2018). In BeamSeg, we adopt a similar perspective to topic tracking (Watanabe et al., 2011) for modeling such interactions. We factor the β in $\alpha_k \hat{\phi}_{k'}$, a precision and mean language model word

probabilities parameters. Assuming some ordering between the topics, k indexes the topic parameters, and k' the parameters of the previous topic. The α_k precision represents the persistence of word usage throughout topics; $\hat{\phi}_k$ models the language model dynamics by assuming that the mean word probabilities at k are the same as those at k'. This entails that there is a single chain of language models, which contrasts with the multiple chains in the original topic tracking model.

To compute the likelihood of the joint under this prior, it is necessary to determine the parameters for all $k \in K$. This is a two-fold process, where we first update the α_k precision parameter using the expression derived from Minka (2000):

$$\alpha_k = \alpha_k \frac{\sum_{w}^{W} \hat{\phi}_{k'w}(\Psi(n_{kw} + \alpha_k \hat{\phi}_{k'w}) - \Psi(\alpha_k \hat{\phi}_{k'w}))}{\Psi(n_k + \alpha_k) - \Psi(\alpha_k)}, \tag{5}$$

where n_{kw} is the number of times word w appear in k; n_k is the total number of words in k; and Ψ is the digamma function. Then, we update the mean word probability parameters:

$$\hat{\phi}_{kw} = \frac{n_{kw} + \alpha_k \hat{\phi}_{k'w}}{n_k + \alpha_k} \tag{6}$$

The update equations are sequentially applied according to a fixed topic order. By following this process, we model long-range dependencies by taking into account the data contribution at each k. Finally, we plug-in the obtained prior parameters in the join likelihood formula in Equation 2.

3.4 Beam Search for Inference

Following Bayesseg (Eisenstein and Barzilay, 2008), inference is viewed as an optimization problem, where the target segmentation maximizes the objective function defined by the joint likelihood. Contrary to Bayesseg, we assume that language models aggregate segments from different documents, making an exhaustive exploration of the segmentation space intractable. To address this problem we combine beam search and a greedy segmentation procedure. Other considered inference alternatives include Gibbs sampling (Bishop, 2006) and Variational Inference (Ghahramani et al., 2008). The difficulty in applying Gibbs sampling is its slow convergence to the stationary distribution, due to the tight coupling of the variables induced by the linear segmentation constraint. A similar problem occurs in the variational inference procedure from Eisenstein (2009), where variational parameters and segmentation are iteratively estimated.

We define $\mathbf{z}_j^*$ as the segmentation that maximizes the objective function up to utterance j. Considering the topic assignment $z_j = k$ and the previous segmentation $\mathbf{z}_{j-1}$, the value for the objective function is written,

$$s(k, j, \mathbf{z}_{j-1}) = p(\{\mathbf{x}_0 ... \mathbf{x}_j\} | \mathbf{z}_{j-1}, z_j = k) \tag{7}$$

Using a recursive definition, we obtain the optimal segmentation using:

$$\mathbf{z}_j^* = \underset{k \in K}{\operatorname{argmax}}\, s(k, j, \mathbf{z}_{j-1}^*) \tag{8}$$

This is a greedy approach since it makes incremental decisions to find the highest likelihood segmentation. This is an error-prone procedure since we should take into account subsequent utterances to discover higher likelihood segmentations. Moreover, once a mistake is made, we cannot recover from it. To address this problem, we add a beam search feature to the algorithm. This is achieved by keeping track of all topic assignments, instead of just the highest likelihood one. At the end of each recursive step, we prune the top-n segmentations.

4 Experiments

We now describe the experimental setup and report the results for the target tasks.

4.1 Datasets

Currently, there are two multi-document segmentation datasets with different document modalities. One of the datasets is comprised of learning materials describing the subject of Adelson-Velsky and Landis' (AVL) trees (Mota et al., 2016). The available modalities are video transcripts, PPT, and HTML. In total, the dataset contains 10 documents, 85 segments, and 17 topics. The other dataset also contains learning materials but from the Physics domain (Mota et al., 2018). In addition, this dataset also has PDF modality. The dataset has 141 documents, 739 segments, and 135 topics from 7 different Physics subjects. This dataset does not provide topic identification labels

for the segments. Therefore, we manually annotated it with this information. In this context, we made an inter-annotator agreement study for the 'Introduction to Kinematics' subject with two annotators. A 0.69 Fleiss-kappa (Shrout and Fleiss, 1979) agreement value was obtained, showing that annotators had a similar perception of whether segments share the same topic. Most of the disagreement cases are due to considering textual and plot-based explanations as different topics.

In addition to the previous datasets, we also used Biography documents from Jeong and Titov (2010). The dataset contains 116 documents regarding 29 personalities; 4 documents per personality with a total of 240 segments; the number of topics is 405; all documents have the same HTML modality. The Biography domain has different topic development characteristics from the previous domains. The documents have fewer and shorter segments when compared with the AVL and Physics domains, leaving less room for topics to be described. All datasets were preprocessed by stemming and stop words were removed.

4.2 Segmentation Experiments

In the experiments, we benchmark syntax similarity and probabilistic approaches: C99, CVS, Bayesseg, PLDA, Bayesseg-MD, and MultiSeg. The hyperparameter tuning of the models is done on a development set. In the Biography dataset, we use documents from one of the personalities. For MultiSeg we use the configurations provided by the authors. In the Physics domain, we use ten documents from one of the subjects. The obtained tuning is also used for the AVL trees domain since both datasets have pedagogical content. The Gibbs sampling for PLDA run for 20000 iterations with a burn-in period of 1000 and a lag value of 200. In BeamSeg, we investigate the role of two factors in segmentation: using the dynamic *vs.* an independent language model prior, and using a modality-based segment duration prior *vs.* using a single prior variable. The beam size was set to 200.

To measure performance, we use the standard Window Difference (WD) metric (Pevzner and Hearst, 2002). WD slides a window through a document and penalizes segmentations according to the difference between the number of expected segment boundaries and the predicted ones. This gives partial credit to near-miss situations. The metric is calculated as follows:

$$\text{WD} = \frac{1}{N-k} \sum_{i=1}^{N-k} |ref - hyp| \neq 0, \quad (9)$$

where N is the length of the document and k the window size. WD is a penalty score between 0 (the best value) and 1. For consistency, we take the output segmentations from all systems and evaluate it using the same software (the python module `segeval` (Fournier, 2013)).

The WD average results for the baseline are in Table 1. In the Biography dataset, MultiSeg is the best performing model, improving the WD of Bayesseg-MD by 0.05. In the AVL dataset, the best results are obtained by Bayesseg-MD. The difference to the second best result, Bayesseg, is 0.02. For the Physics dataset, the single-document model Bayesseg achieves the best results with a WD difference of 0.01. These results show that the performance of the algorithms varies across the different datasets. This suggests that the different modeling approaches do not generalize well to the different characteristics of the datasets. The Biography dataset is characterized by short segments, which does not leave much room for lexical cohesion to be observed. This contrasts with the AVL and Physics datasets where the segments are longer and describe an overarching topic.

Table 1: Segmentation baseline average WD results.

	Bio	**AVL**	**Physics**
C99	0.61	0.59	0.54
PLDA	0.58	0.55	0.49
CVS	0.54	0.45	0.43
Bayesseg	0.53	0.39	**0.42**
Bayesseg-MD	0.42	**0.37**	0.43
MultiSeg	**0.37**	0.41	0.44

The results using different prior configurations are in Table 2. In the table, the LMP and SLP columns correspond to the language model and segment length priors. In the Biography dataset, we can see that using the dynamic LMP instead of the independent improves the the Beta-Bernoulli and Gamma-Poisson results by 0.01 and 0.09, respectively. In the AVL dataset, the dynamic LMP improves the best WD results of the independent LMP by 0.02. When comparing the scope results of the dynamic LMP in the AVL dataset, we observe further improvements when

Table 2: BeamSeg average WD results. The SLP column depicts the Beta-Bernoulli (BB), and Gamma-Poisson (GP) distributions. The scope indicates if the SLP is modality-based (M) or if there is one variable for the whole dataset (D). The Biography dataset has one modality, and, thus, only the D scope exists.

LMP	SLP	Scope	Bio	AVL	Physics
Ind	BB	D	0.54	0.39	0.45
		M	–	0.40	0.42
	GP	D	0.58	0.40	**0.40**
		M	–	0.43	0.42
Dyn	BB	D	0.53	0.44	0.54
		M	–	0.38	0.42
	GP	D	0.49	0.38	0.47
		M	–	**0.37**	**0.40**

Table 3: Number of exact segment boundary matches between hypothesis and reference segmentations.

LMP	SLP	Scope	Bio	AVL	Physics
Ind	BB	D	88	1	16
		M	–	1	8
	GP	D	15	1	5
		M	–	1	20
Dyn	BB	D	147	3	34
		M	–	4	39
	GP	D	244	2	19
		M	–	5	46

using the modality-based SLP; the results differences are 0.06 and 0.01, respectively. In the Physics dataset, a dynamic LMP combined with the modality-based Gamma-Poisson SLP obtains the best results tied with the independent LMP and dataset-based Gamma-Poisson SLP. It should be noted that the former configuration better generalizes across the different datasets since it obtains better results in the Biography and AVL datasets; the WD differences are 0.09 and 0.03, respectively. Looking at the scope results of the dynamic LMP, we observe that the Beta-Bernoulli and the Gamma-Poisson perform better when using the modality prior (0.12 and 0.07 improvements).

WD is a metric that assesses the overall quality of a segmentation, accounting for different types of errors. This can make the WD scores of two very different segmentations to be close, which is the case of the previous results. For example, a segmentation that has no segments and another that only has misplaced segments will have similar WD scores despite being different. To show that the different prior configurations output significantly different segmentations, we provide the counts of the exact segment boundary matches in Table 3. From these results, we can observe that using a dynamic LMP can increase the number of boundary up to 229. A similar observation can be made when comparing the dataset and modality scopes, where the increases are up 27 segments. These increases in exact boundary matches show that despite the small differences in WD the impact on how the segmentation looks like is significant. Therefore, we conclude that using a dynamic LMP with a modality Gamma-Poisson SLP is necessary to achieve the best results.

Comparing BeamSeg's results to the baseline, we see that in the Biography dataset MultiSeg performs better by a 0.12 margin. The main difference between the segmentation of the two approaches is that BeamSeg outputs fewer segments, which is a disadvantage since this dataset has a high number of short segments. In the AVL dataset, the performance is similar to Bayesseg-MD. Looking at the individual documents shows that BeamSeg has better results in five out of ten documents, one tie, and two documents where the WD difference is 0.01. This leaves Bayesseg-MD to perform significantly better only in two documents. Therefore, BeamSeg is more consistent in this dataset. In the Physics dataset, BeamSeg improves the Bayesseg baseline by 4.8%. Taking into account the result analysis, we conclude that BeamSeg's performance depends on the characteristics of the datasets. In datasets where topic development is prominent across the segments (AVL and Physics), BeamSeg is the model with the most consistent results. This is only possible when using a dynamic LMP and a modality Gamma-Poisson SLP, showing that both modeling aspects are relevant to obtain the best segmentation.

To understand the behavior of the priors we provide a segmentation example in Figure 2. From the example, we see that the main difference between the independent and dynamic LMPs is the number of segments. In the independent LMP, the number of segments is low, especially when using the dataset SLP. For the modality SLP, the number of segments is higher but they tend to be mis-

placed. When using dynamic LMP, the behavior changes at the SLP level. The dataset SLP outputs more segments than the modality version. However, most segments do not match the reference. The modality SLP finds fewer segments, but they tend to be more accurate. This makes sense since the over-segmentation of the dataset SLP might be related to the bias towards documents with short segments, and the modality prior is able to adjust to a wider variety of documents.

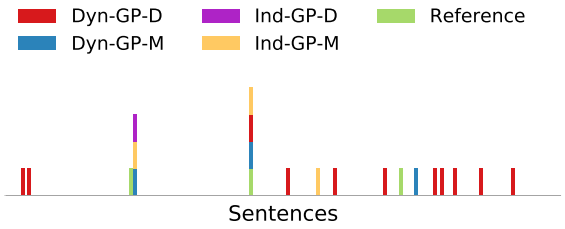

Figure 2: Physics document segmentation using different prior configurations in BeamSeg. Bars with the same color represent segments of the same prior configuration. The names of the configurations start with the LMP type, followed by the SLP, and its scope.

4.3 Topic Identification Experiments

We use the previous datasets to evaluate topic identification and compare multi-document joint models to a pipeline approach. In the pipeline approach, we evaluate clustering and graph-community detection algorithms. The clustering algorithms take the golden standard segments and identify segments sharing the same topic if they are assigned the same cluster. Several clustering algorithms are surveyed (Aggarwal and Reddy, 2014): DBSCAN, Mean Shift, and NMF. For the graph-community detection approach, word communities are obtained from the segments. Then, based on lexical similarity, segments are assigned to one of the communities (Mota et al., 2018). If two segments are assigned to the same community, they share the same topic. Several graph-community detection algorithms are surveyed (Fortunato, 2010): Bigclam, Label Propagation, CNM, Walktraps, and Leading Eigenvector. For conciseness, we only report the results of the best algorithms.

To measure the performance, we use the standard B^3 clustering metric (Amigó et al., 2009). B^3 decomposes uses item-wise precision and recall. Precision represents how many items in the same cluster belong to its class. Recall represents how many items from a class appear in the cluster. The final B^3 value combines precision and recall:

$$B^3 = \frac{1}{0.5(\frac{1}{Pre}) + 0.5(\frac{1}{Rec})} \quad (10)$$

The baseline results are depicted in Table 4. In this benchmark, the pipeline approach performs better than the joint model in all datasets. The differences range between 0.04 and 0.14 in B^3 score. The DBSCAN clustering approach obtains the best performance in the Biography dataset by a 0.09 margin.The Louvain graph-community detection approach obtains the best results in the AVL and Physics datasets with result differences to DBSCAN of 0.04 in both cases.

Table 4: Topic identification baseline results.

	Bio	AVL	Physics
DBSCAN	**0.66**	0.33	0.34
Louvain	0.57	**0.37**	**0.38**
MultiSeg	0.52	0.29	0.30

Table 5 shows the results for different prior configurations. In the Biography domain, we observe that the dynamic LMP improves the results of both SLPs; 0.03 and 0.16, for the Beta-Bernoulli and Gamma-Poisson, respectively. In the AVL datasets, three different configurations obtain the best performance. In the Physics dataset, the dynamic LMP modality Gamma-Poisson SLP performs better. In this case, using a modality SLP instead of the dataset affords a 0.11 improvement. Comparing the independent and dynamic LMPs, we see that the former improves the results by 0.05. This shows that both modeling aspects are contributing for the best results.

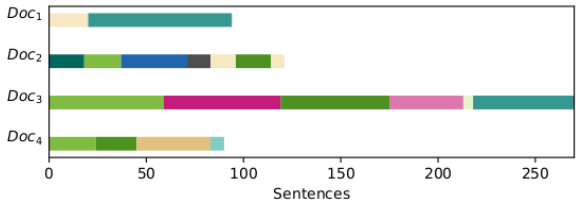

Table 5: BeamSeg topic identification results.

LMP	SLP	Scope	Bio	AVL	Physics
Ind	BB	D	0.51	0.35	0.36
		M	–	**0.39**	0.38
	GP	D	0.37	0.38	0.35
		M	–	0.36	0.37
Dyn	BB	D	0.54	**0.39**	0.30
		M	–	0.32	0.34
	GP	D	0.53	0.38	0.31
		M	–	**0.39**	**0.41**

Comparing BeamSeg's best results to the baseline, we observe that it is only outperformed by DBSCAN in the Biography dataset (a 19.7% difference). DBSCAN obtains better results by putting segments it cannot group in individual clusters, which keep the larger clusters clean. In BeamSeg, the number of identified topics (clusters) is lower, a 385 difference to DBSCAN, which ends up forcing wrong topic segment assignments. In the AVL dataset, BeamSeg improves the Louvain baseline by 5.1%. The topic identification behavior of both approaches is different from the Biography dataset. Louvain only outputs 7 clusters whereas the reference has 17 topics. This is related to the topic development aspect across segments, which makes them hard to distinguish. BeamSeg obtains a higher B^3 score because it is able to identify 15 topics, a number closer to the reference, and, consequently, assign topics more appropriately. In the Physics dataset, BeamSeg improves the baseline by 7.3%. The topic identification patterns are similar to the ones observed in the AVL dataset with BeamSeg outputting more topics than Louvain, 70 and 48 topics, respectively. Another observation is that the performance differences between the Biography and the other datasets are related to the topic structure complexity. In the Biography dataset, there is a tendency for the topic order to persist across documents, whereas in the other datasets the interweaving of the topics is not as regular. This is depicted in Figure 3, where color changes represent a topic changes and similar topics have the same color. In Figure 3a (Biography domain) we can see that the colors sequences in different documents are similar whereas in Figure 3 (Physics domain) the sequence is not constant. Connecting the topic structure differences with the topic order assumptions in BeamSeg explains the performance differences.

5 Conclusions and Future Work

In this work, we propose BeamSeg, an unsupervised Bayesian algorithm that jointly segments documents and identifies topical relationships using a beam search procedure to find high likelihood segmentations during inference. Relationships between topics are modeled using a dynamic prior encoding that word distributions change smoothly in documents with an overarching subject. BeamSeg also models segment length properties based on document modality. To evaluate segmentation, single and multi-document algorithms were used as a baseline. For topic identification, we compared BeamSeg to MultiSeg, another joint model, as well as a pipeline approach. In both tasks, BeamSeg obtains the best results in two of the datasets used for evaluation. The conclusion from the evaluation is that BeamSeg is effective in datasets with prevalent topic development throughout document segments. To achieve the best performance, it is necessary to use a combination of a dynamic LMP with a modality Gamma-Poisson SLP. Therefore, the proposed modeling assumptions fit the data well. This supports the hypothesis that lexical cohesion is a cross-document phenomenon and can be used to leverage multi-document segmentation and topic identification.

Regarding future work, one of the concerns is that the proposed inference procedure is a maximum likelihood estimation approach. Ideally, we want to access the full posterior distribution since it finds more accurate parameters. Another concern is the raw assumption that there is a shared topic ordering among all documents. We believe that addressing these issues will allow BeamSeg to improve its results and to consistently perform in datasets with different characteristics.

Abstract

This paper focuses on how to extract multiple relational facts from unstructured text. Neural encoder-decoder models have provided a viable new approach for jointly extracting relations and entity pairs. However, these models either fail to deal with entity overlapping among relational facts, or neglect to produce the whole entity pairs. In this work, we propose a novel architecture that augments the encoder and decoder in two elegant ways. First, we apply a binary CNN classifier for each relation, which identifies all possible relations maintained in the text, while retaining the target relation representation to aid entity pair recognition. Second, we perform a multi-head attention over the text and a triplet attention with the target relation interacting with every token of the text to precisely produce all possible entity pairs in a sequential manner. Experiments on three benchmark datasets show that our proposed method successfully addresses the multiple relations and multiple entity pairs even with complex overlapping and significantly outperforms the state-of-the-art methods. All source code and documentations are available at https://github.com/chenjiayu1502/MrMep.

1 Introduction

Extracting relational facts from unstructured text is a significant step in building large-scale knowledge graphs. A relational fact is typically represented as a triplet $<h, r, t>$ where h represents a head entity, t represents a tail entity, and r is a relation that connects h to t.

A number of neural models for extracting relational facts have been developed in recent years, and the most successful models all have one thing in common: they extract both relation and its corresponding entity pairs in a manner of joint learning (Zheng et al., 2017; Zeng et al., 2018; Takanobu et al., 2019). However, jointly extracting relation and entity pairs is far from a trivial task due that there might exist more than one relation within the text, while each target relation might correspond to more than one entity pair. A more challenging aspect of this problem is that there might exist complex overlapping among different triplets. As exemplified in Figure 1, the entity "$Indonesia$" overlaps in all triplets within the text, while $<Indonesia, leaderName, Jusuf\ Kalla>$ and $<Indonesia, leaderName, Joko\ Widodo>$ have the same relation type "$leaderName$", $<Bakso, region, Indonesia>$ and $<Bakso, country, Indonesia>$ share the same head and tail entities.

A well-defined relational fact extraction task aims to detect all possible relation types in the text, and extract all candidate entity pairs for each target relation type, while taking into account the complicated overlapping among the triplets.

Zheng et al. (2017) propose a tagging mechanism (referred as Tagging thereafter) to transform the relational fact extraction into a sequence labeling task by injecting the information of relation type and entity position into tags. In this paradigm, Tagging model assigns a unique label to each word, which fails to extract triplets with overlapped entities or even overlapped entity pairs.

Zeng et al. (2018) model the triplet extraction using sequence-to-sequence learning with copy mechanism (referred as CopyR thereafter) that is often used in sentence generation (Gu et al., 2016; He et al., 2017). Takanobu et al. (2019) apply a hierarchical framework with reinforcement learning, which decomposes triplet extraction into a high-level task for relation detection and a low-level task for entity extraction (referred as HRL thereafter). Both CopyR and HRL determine a relation type each time and detect an entity pair for it, then

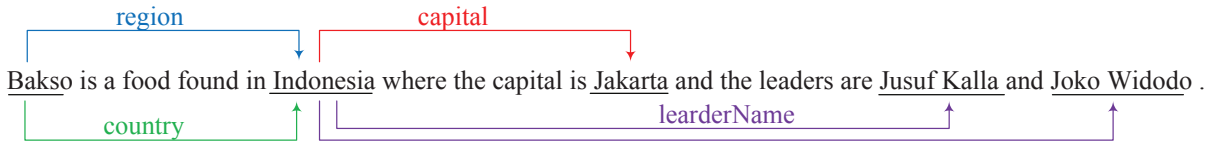

Figure 1: An example of multiple triplets. Entities are underlined, the relation types between entity pairs are connected by colored lines marked with relation types.

repeat the process to extract all triplets. However, to extract multiple entity pairs for a relation type, both CopyR and HRL have to repeatedly predict the relation type in multiple passes, which is computationally inefficient.

In this work, we propose, with simplicity and effectiveness in mind, a novel approach for jointly extracting Multiple Relations and Multiple Entity Pairs (MrMep). MrMep utilizes a triplet attention to exploit connections between relation and its corresponding entity pairs. It first predicts all possible relations, then for each target relation, it uses a variant of the pointer network (Vinyals et al., 2015) to generate boundaries (START/END positions) of all head and tail entities in a sequential manner, whereby the model generates all possible entity pairs as answers. In this way, for each candidate relation type, relation detection only needs to be performed one time, and then all possible entity pairs can be extracted for it, avoiding the repeated process of relation identification that is adopted in both CopyR and HRL. Moreover, we approach entity overlapping problems by a variant of the pointer network. It can sequentially generate entity boundaries in arbitrary position within the text. Therefore, it allows entities freely to participate in different triplets.

Our contributions can be summarized as follows:

- We propose MrMep, a novel neural method which firstly extracts all possible relations and then extracts all possible entity pairs for each target relation, while the two procedures are packed together into a joint model and are trained in a joint manner.
- MrMep uses a triplet attention to strengthen the connections among relation and entity pairs, and is computationally efficient for sophisticated overlapped triplets even with lightweight network architecture.
- Through extensive experiments on three benchmark datasets, we demonstrate MrMep's effectiveness over the most competitive state-of-the-art approach by 7.8%, 7.0% and 9.9% improvement respectively in F1 scores.

2 Related Work

Traditional pipelined approaches (Chan and Roth, 2011; Zelenko et al., 2003; Lin et al., 2016) separately design two subtasks of relation identification and entity pair extraction, ignoring the connection between them (Li and Ji, 2014) and suffering from error propagation.

To address the above problems, several joint models have been proposed. Early work (Li and Ji, 2014; Yu and Lam, 2010; Miwa and Sasaki, 2014) builds the connections between relation identification and entity recognition by designing multiple ingenious features, which needs complicated feature engineering. Recently, with the success of deep learning on many NLP tasks, several pieces of work (Miwa and Bansal, 2016; Gupta et al., 2016; Zhang et al., 2017) jointly model the interaction between the two subtasks based on neural networks, which they firstly apply RNN or CNN to encode the text, then treat entity recognition as a sequence labeling task and regard relation extraction as a multi-class classification problem. Zheng et al. (2017) formulate joint triplet extraction problem to the task of sequence labeling, by deliberately designing a tagging schema that injects information of relation type and entity position into tags. However, due to the limitation that a word can only be assigned a unique label in sequence labeling task and unique relation type can be assigned to each entity pair in multi-class classification problem, the above methods cannot fully address the triplet overlapping problem.

Most recent work aims at further exploring the overlapping triplet extraction. Zeng et al. (2018) propose CopyR, a joint model based on copy mechanism to convert the joint extraction task into a triplet generation task. For simplification, CopyR only copies the last word of the

entity, thereafter it cannot extract the whole entities consisting of multiple words. Takanobu et al. (2019) propose a hierarchical reinforcement learning framework that decomposes the joint extraction task into a high-level task for relation detection and a low-level task for entity extraction. However, both CopyR and HRL generate each relation type along with one entity pair at each time. In this paradigm, both of them have to perform the same relation detection multiple times to explore all possible entity pairs, which is computationally inefficient and principled not graceful enough.

We propose MrMep, a novel joint extraction framework that not only can jointly model triplet extraction task, but also efficiently extract various overlapped triplets. First, MrMep executes multiple relation classifiers by adopting a binary classifier for each relation type. Second, MrMep performs variable-length entity pair predictor. It utilizes a pointer network (Vinyals et al., 2015) alike way to generate the START/END positions for all the candidate head and tail entities in a sequential fashion, which is tracked by an LSTM decoder until it produces a word position beyond the text boundary. Inspired by machine reading and comprehending models (Wang and Jiang, 2016; Seo et al., 2017), we use the relation as a query, and conduct interaction between query and text via a triplet attention with relation peeking all possible entity pairs. We discuss two different principled ways to perform the above triplet attention, and demonstrate the versatility and effectiveness of our methods on both English and Chinese relational fact extraction benchmarks.

The main difference between our models and CopyR and HRL is that ours has the advantage of learning a strategic decoder using triplet attention that can model the interaction between relation and entity pairs. By letting the decoder only predict entity pairs, we relieve it from the burden of having to generate relation types repeatedly.

Das et al. (2019)'s work is similar in spirit to our work in that we both use a machine reading comprehension framework to extract relations and entities. But our approach differs from that of Das et al. (2019): their work aims at extracting newest state from procedural text which mainly describes the entity state at different steps, while our work is proposed for extracting multiple triplets from arbitrary unstructured text. Another similar approach is introduced by Roth et al. (2019), which performs relation argument extraction given a query entity and relation, essentially not for joint triplet extraction.

3 The Approach

3.1 Overview

For relational fact extraction task, the input is a text paragraph with n words $S = [w_1, ..., w_n]$. Let $\mathcal{R}$ be the set of predefined relation types. The task is to predict all possible triplets $<e_i, r_{ij}, e_j>$ maintained in S, where e_i, e_j are sequences of tokens denoting head entity and tail entity respectively, and $r_{ij} \in \mathcal{R}$ is the relation type that connects e_i to e_j.

Figure 2 shows an overview architecture of the proposed MrMep. It consists of three main parts: Encoder, Multiple Relation Classifiers and Variable-length Entity Pair Predictor. The encoder preprocesses the source text and extracts the sequence-level features using a Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), the multiple relation classifiers predict all possible relations maintained in S, and the variable-length entity pair predictor sequentially generates all possible entity pairs for each possible relation type.

3.2 Encoder

Given a text paragraph $S = [w_1, ..., w_n]$, we first embed it to obtain text embedding $E \in \mathbb{R}^{n \times d_e}$, where n is the length of words in text, d_e denotes the dimension of word embedding pretrained using Glove (Pennington et al., 2014). Then an LSTM is used to learn the token representation X_i for each word w_i:

$$X_i = LSTM_{encoder}(E_i, X_{i-1}), \quad (1)$$

where X_{i-1}, $X_i \in \mathbb{R}^d$ denotes word vectors for word w_{i-1} and w_i, yielding the text representation matrix $X = [X_1, ...X_n] \in \mathbb{R}^{n \times d}$.

The LSTM maps the variable length input sequences to a fixed-sized vector, and uses the last hidden state $X_n \in \mathbb{R}^d$ as the representation vector of the text.

3.3 Multiple Relation Classifiers

The relation classifier aims to identify relation types contained in the text. Since a text may contain multiple relations, inspired by the idea of multi-label classification, we design M CNN (Kim, 2014) based binary classifiers, respectively

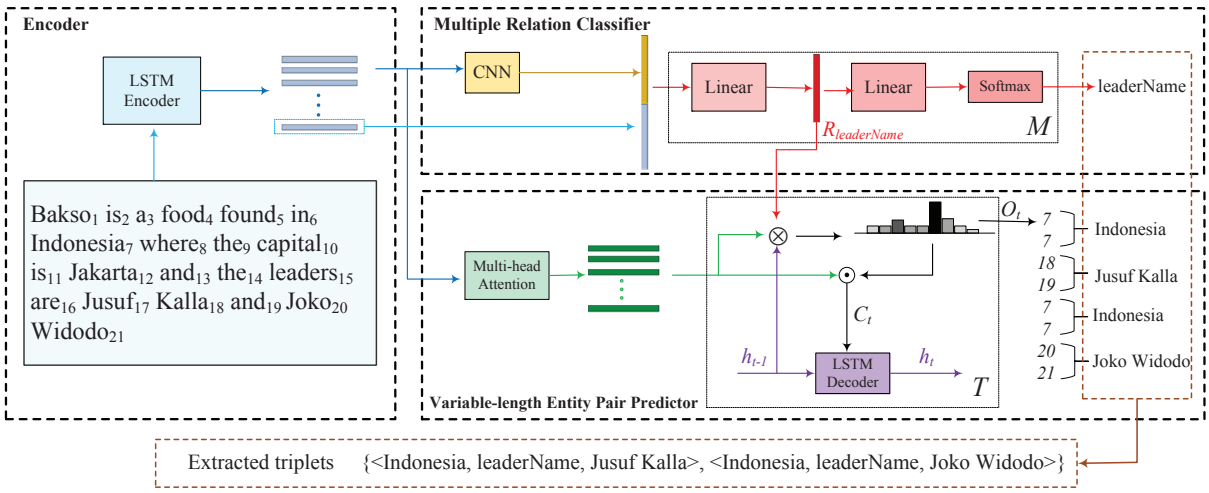

Figure 2: The model architecture of MrMep.

for M relation types, whose output is the probability distribution over whether the corresponding relation is a possible relation or not.

We adopt a convolutional neural network with the same structure as in Kim (2014). Given the text representation $X \in \mathbb{R}^{n \times d}$. A convolution operator and max-over-time pooling (Collobert et al., 2011) operator are applied:

$$C = Conv(X), \tag{2}$$

$$Q = relu(max(C)), \tag{3}$$

where $C \in \mathbb{R}^{m \times (n-l+1)}$ is the feature map output by the convolution operator, m is the number of different filters, n is the length of the text, l is the convolutional filter size. Eq. (3) applies an max-over-time pooling operator on feature map C first, and then a $relu$ activation is used to obtain the text embedding $Q \in \mathbb{R}^m$. When sliding over the text with a window size l, different filters offer a variety of l-gram compositions. Therefore, the text embedding Q is viewed as local feature vector of the text in our model.

In order to make better use of the features extracted by LSTM and CNN, a concatenation operator is used between the last word representation X_n in the encoder and text embedding Q from CNN to produce a fused vector $H \in \mathbb{R}^{m+d}$:

$$H = Concat(Q, X_n). \tag{4}$$

The binary classifier for j-th relation type is shown as follows (We omit the bias b for simplification):

$$R_j = HW_j^H, \tag{5}$$

$$Y^j = softmax(R_j W_j^R). \tag{6}$$

As in Eq. (5), a linear layer is applied to produce the hidden layer state $R_j \in \mathbb{R}^d$. $W_j^H \in \mathbb{R}^{(m+d) \times d}$ is a learnable weight matrix. As in Eq. (6), another linear layer with a $softmax$ activation function is used to predict the probability distribution of whether the text contains the j-th relation type or not, $Y^j \in \mathbb{R}^2$. $W_j^R \in \mathbb{R}^{d \times 2}$ is weight parameter. The hidden layer state R_j is viewed as the relation embedding for j-th relation type.

If the text contains j-th relation type, R_j will be fed into variable-length entity pair predictor to aid entity pair recognition.

3.4 Variable-length Entity Pair Predictor

Given a text, and a target relation type output by the relation classifier, the variable-length entity pair predictor aims to extract its all possible entity pairs in a sequence manner. Inspired by the pointer network (Vinyals et al., 2015), we determine an entity by identifying START and END position indexes of the words in the text. As shown in Figure 2, entity pairs are generated by a sequence of indexes. Each two indexes can identify an entity and each two entities form an entity pair in order. In this paradigm, our model can explore all the possible relations in one pass and predict all possible entity pairs for a given relation via a lightweight sequence decoder, unlike previous work which has to predict the target relation in a multi-pass way (Zeng et al., 2018; Takanobu et al., 2019).

Multi-head Attention. We apply a multi-head attention (Vaswani et al., 2017) on X to obtain a

new text representation P:

$$Q = XW_j^Q, K = XW_j^K, V = XW_j^V, \quad (7)$$

$$head_j = softmax(\frac{QK^T}{\sqrt{d_k}})V, \quad (8)$$

$$P = Concat(head_1, ...head_h)W^O, \quad (9)$$

where different linear layers are used in Eq. (7) to map X into different subspaces by learnable parameters W_j^Q, $W_j^K \in \mathbb{R}^{d \times d_k}$, and $W_j^V \in \mathbb{R}^{d \times d_v}$, yielding query $Q \in \mathbb{R}^{n \times d_k}$, keys $K \in \mathbb{R}^{n \times d_k}$ and values $V \in \mathbb{R}^{n \times d_v}$. By Scaled Dot-Product Attention (Vaswani et al., 2017), $head_j \in \mathbb{R}^{n \times d_v}$ is obtained as the representation of j-th head. A concatenation operator and a linear layer are used in Eq. (9) to produce text representation $P \in \mathbb{R}^{n \times d}$, where h is the number of heads and $W^O \in \mathbb{R}^{hd_v \times d}$ is learnable parameter.

Triplet Attention. At each position of the text, attention mechanism is used to obtain a weighted value that represents the matching degree between the token and the target relation type. Since its aim is to extract the candidate entity pair for the target relation, we call this attention the triplet attention. The triplet attention essentially aggregates the matching of the relation type to each token of the text and used the aggregated matching result to make the entity prediction.

Assume the j-th relation is the target relation identified by the relation classifier in Section 3.3. To get the final attention of j-th relation to i-th token, we study two different modes to implement the triplet attention: paralleled mode and layered mode.

Paralleled Mode. The so-called paralleled mode draws the connections among the target relation, the token, and previous hidden state in a synchronous way:

$$a_t^i = W^a tanh(W^r \circ R_j + W^d \circ d_{t-1} + W^p \circ P_i), \quad (10)$$

where $\circ$ is the element-wise multiplication operator. $R_j \in \mathbb{R}^d$ is j-th relation embedding, $P_i \in \mathbb{R}^d$ is i-th word of text representation P, $d_{t-1} \in \mathbb{R}^d$ is hidden state of LSTM decoder at time step $t-1$ which obtained by Eq. (13). W^r, W^d, W^p, and $W^a \in \mathbb{R}^d$ are learnable parameters. $a_t^i \in \mathbb{R}$ is attention weight of i-th word in the text.

The attention distribution on text $\alpha_t \in \mathbb{R}^n$ is computed as follows:

$$\alpha_t = softmax(a_t), \quad (11)$$

where $\alpha_t = [\alpha_t^1, ...\alpha_t^n]$, n denotes the text length. It is worthy to note that, α_t^i is used as the probability that position index i is selected as output at time step t. At time step t, the position index with the highest probability in α_t is greedily sampled as the output O_t.

Once the attention weights are computed, the context vector c_t is computed by:

$$c_t = \sum_{i=1}^{n} \alpha_t^i \cdot P_i. \quad (12)$$

Then c_t together with d_{t-1} are fed into LSTM decoder at time step t:

$$d_t = LSTM_{decoder}(c_t, d_{t-1}). \quad (13)$$

Therefore, the LSTM decoder is capable of tracking the state of the variable-length entity pair predictor.

Layered Mode. The layered mode first computes the connection between R_j and d_{t-1}:

$$\beta_t = tanh(W^{r'} \circ R_j + W^{d'} \circ d_{t-1}), \quad (14)$$

where W^β, $W^{p'}$, and $W^{a'} \in \mathbb{R}^d$ are learnable parameters.

Then vector β_t is used to calculate triplet attention:

$$a_i^t = W^{a'} tanh(W^\beta \circ \beta_t + W^{p'} \circ P_i), \quad (15)$$

where W^β, $W^{p'} \in \mathbb{R}^d$ are learnable parameters. The following procedure is conducted as the same denoted in Eq. (11)-(13).

3.5 Training

We adopt the cross-entropy loss function to define the loss of multiple relation classifiers and variable-length entity pair predictor respectively, which denoted as L_{rel} and L_{ent}.

To jointly train the model, the loss L is obtained by:

$$L = \lambda \cdot L_{rel} + (1 - \lambda) \cdot L_{ent}, \quad (16)$$

where $\lambda \in \mathbb{R}$ is a hyperparameter to balance the multiple relation classifiers and the variable-length entity pair predictor.

4 Experiments

4.1 Dataset

In order to test our proposed recipe for jointly extracting multiple relations and multiple entity

Dataset	NYT	WebNLG	SKE
Language	English	English	Chinese
Relation	24	246	50
Triplets	104,518	12,863	111,539
Token	90,760	5,051	170,206

Table 1: Statistics of three datasets in language, number of relation types, triplet number and token numbers.

pairs, we conducted experiments on two English benchmark datasets: New York Times (NYT) and WebNLG, and a Chinese public dataset Schema based Knowledge Extraction (SKE).

NYT is produced by distant supervision method (Riedel et al., 2010) and widely used in the triplet extraction (Zheng et al., 2017; Zeng et al., 2018). There are 24 relation types, 61,265 train texts and 5,000 test texts in NYT dataset. We randomly select 5,000 texts from train data as the development set.

WebNLG dataset (Gardent et al., 2017), is originally a dataset for natural language generation task and later used for triplet extraction (Zeng et al., 2018). There are 246 relation types, 5,321 train texts and 695 test texts. We randomly select 500 from train data as the development set.

Different from the two previous English datasets, SKE is a Chinese dataset for information extraction, which is released in the 2019 Language and Intelligence Challenge[1]. SKE contains 50 relation types and training texts exceed 200,000. We build our training set, development set, and test set by randomly selecting 50,000, 5,000 and 5,000 texts respectively.

Following the work of Zeng et al. (2018), we prepropose the three datasets as follows: (1) remove texts that contain no triplets at all; (2) filter out texts if there is an entity in the triplet that is not found in the text.

As shown in Table 1, SKE has a richest vocabulary (170,206 tokens), while WebNLG has a smallest vocabulary (5,051 tokens). In contrast to NYT and SKE which has a medium body of relations (24 and 50, respectively), WebNLG has a significantly big body of relations (246 relations).

4.2 Baseline and Evaluation Metrics

To evaluate our method, we compared against one baseline model and three state-of-the-art models.

[1]http://lic2019.ccf.org.cn/kg

Hyperparameter	value
dropout rate	0.5
learning rate	0.001
batch size	50
hidden size of LSTM	100
filter number of CNN	100
window size of CNN	3
head number	4
λ	0.3

Table 2: Hyperparameter setting.

Baseline: In our proposed baseline model, we design similar architecture with MrMep, in which the encoder and multiple relation classifiers are the same with MrMep, but we use Match-LSTM (Wang and Jiang, 2016) as an implementation of variable-length entity pair predictor. The three main layers of Match-LSTM in our baseline model are as follows: (1) LSTM Preprocessing Layer: we use output of the encoder as passage representation and relation embedding of multiple relation classifiers as the query representation; (2) Match-LSTM Layer: we make concatenation of query representation and each token embedding of passage representation to obtain query-aware token representation, and then fed it into a Bi-LSTM layer; (3) Answer Pointer Layer: this layer is same with Match-LSTM (Wang and Jiang, 2016) and we adopt the sequence model to produce entity pairs.

Tagging (Zheng et al., 2017): This model is a sequence labeling model which assigns to each token a unique tag denoting the information of relation, head or tail entity, even if that the token participates in two different triplets.

CopyR (Zeng et al., 2018): This model is a seq2seq model utilizing copy mechanism that generating a triplet by jointly copying a relation from relation set and copying an entity pair from the source texts in a sequential manner.

HRL (Takanobu et al., 2019): This model applies a hierarchical reinforcement learning framework that decomposes the task into a high-level task for relation detection and a low-level task for entity extraction, which is jointly optimized through a reinforcement learning paradigm.

Following (Zheng et al., 2017; Zeng et al., 2018; Takanobu et al., 2019), we use the standard micro Precision, Recall and F1 score to evaluate the results. Triplets are regarded as correct when the

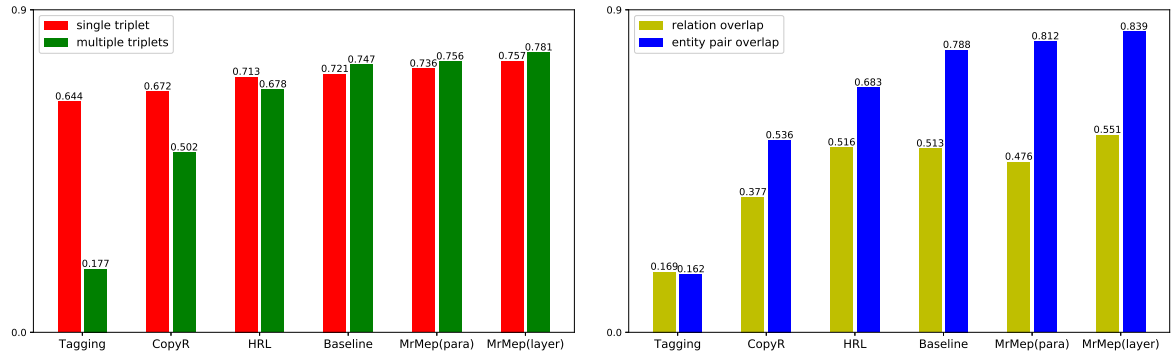
MrMep (layer)	**0.779**	**0.766**	**0.771**	0.694	**0.770**	**0.730**	**0.611**	**0.567**	**0.588**

Table 3: Results of different models in three datasets. MrMep (para) denotes that we adopt paralleled mode of triplet attention in variable-length entity pair predictor. MrMep (layer) denotes the layered mode.

Model	NYT10			NYT11			NYT10-sub			NYT11-plus		
	Prec	Rec	F1	Prec	Rec	F1	Prec	Rec	F1	Prec	Rec	F1
Tagging	0.593	0.381	0.464	0.469	0.489	0.479	0.256	0.237	0.246	0.292	0.220	0.250
CopyR	0.569	0.452	0.504	0.347	0.534	0.421	0.392	0.263	0.315	0.329	0.224	0.264
HRL	0.714	0.586	0.644	**0.538**	**0.538**	**0.538**	0.815	0.475	0.600	0.441	0.321	0.372
MrMep	**0.717**	**0.635**	**0.673**	0.434	0.522	0.474	**0.832**	**0.550**	**0.662**	**0.512**	**0.327**	**0.399**

Table 4: Detailed results of different models in datasets used in HRL (Takanobu et al., 2019). NYT10-sub is selected from NYT10 test set (original version), NYT11-plus is splitted from NYT-11 train set (manually created version). NYT10-sub and NYT11-plus contains a variety of overlapping triplets.

relation type and entity pair are both correct.



4.3 Implementation Details

We evaluate two variants of our approach: MrPep (para) using paralleled mode for triplet attention and MrMep (layer) using layered mode. For both variants, all hyperparameters are tuned on the same validation set. The hyperparameter setting is shown in Table 2. The word embedding are initialized using Glove (Pennington et al., 2014) and are updated during training, and the dimension is set to 100. The cell unit number of LSTM encoder and decoder is set to 100. The filter number used in CNN classifier is 100, filter window is 3, and the following dense layer has a hidden layer with 100 dimensions. The learning rate is set to 0.001. The tradeoff parameter λ in loss function is set to 0.3. The batch size is set to 50. The head number in muti-head attention is set to 4. For training, we use Adam (Kingma and Ba, 2015) to optimize parameters.

4.4 Main Results

Table 3 shows the Precision, Recall and F1 value of different models on the three datasets. When compared to Tagging and CopyR, the proposed model MrMep substantially improves the F1 scores in three datasets. Both the MrMep (para) and MrMep (layer) outperform the most competitive HRL model in three F1 scores. Moreover, compared with HRL, both the baseline model and our proposed models achieve a significant increase in Recall. Specifically, MrMep (layer) achieves 11.5% improvement in NYT, 14.1% improvement in WebNLG, and 14.5% improvement in SKE in Recall value. Our hypothesis is that the state-of-the-art models such as CopyR and HRL are seeking connection between relation and entity pairs in a sequential fashion, whereas we seek this connection in an interactive manner with the relation paying attention to the tokens one by one interactively.

To draw a paralleled comparison with HRL in more details, we compare the results on the same data partition used in HRL: NYT10, NYT11, NYT10-sub and NYT11-plus. The results of different approaches are summarized in Table 4. On NYT10, NYT10-sub and NYT11-plus test set, MrMep (layer) achieves the highest F1 values when compared with three state-of-the-art models. In NYT11 test set, our model gets poorer performance than HRL. But it is worthy to note that NYT11 dataset averagely contains a triplet per text (totally 369 texts with 370 triplets), while NYT10-sub and NYT11-plus test set contain more overlapping triplets. These observations suggest that our model is essentially feasible to extract more complicated triplets.

(a) (b)

Figure 3: Detailed results on different test subsets. The ordinate of the coordinate axis represents the F1 value.

Model	NYT	WebNLG	SKE
MrMep	**0.771**	**0.730**	**0.588**
w/o CNN	0.745	0.724	0.530
w/o Multi-head	0.723	0.616	0.512

Table 5: An ablation study for MrMep (layer) model. All values are F1 scores.

4.5 Detailed Results

To further verify the ability of MrMep in handling the various complex triplets, we conduct a series of qualitative analysis from two distinct views:

Single triplet vs Multiple triplets. According to the number of triplets contained in the text, we divide the NYT test set into two sub-datasets: (1) single triplet test set: each text contains only one triplet, and 3,240 texts are in the set; (2) multi triplet test set: each text contains two or more triplets, and 1,760 texts are in the set.

Relation overlap vs entity pair overlap. According to whether an overlap is relation overlap or entity pair overlap, we obtain two subsets from the test set: (1) relation overlap: one relation connects with two or more different entity pairs (462 texts in NYT test set); (2) entity pair overlap: one entity pair connects with two or more relations (969 texts in NYT test set).

Figure 3 (a) shows the F1 values of different approaches on NYT test data with single triplet and multiple triplets. It can be seen that both MrMep (para) and MrMep (layer) outperform the baseline and the three comparative models. Noticeably, the improvements on multiple triplets are more remarkable.

From Figure 3 (b) we can observe that MrMep (layer) outperforms MrMep (para) and both of them outperform the reference models. It is also interesting to notice that predicting relation overlaps is more challenging than predicting entity pair overlaps.

The baseline model adopts Match-LSTM (Wang and Jiang, 2016) as an implement of entity pair predictor, which sequentially aggregates the matching of the attention-weighted query to each token of the text. Although we could treat the relation as a query, the relation is essentially a tag with much simpler semantics than that of actual queries. Therefore, we design a lightweight MrMep model which is proven to be more elegant and powerful for entity pair extraction.

4.6 Ablation Study

We examine the contributions of two main components, namely, convolutional neural network (CNN) in multiple relation classifiers and multi-head attention in entity pair predictor, using the best-performing MrMep model with layered mode on three dataset. First, instead of using representations learnt by CNN, we use the last hidden state of the LSTM encoder as text presentation, then feed it directly to the multiple binary classifier (MrMep w/o CNN). Second, instead of applying multi-head attention, we use the hidden state at each time step of the LSTM encoder to represent each token, which is directly fed into the following triplet attention to extract entity pairs (MrMep w/o Multi-head). Table 5 shows the results. We can observe that adding either CNN or multi-head attention improves the performance of the model. This suggests that both parts can assist MrMep to jointly extract entities and relations, where the CNN layer seems to be playing a more significant role. One possible reason is that CNN is used for

MrMep (layer)	(NYT): "It 's pretty neat", said Ward, who grew up in the [Edmonton]$_{E_t-contains}$ suburb of Sherwood Park, [Alberta]$_{E_h-contains}$.
MrMep (para)	(NYT): "It 's pretty neat", said Ward, who grew up in the [Edmonton suburb of Sherwood Park]$_{E_t-contains}$, [Alberta]$_{E_h-contains}$.
MrMep (layer)	(WebNLG): [Bakso]$_{E_h-country}$ comes from [Indonesia]$_{E_t-country}$, and celery is a main ingredient. [Jasuf Kalla]$_{E_t-leaderName}$ is a leader in [Indonesia]$_{E_h-leaderName}$.
MrMep (para)	(WebNLG): [Bakso]$_{E_h-country}$ comes from [Indoneisa]$_{E_t-country}$, and [celery is a main ingredient. Jasuf Kalla]$_{E_t-leaderName}$ is a leader in [Indonesia]$_{E_h-leaderName}$.

Table 6: Extracted results from MrMep (para) and MrMep (layer). The words in a bracket represents an entity, E_h stands for the head entity and E_t stands for the tail entity. Red is marked as identifying the wrong.

extracting local feature of input text, which is not only beneficial for relation extraction but also assist producing better relation embedding to aid entity pair predition.

4.7 Case Study

Table 6 shows two examples of extracted results from MrMep (para) and MrMep (layer). In the first example, MrMep (layer) precisely extracts the correct triplet <Alberta, contains, Edmonton>, while MrMep (para) recognizes incorrect tail entity " Edmonton suburb of Sherwood Park". In the second example, MrMep (layer) precisely extracts correct triplet <Indoneisa, leaderName, Jasuf Kalla> while MrMep (para) wrongly recognizes the tail entity " celery is a main ingredient. Jasuf Kalla". Taking NYT test set as example, among 1250 differences between the output of MrMep (para) and MrMep (layer), there are 885 differences resulting from the wrong entity boundaries identified by MrMep (para). The most likely reason might be that the hidden state of the decoder plays as crucial role as the relation in sequentially producing different entity pairs.

5 Conclusion

We propose a joint multiple relation and multiple entity pair extraction model. The model uses a triplet attention to model the connection of relation and entities in a novel and lightweight framework. It gives state-of-the-art performance on three benchmark datasets.

Effective Attention Modeling for Neural Relation Extraction

Tapas Nayak and **Hwee Tou Ng**

Abstract

Relation extraction is the task of determining the relation between two entities in a sentence. Distantly-supervised models are popular for this task. However, sentences can be long and two entities can be located far from each other in a sentence. The pieces of evidence supporting the presence of a relation between two entities may not be very direct, since the entities may be connected via some indirect links such as a third entity or via co-reference. Relation extraction in such scenarios becomes more challenging as we need to capture the long-distance interactions among the entities and other words in the sentence. Also, the words in a sentence do not contribute equally in identifying the relation between the two entities. To address this issue, we propose a novel and effective attention model which incorporates syntactic information of the sentence and a multi-factor attention mechanism. Experiments on the New York Times corpus show that our proposed model outperforms prior state-of-the-art models.

1 Introduction

Relation extraction from unstructured text is an important task to build knowledge bases (KB) automatically. Banko et al. (2007) used open information extraction (Open IE) to extract relation triples from sentences where verbs were considered as the relation, whereas supervised information extraction systems extract a set of pre-defined relations from text. Mintz et al. (2009), Riedel et al. (2010), and Hoffmann et al. (2011) proposed distant supervision to generate the training data for sentence-level relation extraction, where relation tuples (two entities and the relation between them) from a knowledge base such as Freebase (Bollacker et al., 2008) were mapped to free text (Wikipedia articles or New York Times articles). The idea is that if a sentence contains both entities of a tuple, it is chosen as a training sentence of that tuple. Although this process can generate some noisy training instances, it can give a significant amount of training data which can be used to build supervised models for this task.

Mintz et al. (2009), Riedel et al. (2010), and Hoffmann et al. (2011) proposed feature-based learning models and used entity tokens and their nearby tokens, their part-of-speech tags, and other linguistic features to train their models. Recently, many neural network-based models have been proposed to avoid feature engineering. Zeng et al. (2014, 2015) used convolutional neural networks (CNN) with max-pooling to find the relation between two given entities. Though these models have been shown to perform reasonably well on distantly supervised data, they sometimes fail to find the relation when sentences are long and entities are located far from each other. CNN models with max-pooling have limitations in understanding the semantic similarity of words with the given entities and they also fail to capture the long-distance dependencies among the words and entities such as co-reference. In addition, all the words in a sentence may not be equally important in finding the relation and this issue is more prominent in long sentences. Prior CNN-based models have limitations in identifying the multiple important factors to focus on in sentence-level relation extraction.

To address this issue, we propose a *novel* multi-factor attention model[1] focusing on the syntactic structure of a sentence for relation extraction. We use a dependency parser to obtain the syntactic structure of a sentence. We use a linear form of attention to measure the semantic similarity of words with the given entities and combine

[1]The code and data of this paper can be found at https://github.com/nusnlp/MFA4RE

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 603–612
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

it with the dependency distance of words from the given entities to measure their influence in identifying the relation. Also, single attention may not be able to capture all pieces of evidence for identifying the relation due to normalization of attention scores. Thus we use multi-factor attention in the proposed model. Experiments on the New York Times (NYT) corpus show that the proposed model outperforms prior work in terms of F1 scores on sentence-level relation extraction.

2 Task Description

Sentence-level relation extraction is defined as follows: Given a sentence S and two entities $\{E_1, E_2\}$ marked in the sentence, find the relation $r(E_1, E_2)$ between these two entities in S from a pre-defined set of relations $R \cup \{None\}$. *None* indicates that none of the relations in R holds between the two marked entities in the sentence. The relation between the entities is argument order-specific, i.e., $r(E_1, E_2)$ and $r(E_2, E_1)$ are not the same. Input to the system is a sentence S and two entities E_1 and E_2, and output is the relation $r(E_1, E_2) \in R \cup \{None\}$.

3 Model Description

We use four types of embedding vectors in our model: (1) word embedding vector $\mathbf{w} \in \mathbb{R}^{d_w}$ (2) entity token indicator embedding vector $\mathbf{z} \in \mathbb{R}^{d_z}$, which indicates if a word belongs to entity 1, entity 2, or does not belong to any entity (3) a positional embedding vector $\mathbf{u}^1 \in \mathbb{R}^{d_u}$ which represents the linear distance of a word from the start token of entity 1 (4) another positional embedding vector $\mathbf{u}^2 \in \mathbb{R}^{d_u}$ which represents the linear distance of a word from the start token of entity 2.

We use a bi-directional long short-term memory (Bi-LSTM) (Hochreiter and Schmidhuber, 1997) layer to capture the interaction among words in a sentence $S = \{w_1, w_2, ..., w_n\}$, where n is the sentence length. The input to this layer is the concatenated vector $\mathbf{x} \in \mathbb{R}^{d_w+d_z}$ of word embedding vector $\mathbf{w}$ and entity token indicator embedding vector $\mathbf{z}$.

$$\mathbf{x}_t = \mathbf{w}_t \mid\mid \mathbf{z}_t$$
$$\overrightarrow{\mathbf{h}_t} = \overrightarrow{\text{LSTM}}(\mathbf{x}_t, \mathbf{h}_{t-1})$$
$$\overleftarrow{\mathbf{h}_t} = \overleftarrow{\text{LSTM}}(\mathbf{x}_t, \mathbf{h}_{t+1})$$
$$\mathbf{h}_t = \overrightarrow{\mathbf{h}_t} || \overleftarrow{\mathbf{h}_t}$$

$\overrightarrow{\mathbf{h}_t} \in \mathbb{R}^{d_w+d_z}$ and $\overleftarrow{\mathbf{h}_t} \in \mathbb{R}^{d_w+d_z}$ are the output at the tth step of the forward LSTM and backward LSTM respectively. We concatenate them to obtain the tth Bi-LSTM output $\mathbf{h}_t \in \mathbb{R}^{2(d_w+d_z)}$.

3.1 Global Feature Extraction

We use a convolutional neural network (CNN) to extract the sentence-level global features for relation extraction. We concatenate the positional embeddings $\mathbf{u}^1$ and $\mathbf{u}^2$ of words with the hidden representation of the Bi-LSTM layer and use the convolution operation with max-pooling on concatenated vectors to extract the global feature vector.

$$\mathbf{q}_t = \mathbf{h}_t \| \mathbf{u}_t^1 \| \mathbf{u}_t^2$$
$$c_i = \mathbf{f}^T(\mathbf{q}_i \| \mathbf{q}_{i+1} \| .... \| \mathbf{q}_{i+k-1})$$
$$c_{max} = \max(c_1, c_2, ..., c_n)$$
$$\mathbf{v}_g = [c_{max}^1, c_{max}^2, ..., c_{max}^{f_g}]$$

$\mathbf{q}_t \in \mathbb{R}^{2(d_w+d_z+d_u)}$ is the concatenated vector for the tth word and $\mathbf{f}$ is a convolutional filter vector of dimension $2k(d_w + d_z + d_u)$ where k is the filter width. The index i moves from 1 to n and produces a set of scalar values $\{c_1, c_2, ..., c_n\}$. The max-pooling operation chooses the maximum c_{max} from these values as a feature. With f_g number of filters, we get a global feature vector $\mathbf{v}_g \in \mathbb{R}^{f_g}$.

3.2 Attention Modeling

Figure 1 shows the architecture of our attention model. We use a linear form of attention to find the semantically meaningful words in a sentence with respect to the entities which provide the pieces of evidence for the relation between them. Our attention mechanism uses the entities as attention queries and their vector representation is very important for our model. Named entities mostly consist of multiple tokens and many of them may not be present in the training data or their frequency may be low. The nearby words of an entity can give significant information about the entity. Thus we use the tokens of an entity and its nearby tokens to obtain its vector representation. We use the convolution operation with max-pooling in the context of an entity to get its vector representation.

$$c_i = \mathbf{f}^T(\mathbf{x}_i \| \mathbf{x}_{i+1} \| .... \| \mathbf{x}_{i+k-1})$$
$$c_{max} = \max(c_b, c_{b+1}, ..., c_e)$$
$$\mathbf{v}_e = [c_{max}^1, c_{max}^2, ..., c_{max}^{f_e}]$$

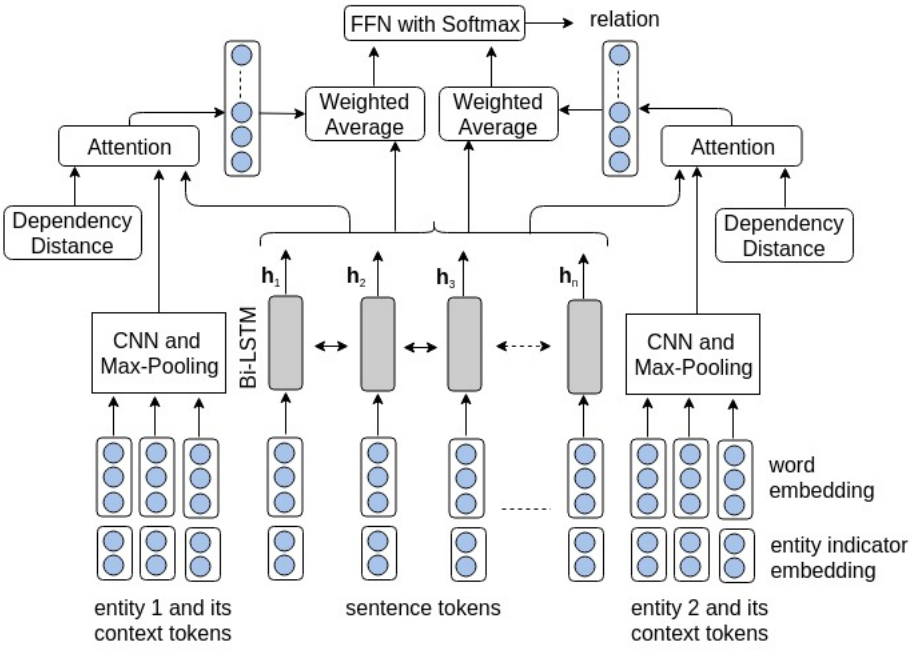

Figure 1: Architecture of our attention model with $m = 1$. We have not shown the CNN-based global feature extraction here. FFN=feed-forward network.

$\mathbf{f}$ is a convolutional filter vector of size $k(d_w + d_z)$ where k is the filter width and $\mathbf{x}$ is the concatenated vector of word embedding vector ($\mathbf{w}$) and entity token indicator embedding vector ($\mathbf{z}$). b and e are the start and end index of the sequence of words comprising an entity and its neighboring context in the sentence, where $1 \leq b \leq e \leq n$. The index i moves from b to e and produces a set of scalar values $\{c_b, c_{b+1}, ..., c_e\}$. The max-pooling operation chooses the maximum c_{max} from these values as a feature. With f_e number of filters, we get the entity vector $\mathbf{v}_e \in \mathbb{R}^{f_e}$. We do this for both entities and get $\mathbf{v}_e^1 \in \mathbb{R}^{f_e}$ and $\mathbf{v}_e^2 \in \mathbb{R}^{f_e}$ as their vector representation. We adopt a simple linear function as follows to measure the semantic similarity of words with the given entities:

$$\mathrm{f}^1_{\mathrm{score}}(\mathbf{h}_i, \mathbf{v}_e^1) = \mathbf{h}_i^T \mathbf{W}_a^1 \mathbf{v}_e^1$$
$$\mathrm{f}^2_{\mathrm{score}}(\mathbf{h}_i, \mathbf{v}_e^2) = \mathbf{h}_i^T \mathbf{W}_a^2 \mathbf{v}_e^2$$

$\mathbf{h}_i$ is the Bi-LSTM hidden representation of the ith word. $\mathbf{W}_a^1, \mathbf{W}_a^2 \in \mathbb{R}^{2(d_w+d_z)\times f_e}$ are trainable weight matrices. $\mathrm{f}^1_{\mathrm{score}}(\mathbf{h}_i, \mathbf{v}_e^1)$ and $\mathrm{f}^2_{\mathrm{score}}(\mathbf{h}_i, \mathbf{v}_e^2)$ represent the semantic similarity score of the ith word and the two given entities.

Not all words in a sentence are equally important in finding the relation between the two entities. The words which are closer to the entities are generally more important. To address this issue, we propose to incorporate the syntactic structure of a sentence in our attention mechanism. The syntactic structure is obtained from the dependency parse tree of the sentence. Words which are closer to the entities in the dependency parse tree are more relevant to finding the relation. In our model, we define the dependency distance to every word from the head token (last token) of an entity as the number of edges along the dependency path (See Figure 2 for an example). We use a distance window size ws and words whose dependency distance is within this window receive attention and the other words are ignored. The details of our attention mechanism follow.

$$d_i^1 = \begin{cases} \frac{1}{2^{l_i^1 - 1}} \exp(\mathrm{f}^1_{\mathrm{score}}(\mathbf{h}_i, \mathbf{v}_e^1)) & \text{if } l_i^1 \in [1, ws] \\ \frac{1}{2^{ws}} \exp(\mathrm{f}^1_{\mathrm{score}}(\mathbf{h}_i, \mathbf{v}_e^1)) & \text{otherwise} \end{cases}$$

$$d_i^2 = \begin{cases} \frac{1}{2^{l_i^2 - 1}} \exp(\mathrm{f}^2_{\mathrm{score}}(\mathbf{h}_i, \mathbf{v}_e^2)) & \text{if } l_i^2 \in [1, ws] \\ \frac{1}{2^{ws}} \exp(\mathrm{f}^2_{\mathrm{score}}(\mathbf{h}_i, \mathbf{v}_e^2)) & \text{otherwise} \end{cases}$$

$$p_i^1 = \frac{d_i^1}{\sum_j d_j^1}, \qquad p_i^2 = \frac{d_i^2}{\sum_j d_j^2}$$

d_i^1 and d_i^2 are un-normalized attention scores and p_i^1 and p_i^2 are the normalized attention scores for the ith word with respect to entity 1 and entity 2 respectively. l_i^1 and l_i^2 are the dependency distances

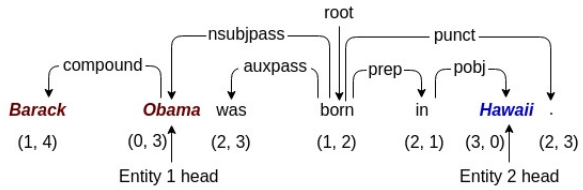

Figure 2: An example dependency tree. The two numbers indicate the distance of the word from the head token of the two entities respectively along the dependency tree path.

of the ith word from the two entities. We mask those words whose average dependency distance from the two entities is larger than ws. We use the semantic meaning of the words and their dependency distance from the two entities together in our attention mechanism. The attention feature vectors $\mathbf{v}_a^1$ and $\mathbf{v}_a^1$ with respect to the two entities are determined as follows:

$$\mathbf{v}_a^1 = \sum_{i=1}^{n} p_i^1 \mathbf{h}_i, \qquad \mathbf{v}_a^2 = \sum_{i=1}^{n} p_i^2 \mathbf{h}_i$$

3.3 Multi-Factor Attention

Two entities in a sentence, when located far from each other, can be linked via more than one coreference chain or more than one important word. Due to the normalization of the attention scores as described above, single attention cannot capture all relevant information needed to find the relation between two entities. Thus we use a multi-factor attention mechanism, where the number of factors is a hyper-parameter, to gather all relevant information for identifying the relation. We replace the attention matrix $\mathbf{W}_a$ with an attention tensor $\mathbf{W}_a^{1:m} \in \mathbb{R}^{m \times 2(d_w+d_z) \times 2f_e}$ where m is the factor count. This gives us m attention vectors with respect to each entity. We concatenate all the feature vectors obtained using these attention vectors to get the multi-attentive feature vector $\mathbf{v}_{ma} \in \mathbb{R}^{4m(d_w+d_z)}$.

3.4 Relation Extraction

We concatenate $\mathbf{v}_g$, $\mathbf{v}_{ma}$, $\mathbf{v}_e^1$, and $\mathbf{v}_e^2$, and this concatenated feature vector is given to a feed-forward layer with softmax activation to predict the normalized probabilities for the relation labels.

$$\mathbf{r} = \text{softmax}(\mathbf{W}_r(\mathbf{v}_g \mid\mid \mathbf{v}_{ma} \mid\mid \mathbf{v}_e^1 \mid\mid \mathbf{v}_e^2) + \mathbf{b}_r)$$

$\mathbf{W}_r \in \mathbb{R}^{(f_g+2f_e+4m(d_w+d_z)) \times (|R|+1)}$ is the weight matrix, $\mathbf{b}_r \in \mathbb{R}^{|R|+1}$ is the bias vector of the feed-forward layer for relation extraction, and $\mathbf{r}$ is the vector of normalized probabilities of relation labels.

3.5 Loss Function

We calculate the loss over each mini-batch of size B. We use the following negative log-likelihood as our objective function for relation extraction:

$$\mathcal{L} = -\frac{1}{B} \sum_{i=1}^{B} \log(p(r_i|s_i, e_i^1, e_i^2, \theta))$$

where $p(r_i|s_i, e_i^1, e_i^2, \theta)$ is the conditional probability of the true relation r_i when the sentence s_i, two entities e_i^1 and e_i^2, and the model parameters θ are given.

4 Experiments

4.1 Datasets

We use the New York Times (NYT) corpus (Riedel et al., 2010) in our experiments. There are two versions of this corpus: (1) The original NYT corpus created by Riedel et al. (2010) which has 52 valid relations and a *None* relation. We name this dataset NYT10. The training dataset has $455,412$ instances and $330,776$ of the instances belong to the *None* relation and the remaining $124,636$ instances have valid relations. The test dataset has $172,415$ instances and $165,974$ of the instances belong to the *None* relation and the remaining $6,441$ instances have valid relations. Both the training and test datasets have been created by aligning Freebase (Bollacker et al., 2008) tuples to New York Times articles. (2) Another version created by Hoffmann et al. (2011) which has 24 valid relations and a *None* relation. We name this dataset NYT11. The corresponding statistics for NYT11 are given in Table 1. The training dataset is created by aligning Freebase tuples to NYT articles, but the test dataset is manually annotated.

4.2 Evaluation Metrics

We use precision, recall, and F1 scores to evaluate the performance of models on relation extraction after removing the *None* labels. We use a confidence threshold to decide if the relation of a test instance belongs to the set of relations R or *None*. If the network predicts *None* for a test instance, then it is considered as *None* only. But if the network predicts a relation from the set R and the corresponding softmax score is below the confidence threshold, then the final class is changed to *None*.

		NYT10	NYT11
	# relations	53	25
Train	# instances	455,412	335,843
	# valid relation tuples	124,636	100,671
	# None relation tuples	330,776	235,172
	avg. sentence length	41.1	37.2
	avg. distance between entity pairs	12.8	12.2
Test	# instances	172,415	1,450
	# valid relation tuples	6,441	520
	# None relation tuples	165,974	930
	avg. sentence length	41.7	39.7
	avg. distance between entity pairs	13.1	11.0

Table 1: Statistics of the NYT10 and NYT11 dataset.

This confidence threshold is the one that achieves the highest F1 score on the validation dataset. We also include the precision-recall curves for all the models.

4.3 Parameter Settings

We run word2vec (Mikolov et al., 2013) on the NYT corpus to obtain the initial word embeddings with dimension $d_w = 50$ and update the embeddings during training. We set the dimension of entity token indicator embedding vector $d_z = 10$ and positional embedding vector $d_u = 5$. The hidden layer dimension of the forward and backward LSTM is 60, which is the same as the dimension of input word representation vector $\mathbf{x}$. The dimension of Bi-LSTM output is 120. We use $f_g = f_e = 230$ filters of width $k = 3$ for feature extraction whenever we apply the convolution operation. We use dropout in our network with a dropout rate of 0.5, and in convolutional layers, we use the tanh activation function. We use the sequence of tokens starting from 5 words before the entity to 5 words after the entity as its context. We train our models with mini-batch size of 50 and optimize the network parameters using the Adagrad optimizer (Duchi et al., 2011). We use the dependency parser from spaCy[2] to obtain the dependency distance of the words from the entities and use $ws = 5$ as the window size for dependency distance-based attention.

4.4 Comparison to Prior Work

We compare our proposed model with the following state-of-the-art models.

(1) CNN (Zeng et al., 2014): Words are represented using word embeddings and two positional embeddings. A convolutional neural network (CNN) with max-pooling is applied to extract the sentence-level feature vector. This feature vector is passed to a feed-forward layer with softmax to classify the relation.

(2) PCNN (Zeng et al., 2015): Words are represented using word embeddings and two positional embeddings. A convolutional neural network (CNN) is applied to the word representations. Rather than applying a global max-pooling operation on the entire sentence, three max-pooling operations are applied on three segments of the sentence based on the location of the two entities (hence the name Piecewise Convolutional Neural Network (PCNN)). The first max-pooling operation is applied from the beginning of the sentence to the end of the entity appearing first in the sentence. The second max-pooling operation is applied from the beginning of the entity appearing first in the sentence to the end of the entity appearing second in the sentence. The third max-pooling operation is applied from the beginning of the entity appearing second in the sentence to the end of the sentence. Max-pooled features are concatenated and passed to a feed-forward layer with softmax to determine the relation.

(3) Entity Attention (EA) (Shen and Huang, 2016): This is the combination of a CNN model and an attention model. Words are represented using word embeddings and two positional embeddings. A CNN with max-pooling is used to extract global features. Attention is applied with respect to the two entities separately. The vector representation of every word is concatenated with the word embedding of the last token of the entity. This concatenated representation is passed to a feed-forward layer with tanh activation and then another feed-forward layer to get a scalar attention score for every word. The original word representations are averaged based on the attention scores to get the attentive feature vectors. A CNN-extracted feature vector and two attentive feature vectors with respect to the two entities are concatenated and passed to a feed-forward layer with softmax to determine the relation.

(4) BiGRU Word Attention (BGWA) (Jat et al., 2017): Words are represented using word embeddings and two positional embeddings. They are passed to a bidirectional gated recurrent unit (BiGRU) (Cho et al., 2014) layer. Hidden vectors of the BiGRU layer are passed to a bilinear operator (a combination of two feed-forward layers)

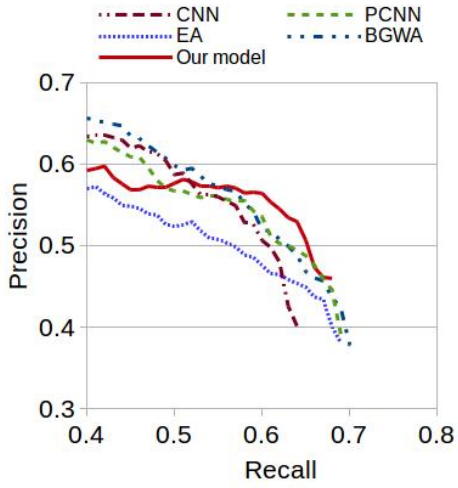

Figure 4: Precision-Recall curve for the NYT11 dataset.

to compute a scalar attention score for each word. Hidden vectors of the BiGRU layer are multiplied by their corresponding attention scores. A piecewise CNN is applied on the weighted hidden vectors to obtain the feature vector. This feature vector is passed to a feed-forward layer with softmax to determine the relation.

(5) BiLSTM-CNN: This is our own baseline. Words are represented using word embeddings and entity indicator embeddings. They are passed to a bidirectional LSTM. Hidden representations of the LSTMs are concatenated with two positional embeddings. We use CNN and max-pooling on the concatenated representations to extract the feature vector. Also, we use CNN and max-pooling on the word embeddings and entity indicator embeddings of the context words of entities to obtain entity-specific features. These features are concatenated and passed to a feed-forward layer to determine the relation.

4.5 Experimental Results

We present the results of our final model on the relation extraction task on the two datasets in Table 2. Our model outperforms the previous state-of-the-art models on both datasets in terms of F1 score. On the NYT10 dataset, it achieves 4.3% higher F1 score compared to the previous best state-of-the-art model EA. Similarly, it achieves 3.3% higher F1 score compared to the previous best state-of-the-model PCNN on the NYT11 dataset. Our model improves the precision scores on both datasets with good recall scores. This will help to build a cleaner knowledge base with fewer false positives. We also show the precision-recall curves for the NYT10 and NYT11 datasets in Figures 3 and 4 respectively. The goal of any relation extraction system is to extract as many relations as possible with minimal false positives. If the recall score becomes very low, the coverage of

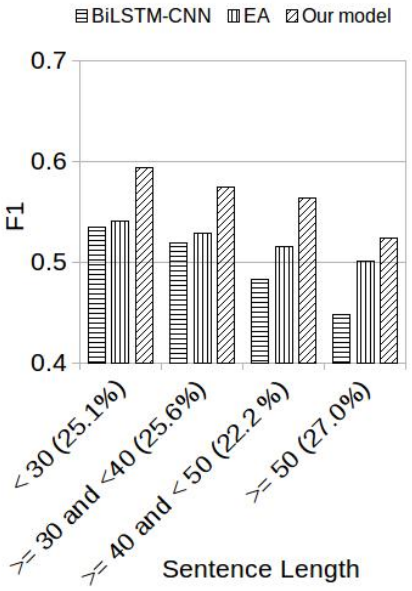

Figure 5: Performance comparison across different sentence lengths on the NYT10 dataset.

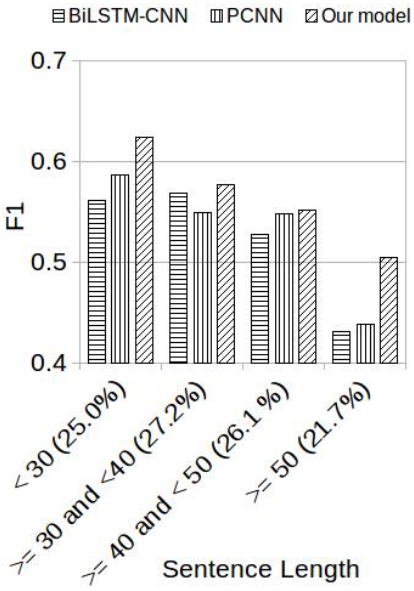

Figure 6: Performance comparison across different sentence lengths on the NYT11 dataset.

the KB will be poor. From Figure 3, we observe that when the recall score is above 0.4, our model achieves higher precision than all the competing models on the NYT10 dataset. On the NYT11 dataset (Figure 4), when recall score is above 0.6, our model achieves higher precision than the competing models. Achieving higher precision with high recall score helps to build a cleaner KB with good coverage.

5 Analysis and Discussion

5.1 Varying the number of factors (m)

We investigate the effects of the multi-factor count (m) in our final model on the test datasets in Table 3. We observe that for the NYT10 dataset, $m = \{1, 2, 3\}$ gives good performance with $m = 1$ achieving the highest F1 score. On the NYT11 dataset, $m = 4$ gives the best performance. These experiments show that the number of factors giving the best performance may vary depending on the underlying data distribution.

5.2 Effectiveness of Model Components

We include the ablation results on the NYT11 dataset in Table 4. When we add multi-factor attention to the baseline BiLSTM-CNN model without the dependency distance-based weight factor in the attention mechanism, we get 0.8% F1 score improvement (A2$-$A1). Adding the dependency weight factor with a window size of 5 improves

	NYT10			NYT11		
m	Prec.	Rec.	F1	Prec.	Rec.	F1
1	0.541	0.595	**0.566**	0.495	0.621	0.551
2	0.521	0.597	0.556	0.482	0.656	0.555
3	0.490	0.617	0.547	0.509	0.633	0.564
4	0.449	0.623	0.522	0.507	0.652	**0.571**
5	0.467	0.609	0.529	0.488	0.677	0.567

Table 3: Performance comparison of our model with different values of m on the two datasets.

the F1 score by 3.2% (A3$-$A2). Increasing the window size to 10 reduces the F1 score marginally (A3$-$A4). Replacing the attention normalizing function with softmax operation also reduces the F1 score marginally (A3$-$A5). In our model, we concatenate the features extracted by each attention layer. Rather than concatenating them, we can apply max-pooling operation across the multiple attention scores to compute the final attention scores. These max-pooled attention scores are used to obtain the weighted average vector of Bi-LSTM hidden vectors. This affects the model performance negatively and F1 score of the model decreases by 3.0% (A3$-$A6).

5.3 Performance with Varying Sentence Length and Varying Entity Pair Distance

We analyze the effects of our attention model with different sentence lengths in the two datasets in Figures 5 and 6. We also analyze the effects of our attention model with different distances be-

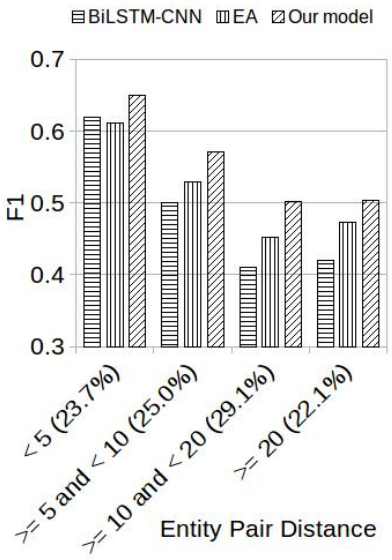

Figure 7: Performance comparison across different distances between entities on the NYT10 dataset.

	Prec.	Rec.	F1
(A1) BiLSTM-CNN	0.473	0.606	0.531
(A2) Standard attention	0.466	0.638	0.539
(A3) Window size $(ws) = 5$	0.507	0.652	**0.571**
(A4) Window size $(ws) = 10$	0.510	0.640	0.568
(A5) Softmax	0.490	0.658	0.562
(A6) Max-pool	0.492	0.600	0.541

Table 4: Effectiveness of model components ($m = 4$) on the NYT11 dataset.

tween the two entities in the two datasets in Figures 7 and 8. We observe that with increasing sentence length and increasing distance between the two entities, the performance of all models drops. This shows that finding the relation between entities located far from each other is a more difficult task. Our multi-factor attention model with dependency-distance weight factor increases the F1 score in all configurations when compared to previous state-of-the-art models on both datasets.

6 Related Work

Relation extraction from a distantly supervised dataset is an important task and many researchers (Mintz et al., 2009; Riedel et al., 2010; Hoffmann et al., 2011) tried to solve this task using feature-based classification models. Recently, Zeng et al. (2014, 2015) used CNN models for this task which can extract features automatically. Shen and Huang (2016) and Jat et al. (2017) used attention mechanism in their model to improve performance. Surdeanu et al. (2012), Lin et al. (2016), Vashishth et al. (2018), Wu et al. (2019), and Ye and Ling (2019) used multiple sentences in a multi-instance relation extraction setting to capture the features located in multiple sentences for a pair of entities. In their evaluation setting, they evaluated model performance by considering multiple sentences having the same pair of entities as a single test instance. On the other hand, our model and the previous models that we compare to in this paper (Zeng et al., 2014, 2015; Shen and Huang, 2016; Jat et al., 2017) work on each sentence independently and are evaluated at the sentence level. Since there may not be multiple sentences that contain a pair of entities, it is important to improve the task performance at the sentence level. Future work can explore the integration of our sentence-level attention model in a multi-instance relation extraction framework.

Not much previous research has exploited the dependency structure of a sentence in different ways for relation extraction. Xu et al. (2015) and Miwa and Bansal (2016) used an LSTM network and the shortest dependency path between two entities to find the relation between them. Huang et al. (2017) used the dependency structure of a sentence for the slot-filling task which is close to the relation extraction task. Liu et al. (2015) exploited the shortest dependency path between two entities and the sub-trees attached to that path (augmented dependency path) for relation extraction. Zhang et al. (2018) and Guo et al. (2019)

used graph convolution networks with pruned dependency tree structures for this task. In this work, we have incorporated the dependency distance of the words in a sentence from the two entities in a multi-factor attention mechanism to improve sentence-level relation extraction.

Attention-based neural networks are quite successful for many other NLP tasks. Bahdanau et al. (2015) and Luong et al. (2015) used attention models for neural machine translation, Seo et al. (2017) used attention mechanism for answer span extraction. Vaswani et al. (2017) and Kundu and Ng (2018) used multi-head or multi-factor attention models for machine translation and answer span extraction respectively. He et al. (2018) used dependency distance-focused word attention model for aspect-based sentiment analysis.

7 Conclusion

In this paper, we have proposed a multi-factor attention model utilizing syntactic structure for relation extraction. The syntactic structure component of our model helps to identify important words in a sentence and the multi-factor component helps to gather different pieces of evidence present in a sentence. Together, these two components improve the performance of our model on this task, and our model outperforms previous state-of-the-art models when evaluated on the New York Times (NYT) corpus, achieving significantly higher F1 scores.

Exploiting the Entity Type Sequence to Benefit Event Detection

Abstract

Event Detection (ED) is one of the most important tasks in the field of information extraction. The goal of ED is to find triggers in sentences and classify them into different event types. In previous works, the information of entity types are commonly utilized to benefit event detection. However, the sequential features of entity types have not been well utilized yet in the existing ED methods. In this paper, we propose a novel ED approach which learns sequential features from word sequences and entity type sequences separately, and combines these two types of sequential features with the help of a trigger-entity interaction learning module. The experimental results demonstrate that our proposed approach outperforms the state-of-the-art methods.

1 Introduction

Event Extraction (EE) is one of the essential tasks of Information Extraction, which aims to extract structured events from unstructured texts. According to ACE (Automatic Context Extraction) event annotation guideline[1], an event is represented by an event trigger, which is often a single verb or noun, and a set of event arguments, the participants of the event. Event Detection (ED), as a crucial step in EE task, focuses on finding event trigger words and classifying them into different event types. As pointed out in (Liu et al., 2019; Ritter et al., 2012), the ambiguity in natural languages makes ED a challenging task. On the one hand, various expressions can be used to represent the same event type; on the other hand, the same event triggers, when placed in different context, can be categorized in totally different event types. To illustrate the second phenomenon, we present two examples from the widely used ACE 2005[2] dataset:

1) A Russian Soyuz capsule (VEH) **dropped** (*Transport*) the astronauts (PER) off this morning.

2) U.S. planes (VEH) **dropped** (*Attack*) a bomb (WEA) near northern Iraq.

Notice that the same annotated event trigger **dropped** has different meanings in the two sentences above and thus evokes entirely different event types. In the first sentence, **dropped** evokes a *Transport* event, but in the second sentence, **dropped** represents an *Attack* event. According to Liu et al. (2018a), in the ACE 2005 dataset, 57% of the event triggers are ambiguous. How to alleviate the ambiguity of event triggers has become a crucial problem in the ED task.

In several previous works, researchers have proved that entity mentions could play a positive role on alleviating the ambiguity of event triggers (Hong et al., 2011; Li et al., 2013; Feng et al., 2016; Liu et al., 2017, 2019, 2018a). An entity mention, as described in ACE 2005 dataset, is a reference to an object or a set of objects in the world. Back to the two sentences above, entity mentions are the underlined word tokens. In the first sentence, before classifying the event trigger **dropped**, if an event detector can obtain the information that "Soyuz capsule" is an entity mention with the type VEHICLE, and "astronauts" has the entity type PERSON, the event detector may tend to consider the potential link between VEHICLE and PERSON, which makes the event more likely to be a *Transport* event. In the second sentence, besides "planes" which is a VEHICLE type entity mention, another entity mention "bomb", which has the type WEAPON, can largely effect on the

ED result. The appearance of WEAPON tells the event detector that there is a weapon in the context, and this clue leads the detector to recognize an *Attack* event with less ambiguity.

Liu et al. (2017) utilize raw entity types directly as local context of words to calculate the attention value between entity types and candidate triggers, aiming to catch the most important entity type information. After that, Liu et al. (2018b, 2019); Nguyen and Grishman (2018) apply entity types as a kind of supplementary information of the word tokens. They concatenate these two types of features and feed them into neural networks to learn mixed representations.

Intuitively, we understand that the sequential features of words are very important in modeling the sentence information, since the order of tokens can largely influence the meaning of the sentence. In the previous works, different neural network architectures have been employed to capture the sequential features from word sequences (Chen et al., 2015; Lin et al., 2018; Sha et al., 2018). Similar to the word sequences, entity type sequences, which consist of entity type annotations for each token in the word sequences, also contain sequential features, because the position of an entity mention's type in the sequences may affect its importance in the ED process. However, to the best of our knowledge, there is no study which regards the entity type sequence as an independent sequence to capture the sequential features and discusses what influence the entity types' sequential features would take to the ED task.

In order to make use of the information from both entity type sequences and word sequences, in this paper, we propose a novel ED approach Entity-Type-Enhanced-Event-Detection (**ETEED**). We consider that the word sequence and the entity type sequence have equal importance and thus the representation of each sequence should be learned separately. In this procedure, the Transformer Encoder structure (Vaswani et al., 2017) is utilized to capture the sequential features. Besides, an attention based trigger-entity interaction learning module is proposed to learn the correlation between triggers and entity types. Different from previous works which calculate the attention value between a candidate trigger and the whole entity type sequence, this module only learns the relation between entity mentions' types and the candidate trigger, and returns weighted summed entity mention type representations to benefit the classification. In this way, we can avoid the disturbance from irrelevant entity types, and focus only on the effect brought by entity mentions.

In summary, our contribution in this work is as follows:

- we propose to learn entity type representations separately from word representations, in order to make full use of the sequential features from entity type sequences.
- we propose an attention-based trigger-entity interaction learning module, which focuses only on the relation between entity mentions and candidate triggers, thus can eliminate the influence brought by irrelative entity types.
- we extensively evaluate our approach on a widely used benchmark dataset ACE 2005, and the evaluation result shows that our method can achieve competitive results compared with the state-of-the-art methods.

2 Approach

In this section, we elaborate the proposed **ETEED** method. Similar to the existing works, we regard ED as a classification problem. Specifically, in each sample, there is a candidate trigger, and our goal is to classify this candidate trigger into 34 event types (33 event subtypes and a NA type). We present the overall framework of our method in Figure 1. To well illustrate our model, we divide this section into three different parts: i) token representation learning, which involves representing the word sequences and entity type sequences, ii) attention-based feature learning, which interprets how the attention module works to learn the relation between entity mentions and candidate triggers, and iii) trigger classification, which concatenates all the continuous representation together and produce the final output for the trigger classification.

2.1 Token Representation Learning

For each sample with length n in the dataset, we represent its word sequence as $w = \{w_1, w_2, .., w_n\}$, in which w_i means the i-th word in the sentence. Similarly, let $e = \{e_1, e_2, ..., e_n\}$ be the entity types

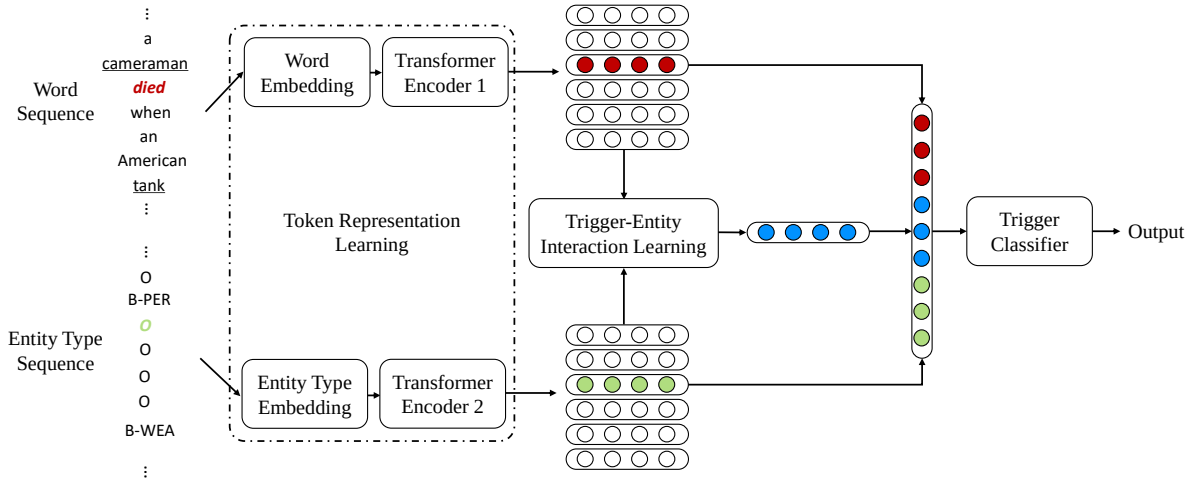

Figure 1: Global structure of our method.

corresponding to w. In consideration that cross-word entity mentions occur frequently in the ACE 2005 dataset, we apply BIO annotation schema to assign entity types for each token in the word sequence. Besides, we use c to represent the position of a candidate trigger in the sequence, so w_c and e_c show the word and entity type information of the candidate trigger respectively. In order to learn vector representations in local semantic context for the word and entity type tokens, firstly, we use embedding layers to transform the symbolic representations w and e to real-value vectors. Then, the Transformer Encoders are applied to capture the semantic relation between tokens, and learn a specific vector representation for each token.

Embedding Layer

With the help of the embedding layer, we transform the word token w_i and entity type token e_i in the input sequences into real-value representations. By looking up pre-trained word embedding matrix for w_i, a fixed sized vector representation x_{w_i} can be obtained. On the other side, for embedding entity type tokens, following existing works (Li et al., 2013; Chen et al., 2015; Liu et al., 2017; Nguyen and Grishman, 2015), we randomly initialize the real-value representation for each entity type and update it during the training process. The vector representation of e_i is marked as x_{e_i}.

Transformer Encoder Structure

Proposed by Vaswani et al. (2017), the Transformer has proved its effectiveness on the machine translation task. Different from most neural network based machine translation models (Cho et al., 2014; Bahdanau et al., 2015; Gehring et al., 2017), the Transformer is solely based on attention mechanisms, dispensing with recurrences and convolutions entirely. One of the most important reasons is that it is easier for attention mechanisms to learn long-range dependencies, which is a key challenge in sequential data modeling, than recurrent and convolutional neural networks. The Transformer has an encoder-decoder structure, the encoder maps the input sequence to new continuous representations, then the decoder receives the representations and generates an output sequence. The encoder-decoder structure is suitable for the machine translation task, however, in our approach, we only need to produce token representations for input sequences based on their local context. So, only the Transformer Encoder is used in our model.

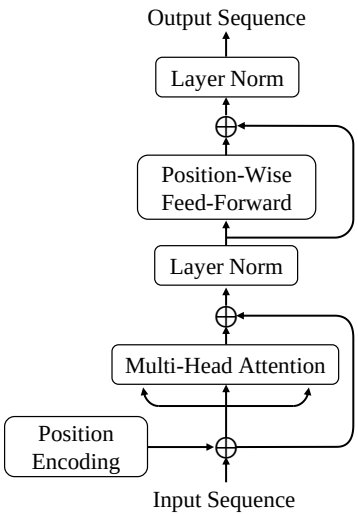

Figure 2: Architecture of the Transformer Encoder.

Figure 2 shows the architecture of the Transformer Encoder employed in our approach. For an input sequence consists of vector representations $\{x_1, x_2, ..., x_n\}$ with $x_i \in \mathbb{R}^d$, the Transformer Encoder produces the output sequence $\{z_1, z_2, ..., z_n\}$ of the same dimension with the input sequence. There are two sub-layers in the Transformer Encoder, one is a multi-head self attention layer, and the ohter is a position-wise feed-forward layer. Each sub-layer is followed by a residual connection (He et al., 2016) and a layer normalization (Lei Ba et al., 2016).

Based on single attention function, multi-head attention mechanism jointly captures the information from different representation subspaces. It firstly does h times different linear projections on the same input, then performs h single attention functions in parallel. Finally, in order to integrate all the information together, h output values from single attention functions are concatenated and projected to the same dimension with the input.

$$A_i(x) = softmax\left(\frac{\left(xW_i^Q\right)\left(xW_i^K\right)^T}{\sqrt{d_k}}\right) \quad (1)$$

$$head_i = A_i(x) \cdot \left(xW_i^V\right) \quad (2)$$

$$MultiHead(x) = [head_1, ..., head_h] \cdot W^O \quad (3)$$

where $x \in \mathbb{R}^{n\times d}$ is the input of the multi-head attention layer, $W_i^Q \in \mathbb{R}^{d\times d_k}$, $W_i^K \in \mathbb{R}^{d\times d_k}$, $W_i^V \in \mathbb{R}^{d\times d_v}$ are parameters to perform linear projections on input vectors, $W^O \in \mathbb{R}^{hd_v\times d}$ projects the concatenation of h single attention results to the same dimension with x. d_k, d_v are hyper-parameters determining projection dimensions.

In addition to the multi-head attention layer, a position-wise feed-forward layer is employed to enhance the representation capability of the Transformer Encoder.

$$FFN(x') = relu\left(x'W_1 + b_1\right)W_2 + b_2 \quad (4)$$

where $x' \in \mathbb{R}^{n\times d}$ is the input of the feed-forward layer, $W_1 \in \mathbb{R}^{d\times d_{hidden}}$, $b_1 \in \mathbb{R}^{d_{hidden}}$, $W_2 \in \mathbb{R}^{d_{hidden}\times d}$, $b_2 \in \mathbb{R}^d$, in which d_{hidden} is a hyper-parameter. Besides, since the Transformer Encoder contains neither recurrence nor convolution, in order to utilize the order information of sequence, position encodings are added to the input sequence at the beginning of the Transformer Encoder. The position encodings are calculated with the following equations:

$$PE(pos, 2i) = sin\left(pos/10000^{2i/d}\right) \quad (5)$$

$$PE(pos, 2i+1) = cos\left(pos/10000^{2i/d}\right) \quad (6)$$

where pos is the position and i is the dimension.

With the Transformer Encoder architecture described above, we obtain the vector representations from word sequence x_w and entity type sequence x_e separately, which will be marked as $z_w = \{z_{w_1}, ..., z_{w_n}\}$, $z_{w_i} \in \mathbb{R}^{d_w}$ and $z_e = \{z_{e_1}, ..., z_{e_n}\}$, $z_{e_i} \in \mathbb{R}^{d_e}$ in the following paragraph.

2.2 Trigger-Entity Interaction Learning

After the token representation learning, we get two sequences z_w and z_e. In order to encode the interaction between entity types and the candidate trigger, we introduce a trigger-entity interaction learning module in this subsection. It is an attention-based module which calculates the attention factors between the candidate trigger and entity types. In this procedure, we notice that there are many tokens with type O in the entity type sequence, which may prevent the method from explicitly modeling the relation between entity mentions' types (non-O entity types) and candidate trigger. Inspired by Nguyen and Grishman (2018), in this paper, we exclusively calculate the relation between the type of entity mentions and the candidate trigger. Given the vector representation of the candidate trigger z_{w_c} and the entity type sequence z_e, the attention values will be calculate as:

$$z_{em} = \{z_{e_i} | 1 \le i \le n \text{ and } e_i \neq O\} \quad (7)$$

$$\alpha = \sigma\left(\frac{(z_{w_c}U_1)\cdot(z_{em}U_2)^T}{\sqrt{d_w}} + b_3\right) \quad (8)$$

$$\alpha' = softmax\left(\alpha\right) \quad (9)$$

where $z_{em} \in \mathbb{R}^{k\times d_e}$ with supposing that there are k entity mentions in the sample, $U_1 \in \mathbb{R}^{d_w\times d_w}$, $U_2 \in \mathbb{R}^{d_e\times d_w}$, $b_3 \in \mathbb{R}^k$. As mentioned by Vaswani et al. (2017), to counteract the effect that the large values of d_w may impact the softmax result, we employ a coefficient $\frac{1}{\sqrt{d_w}}$ to scale the dot product.

Finally, with the help of the attention values α' and the entity mention type sequence z_{em}, we can calculate the vector representation for the trigger-entity interaction. Before doing the dot product

with α', in order to reinforce the capability of the model, we employ a fully connected layer on z_{em} with ReLU as activation function.

$$r = \alpha' \cdot relu(z_{em}U_3 + b_4) \quad (10)$$

where $U_3 \in \mathbb{R}^{d_e \times d_w}$, $b_4 \in \mathbb{R}^{d_w}$, and $r \in \mathbb{R}^{d_w}$ represents the output of trigger-entity interaction learning.

2.3 Trigger Classification

As illustrated in Figure 1, for each sample, we concatenate the trigger-entity interaction r with the candidate trigger z_{w_c} and the corresponding entity type representation z_{e_c}, to form the complete candidate trigger representation. Then, a multi-layer perceptron is employed as the trigger classifier to model the candidate trigger representation. The activation function SELU (Klambauer et al., 2017) is utilized in this multi-layer perceptron. Finally, the softmax function is applied to calculate the conditional probabilities that the candidate trigger belongs to each event type.

$$H_{c_1} = selu\left([z_{w_c}, z_{e_c}, r]W_{c_1} + b_{c_1}\right) \quad (11)$$
$$H_{c_2} = selu\left(H_{c_1}W_{c_2} + b_{c_2}\right) \quad (12)$$
$$O = softmax\left(H_{c_2}W_o + b_o\right) \quad (13)$$

where $W_{c_1} \in \mathbb{R}^{(d_e+2d_w)\times d_{c_1}}$, $W_{c_2} \in \mathbb{R}^{d_{c_1}\times d_{c_2}}$, $W_o \in \mathbb{R}^{d_{c_2}\times d_T}$ are weight metrics, in which d_{c_i} $(i \in \{1, 2\})$ are dimensions of the hidden states, d_T demonstrates the number of event types.

During the training procedure, we set the cross-entropy error as the loss function of our model, and the Adam optimizer (Kingma and Ba, 2015) is utilized to update the parameters. To keep the scale of gradients roughly the same in all layers, all the parameters are initialized by Xavier initializer (Glorot and Bengio, 2010). Table 1 shows the hyper-parameter settings in our experiments.

Module	Parameter	Value
Embedding	word	200
	entity	128
Transformer Encoder (Common)	head number	4
	layer number	1
	d_{hidden}	2048
Transformer Encoder (Word)	d_k	200
	d_v	200
Transformer Encoder (Entity)	d_k	128
	d_v	128
Trigger Classifier	d_{c_1}	256
	d_{c_2}	64
Adam Optimizer	lr	5e-5
	β_1	0.9
	β_2	0.999
	ϵ	1e-8

Table 1: Hyper-parameter settings in our experiments.

3 Experiments

3.1 Dataset

We evaluate our approach on a widely used benchmark dataset ACE 2005. In this dataset, event triggers are categorized into 33 subtypes (e.g., Be-Born, Marry, Attack). Besides, we annotate the candidate triggers which have no event types with the NA type. So, in total 34 event types are involved in our experiments. We also utilize the golden entity mentions annotated in ACE 2005 with BIO schema to produce the entity type sequences. Following the previous studies (Liu et al., 2019; Hong et al., 2018; Ji and Grishman, 2008), from the ACE 2005 English corpus, we choose randomly 40 newswire articles as the test set, 30 other articles as the development set, and pick the remaining 529 articles as the training set.

Following the ACE 2005's guideline document and Liu et al. (2019), we enumerate every noun, verb and adjective in sentences as candidate triggers. The NLP toolkit NLTK[3] is employed to parse and annotate the POS tags for sentences. We use pre-trained GloVe (Pennington et al., 2014) vectors as the embeddings for word tokens, and randomly initialize the embeddings for entity types then update them during the training procedure.

3.2 Overall Performance

We compare our ETEED model with the following state-of-the-art methods:

1) **JointBeam** is a feature-based method proposed by Li et al. (2013), which combines the manually designed local and global features to extract events.

2) **RBPB** is proposed by Sha et al. (2016), which simultaneously utilizes patterns and elaborately designed features to extract event triggers. In addition, a regularization method is applied to further improve the performance of the model.

3) **JRNN** is proposed by Nguyen et al. (2016), which combines the manually designed features with BiGRU to jointly extract triggers and arguments.

4) **HNN** is a language independent neural net-

[3]http://www.nltk.org/

Method	Trigger Identification(%)			Trigger Classification(%)		
	P	R	F1	P	R	F1
JointBeam	76.9	65.0	70.4	73.7	62.3	67.5
RBPB		N/A		70.3	67.5	68.9
JRNN	68.5	75.7	71.9	66.0	73.0	69.3
HNN*	**80.8**	71.5	75.9	**84.6**	64.9	73.4
SELF	75.3	78.8	77.0	71.3	74.7	73.0
DEEB-RNN		N/A		72.3	75.8	74.0
TEACHER		N/A		76.8	72.9	74.8
ETEED (ours)	78.1	**82.5**	**80.2**	74.1	**78.2**	**76.1**

Table 2: Overall performance with golden entity labels. * represents the model doesn't utilize entity type information.

work architecture proposed by Feng et al. (2016). With the structure which combines BiLSTM with CNN, this method can capture both the sequence and chunk information of words to benefit ED.

5) **DEEB-RNN** is proposed by Zhao et al. (2018), which incorporates the document-level clues with BiGRU to enhance ED.

6) **SELF** is proposed by Hong et al. (2018), which integrates BiLSTM into GAN structure, in order to distinguish the authentic information from spurious features.

7) **TEACHER** is an adversarial imitation based knowledge distillation approach proposed by Liu et al. (2019). This model contains two modules, one is a "teacher" module which combines the word sequences with the golden annotations of entity types and argument roles to learn knowledge representations. The other one is a "student" module which tries to imitate the representations from the "teacher" module.

We evaluate the performance via Precision (P), Recall (R) and F1-score (F1). Table 2 shows the overall performance of different approaches on the ED task. From the results, it can be found that our approach outperforms the state-of-the-art methods in both trigger identification and trigger classification. In the trigger identification, our approach achieves better results than all the previous methods in recall and F1-score (promote respectively 3.7% and 3.2% against the best baseline model SELF). Besides, although lower in precision by 2.8% , ETEED is 11% higher than the HNN model in recall. The same conclusion can be made in the trigger classification, our methods produces the highest recall and F1-score, and the improvement of F1-score is 1.3% over the best baseline model TEACHER. To summarize, on the one hand, ETEED significantly improves the recall values compared with the state-of-the-art methods. On the other hand, ETEED produces relatively comparable precisions to the existing methods, which ensures the good F1-score.

Method	Classification F1(%)
JointBeam	65.6 (↓1.9)
RBPB	67.8 (↓1.1)
TEACHER	71.2 (↓3.6)
ETEED (ours)	**74.8** (↓1.3)

Table 3: Performance with predicted entity labels. ↓ represents the performance drop from golden annotations.

To further verify the performance of our model in the real testing scenario, where the golden entity annotations are missing, we utilize the predicted entity type labels in the test procedure. Following Liu et al. (2019), we train a BiLSTM-CRF model on the training set, then apply it on the test set to get the predicted entity type sequences. The F1-score of the BiLSTM-CRF model on the test set is 82.7%. The JointBeam, RBPB and TEACHER are selected as baseline methods. Table 3 shows that our approach has significant improvement compared with the baseline methods. Besides, our model has relatively small performance descent with using predicted annotations than using golden annotations.

3.3 Effect of Entity Type Representation

In order to evaluate the effect of the entity type representation, we design the two following experiments:

Method	Trigger Identification(%)			Trigger Classification(%)		
	P	R	F1	P	R	F1
ETEED$_{no_entity}$	82.1	74.4	78.0	77.8	70.5	74.0
ETEED$_{concat}$	**83.2**	73.9	78.3	**78.4**	69.7	73.8
ETEED	78.1	**82.5**	**80.2**	74.1	**78.2**	**76.1**

Table 4: Effect of entity type sequence representation.

Method	Trigger Identification(%)			Trigger Classification(%)		
	P	R	F1	P	R	F1
ETEED$_{no_interaction}$	**82.6**	75.2	78.7	**79.3**	72.2	75.6
ETEED$_{all_entity}$	82.3	77.4	79.7	78.2	73.5	75.8
ETEED	78.1	**82.5**	**80.2**	74.1	**78.2**	**76.1**
TEACHER	N/A			76.8	72.9	74.8
ETEED$_{argument}$	87.4	82.9	85.1	**86.0**	**81.6**	**83.8**

Table 5: Effect of trigger-entity interaction.

1) **ETEED**$_{no_entity}$ utilizes only word token sequences, which means there is no more entity information used in the model. For each sample, firstly the word sequence is encoded by the Transformer Encoder, then the candidate trigger's representation x_{w_c} is fed into the trigger classifier to get its event type.

2) **ETEED**$_{concat}$ follows some previous works (Liu et al., 2019, 2017), this model utilizes the concatenation of the word representations and the entity type representations as the input of downstream structures. In ETEED$_{concat}$, the concatenated representations are sent into the Transformer Encoder, then the features of the candidate triggers are picked from the output results to be classified by the trigger classifier.

The hyper-parameter settings keep the same with the ETEED. Table 4 shows that, our approach significantly outperforms the baseline models on F1-score (1.9% on identification and 2.1% on classification). In the meanwhile, our method has higher recall values but slightly lower precision values than the baseline models. This phenomenon shows that our method can largely improve the recall values with few precision loss. Especially, when compared with ETEED$_{concat}$, ETEED produces large performance gain on F1-score (1.9% and 2.1% on identification and classification respectively), which proves the effectiveness of our method. With the entity types' sequential features, our method can bring more entity information to trigger classifier than the baseline models.

3.4 Effect of Trigger-Entity Interaction

In this subsection, we conduct three comparison experiments to evaluate the effect of the trigger-entity interaction learning.

1) **ETEED**$_{no_interaction}$ removes the trigger-entity learning from the complete model.

2) **ETEED**$_{all_entity}$ uses all entity type information rather than the entity mentions' type information to learn trigger-entity interaction.

3) **ETEED**$_{argument}$ is a model designed to evaluate the effect of the argument role sequence. As mentioned in (Liu et al., 2019), TEACHER needs to utilize both the entity type and the argument role information to get the best performance. In the ETEED$_{argument}$, we replace the entity type sequences by the argument role sequences to compare with the TEACHER model.

Table 5 shows the results. Compared with ETEED$_{no_interaction}$, the complete ETEED model performs larger improvement on identification than classification on F1-score (1.5% to 0.5%). This result reveals that the use of entity mentions' types is obviously helpful when judging the occurrence of an event, but when it comes to trigger classification, the entity mention information brings less improvement. In order to explicitly capture the entity mention information, we only use entity mention features in our approach. To evaluate its effect, we compare ETEED$_{all_entity}$ with ETEED. Although the performance gain are

not significant, focusing on entity mentions can still bring 0.5% and 0.3% F1-score improvement on trigger identification and classification.

When comparing ETEED$_{argument}$ with ETEED, we can find that the use of argument role information can dramatically improve the performance of ED, because argument roles contain more information than entity types. Besides, some special argument roles can point to specific event types. As methods which use argument role information, ETEED$_{argument}$ significantly outperforms TEACHER, this result further proves the effectiveness of our model. However, in the real testing and application scenarios, we can hardly obtain the arguments role information before getting the event types of the candidate triggers. Instead, using predicted entity type information is more feasible.

4 Related Work

Event Detection is an important task in Information Extraction. The majority of existing approaches regard this task as a classification problem, and we summarize these approaches into two categories globally.

Feature-based methods are proposed as the first kind of approach to tackle the ED task by introducing feature-engineering to convert the classification clues like POS tags and dependency features into feature vectors (Ahn, 2006; Ji and Grishman, 2008; Hong et al., 2011; Li et al., 2013; Patwardhan and Riloff, 2009; Gupta and Ji, 2009; Liao and Grishman, 2010; Liu et al., 2016). This kind of approach depends heavily on expert knowledge and manual feature design, which makes these approaches time-consuming and low adaptability on different datasets. Chambers and Jurafsky (2011) design a weakly supervised system, which can automatically induce the event templates and extract event information from unlabeled corpus, to alleviate the need of expert knowledge. However, the required external resources are not always available for some low-resource languages.

In recent years, deep learning methods have proved their effectiveness on the ED task. (Chen et al., 2015; Nguyen and Grishman, 2016; Lin et al., 2018) utilize CNN to automatically capture the high-level vector representations of sentences. Nguyen et al. (2016) apply RNN in their model in order to capture the sequential features in the sentences. Feng et al. (2016) combine CNN with RNN and propose a hybrid neural network. Araki and Mitamura (2018) make use of the distant supervision mechanism to detect the events regardless of domains. Liu et al. (2017); Zhao et al. (2018) utilize attention mechanisms aiming to fuse the external sentence features (i.e. entity type features, document features) with the word features. (Hong et al., 2018; Liu et al., 2019) implement adversarial training to distinguish effective information from spurious features. GCN is a powerful neural network architecture on graphs, Nguyen and Grishman (2018) use this architecture to represent dependency relations in sentences. Compared with the feature-based methods, the deep learning methods need no more feature-engineering, which means less financial/time cost and better adaptability. Among them, there are several approaches which utilize the entity type information in their neural networks. Liu et al. (2017) utilize the entity type embedding directly as local context of the current word, and calculate the attention values between them; others (Liu et al., 2018b, 2019; Nguyen and Grishman, 2018) concatenate the entity type embeddings with the work token embeddings, in order to integrate these two types of features into mixed representations with the help of neural networks. However, these existing studies ignore the entity types' sequential features which may benefit the ED task.

In our approach, we learn the word features and the entity type features separately, which allows us to capture the sequential features of entity types and thus make full use of the entity type information. Besides, an attention-based trigger-entity interaction learning is introduced in our work to learn relations between the candidate trigger words and the entity mentions' type features.

5 Conclusion

In this work, we propose a novel neural network architecture ETEED for the ED task. In order to capture the sequential features from both the word sequences and the entity type sequences, our approach proposes to model these two types of sequences separately. The two types of sequences are firstly modeled by two isolated Transformer Encoders, then, an attention-based trigger-entity interaction learning module is applied to capture the correlations between the candidate trigger's word representation and the entity type representations of the sequence. Aiming to obtain a more

accurate interaction representation, this module utilizes only the entity mentions' type information rather than the whole entity type sequence to calculate the attention values. Finally, the concatenation of the candidate trigger's word, entity type representations and the trigger-entity interaction representation is fed into the trigger classifier to obtain the final event category. In the future, we plan to extend our method to the Event Extraction task, which means not only to extract triggers from sentences, but also to identify and classify the corresponding event arguments.

Abstract

Recent developments in Named Entity Recognition (NER) have resulted in better and better models. However, is there a glass ceiling? Do we know which types of errors are still hard or even impossible to correct? In this paper, we present a detailed analysis of the types of errors in state-of-the-art machine learning (ML) methods. Our study reveals the weak and strong points of the Stanford, CMU, FLAIR, ELMO and BERT models, as well as their shared limitations. We also introduce new techniques for improving annotation, for training processes and for checking a model's quality and stability.

Presented results are based on the CoNLL 2003 data set for the English language. A new enriched semantic annotation of errors for this data set and new diagnostic data sets are attached in the supplementary materials.

1 Introduction

The problem of Named Entity Recognition (NER) was defined over 20 years ago at the Message Understanding Conference (MUC, 1995; Sundheim, 1995). Nowadays, there are a lot of solutions capable of a very high accuracy even on very hard and multi-domain data sets (Yadav and Bethard, 2018; Li et al., 2018).

Many of these solutions benefit from large available data sets or from recent developments in deep neural networks. However, in order to progress further with this last mile, we need a better understanding of the sources of errors in NER problem; as it is stated that *"The first step to address any problem is to understand it"*. We performed a detailed analysis of errors on the popular CoNLL 2003 data set (Tjong Kim Sang and De Meulder, 2003).

Of course, different models make different mistakes. Here, we have focused on models that constitute a kind of breakthrough in the NER domain. These models are: Stanford NER (Finkel et al., 2005), the model made by the NLP team from Carnegie Mellon University (CMU) (Lample et al., 2016), ELMO (Peters et al., 2018), FLAIR (Akbik et al., 2018) and BERT-Base (Devlin et al., 2018). In the Stanford model, Conditional Random Fields (CRF) with manually created features were tackled. Lample and the team (at CMU) used an LSTM deep neural network with an output with CRF for the first time. ELMO and FLAIR are new language modeling techniques as an encoder, and LSTM with a CRF layer as an output decoder. A team from Google used a fine-tuning approach with the BERT model in a NER problem for the first time, based on a Bi-diREctional Transformer language model (LM).

We analyzed the data set from a linguistic point of view in order to understand problems at a deeper level. As far as we know only a few studies analyse in details errors for NER problems (Niklaus et al., 2018; Abudukelimu et al., 2018; Ichihara et al., 2015). They mainly explore a range of name entities (boundaries in a text) and the precision and popular metrics of a class prediction (precision, recall, F1). We found the following discussions valuable:

- (Abudukelimu et al., 2018) on annotation and extraction of Named Entities,
- (Braşoveanu et al., 2018) on an analysis of errors in Named Entity Linking systems,
- (Manning, 2011) on linguistic limitations in building a perfect Part-of-Speech Tagger.

We took a different approach. First, our team of data scientists and linguists defined 4 major and

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 624–633
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

11 minor categories of types of problems typical for NLP (see Tab. 2). Next, we acquired all erroneous samples (containing errors in model outputs) and we assigned them to the newly defined categories. Finally, we characterized the incorrect output of the models with regard to gold standard annotations and following our team's consensus.

Accordingly, our overall contribution is a conceptualization and classification of the roots of problems with NER models as well as their characterization. Moreover, we have prepared new diagnostic sets for some of our categories so that other researchers can check the weakest points of their NER models.

In the following sections, we introduce our approach regarding the re-annotation process and model evaluation (section 2); we also show and discuss the results (section 3). Finally, we conclude our paper with a discussion (section 4) and draw conclusions (section 5).

2 Method

We commenced our research by reproducing the selected models for the CoNLL 2003 data set[1]. Then, we analysed the erroneous samples, sentences from the test set. It is worth mentioning that we analysed the most common types of named entities, i.e. PER - names of persons, LOC - location names, ORG - organization names. Having several times reviewed the model results and the error-prone data set, we defined the linguistic categories that are the most probable sources of model mistakes. As a result, we were able to annotate the samples with these categories; we then analysed the results and found a few possible improvements.

2.1 Models description

A brief history of the key developments of NER models for the CoNLL data is listed in Table 1. In our analysis, we chose 5 models (bold in the table) that make up significant progress.

Stanford NER CRF was the first industry-wide library to recognize NERs (Finkel et al., 2005). The LSTM layer put forward by Lample from Carnegie Mellon University (CMU) was the first deep learning architecture with a CRF output layer (Lample et al., 2016). The following: a token-based language model (LM) with bi-LSTM with CRF (ELMO) (Peters et al., 2018), a character-based LM with the same output (FLAIR) (Akbik et al., 2018) and a bi-directional language model based on an encoder block from the transformer architecture (BERT) with a fine tune classification output layer (Devlin et al., 2018) are very important techniques; and that not only in the domain of NER.

Model	F1
Ensemble of HMM, TBL, MaxEnt, RRM (Florian et al., 2003)	88.76
Semi-supervised learning (Ando and Zhang, 2005)	89.31
Stanford CRF (Finkel et al., 2005)	87.94
Neural network (Collobert et al., 2011)	89.59
CRF & lexicon embeddings (Passos et al., 2014)	90.90
CMU LSTM-CRF (Lample et al., 2016)	90.94
Bi-LSTM-CNNs-CRF (Ma and Hovy, 2016)	91.21
ELMO: Token based LM Bi-LSTM-CRF (Peters et al., 2018)	92.22
BERT-base: Fine tune Bi-Transformer LM with BPE token encoding (Devlin et al., 2018)	92.4 (*)
CVT: Cross-view training with Bi-LSTM-CRF (Clark et al., 2018)	92.61
BERT-large: Fine tune Bi-Transformer LM with BPE token encoding (Devlin et al., 2018)	92.8 (*)
FLAIR: Char based LM + Glove with Bi-LSTM-CRF (Akbik et al., 2018)	93.09 (**)
Fine tune Bi-Transformer LM with CNN token encoding (Baevski et al., 2019)	93.5

Table 1: Results reported in authors' publications about NER models on the original CoNLL 2003 test set. (*) There is no script for replicating these results and also hyper-parameters were not given. See a discussion at (google bert, 2019) (**) This result was not achieved with the current version of the library. See a discussion at (Flair, 2018) and the reported results at (Akbik et al., 2019)

2.2 Linguistic categories

From a human perspective, the task of NER involves several sources of knowledge: the situation in which the utterance was made, the context of

[1] The details of the model parameters are described in our supplementary materials.

other texts and utterances in the particular domain, the structure of the sentence, the meaning of the sentence, and general knowledge about the world.

While designing categories for annotation, we tried to define these layers of NEs understanding; however, some of them are particularly problematic. For example, there is a problem with a distinction between the meaning (of lexical items and of a whole sentence) and general knowledge. Since there is an enormous and relentless linguistic and philosophical debate on this topic (Rey, 2018), we decided not to delimit these categories and not to distinguish them. Therefore, they have been labeled together as 'sentence level context' (SL-C).

Consequently, we ended up with a set of categories for annotating the items (sentences) from our data set, which are presented in Table 2 as well as described briefly in the following sections and more precisely in the supplementary materials. We have also added more examples for each category in this material.

shortcut	linguistic property
DE-	Data set Errors
DE-A	Annotation errors
DE-WT	Word Typos
DE-BS	Word/Sentence Bad Segmentation
SL-	Sentence Level dependency
SL-S	Sentence Level Structure
SL-C	Sentence Level Context
DL-	Document Level dependency
DL-CR	Document Co-Reference
DL-S	Document Structure
DL-C	Document Context
G-	General properties
G-A	General Ambiguity
G-HC	General Hard Case
G-I	General Inconsistency

Table 2: Linguistic categories prepared for our annotation procedure.

DE-A: Annotation errors are obvious errors in the preliminary annotations (the gold standard in the CoNLL test data set). For example: in the sentence *"SOCCER - JAPAN GET LUCKY WIN, CHINA IN SURPRISE DEFEAT"* as a gold standard annotation *"CHINA"* is assigned a person type; it should, however, be defined as a location so as to be consistent with the other sentence annotations.

DE-WT: Word typos are simple typos in any word in a sample sentence, for exmple: *"Pollish"* instead of *"Polish"*.

DE-BS: Word-sentence bad segmentation. We annotated this case if a few words, joined together with a hyphen or separated by a space, were incorrectly divided into tokens (e.g. *"India-South"*), or where a sentence was erroneously divided inside a boundary of a named entity, which prevented its correct interpretation. For example: in the data set there is a sentence divided into two parts: *"Results of National Hockey"* and *"League"*.

SL-S: Sentence level structure dependency occurs when there is a special construction within a sentence (a syntactic linguistic property) that is a strong premise for defining an entity. In the studied material, we distinguished two such constructions: brackets and bullets. The error receives the SL-S annotation, when the system should have been able to recognize a syntactic linguistic property that leads to correct NER tagging but failed to do so and made a NER mistake. For example: one of the analysed NER systems did recognize all locations except *"Philippines"* in the following enumerating sentence: *"ASEAN groups Brunei, Indonesia, Malaysia, the Philippines, Singapore, Thailand and Vietnam."*.

SL-C: Sentence level context cases are those in which one is able to define an appropriate category of NE based only on the sentence context. For example: one of NER systems has a problem with recognizing the organization *"Office of Fair Trading"* in the sentence: *"Lang said he supported conditions proposed by Britain's Office of Fair Trading, which was asked to examine the case last month."*.

DL-CR: Document level co-reference category was annotated if there was a reference within a sentence to an object that was also referred to in another sentence in the same document. For example: evaluating the *"Zywiec"* named entity in the sentence *"Van Boxmeer said Zywiec had its eye on Okocim ..."*, it has to be considered that there is another sentence in the same document in the data set that explains the organization name, which is: *"Polish brewer Zywiec's 1996 profit..."*.

DL-S: Document level structure cases are those in which the structure of a document plays an important role, i.e. the occurrence of objects in the table (for example the headings determine

the scope of an entity itself and its category). For example: look at the following three sentences, which obviously compose a table: *"Port Loading Waiting"*; *"Vancouver 5 7"*, *"Prince Rupert 1 3"*. One of our NER systems had a problem with recognizing each localisation inside the table; however, the system recognized the header as a named entity.

DL-C: Document level context is a type of a linguistic category in which the entire context of a document (containing an annotated sentence) is needed in order to determine a category of an analysed entity, and in which none of the sentence level linguistic categories has been assigned (neither SL-S and SL-C).

G-A: General ambiguity are those situations in which an entity occurs in a different sense from that in which this word (entity) is used in its most common understanding and usage. For example: the common word *'pace'* may as well be occur to be a surname, as in the following sentence: *"Pace, a junior, helped Ohio State..."*.

G-HC: General hard cases are cases occurring for the first time in a set in a given subtype, and which can be interpreted in two different ways. For example: *"Real Madrid's Balkan strike force..."* where the word *'Balkan'* can be a localisation or an adjective.

G-I: General inconsistency are cases of inconsistencies in the annotation (in the test set itself as well as between the training and test sets). For example in the sentence: *"... Finance Minister Eduardo Aninat said."*, the word *'Finance'* is annotated as an organisation but in the whole data set the names of ministries are not annotated in the context of the role of a person.

2.3 Annotation procedure

All those entities that had been incorrectly recognized by any of the tested modelsfalse positives, false negatives and wrongly tagged entities were annotated in our research by two teams. Each team consisted of a linguist and a data scientist. We did not analyse errors with the MISC entity type, but the person, localisation and organisation names. The MISC type comprises a variety of NERs that are not of other types. Its definition is rather vague and it is hard to conceptualize what it actually means, e.g. if whether it comprises events or proper names, or even adjectives.

The annotation process was performed in four steps:

1. a set of linguistic annotation categories was established, see the previous section 2.2;

2. the data set was split into two equal parts: one part for each team; all entities were annotated twice, by a linguist and by a data scientist, each working independently;

3. the annotations were compared and all inconsistencies were solved within each team;

4. two teams checked the consistency of the other team's annotations; all borderline and dubious cases were discussed by all team members and reconciled.

The inter-annotator agreement statistics and Kappa are presented in Table 3. A few categories were very difficult to conceptualize, so it took more time to solve these inconsistencies. In these inconsistent cases, two annotators (a linguist and a data scientist) thoroughly discussed each example.

Not all categories (see Table 2) were annotated by the whole team. Those easy to annotate, as the categories regarding simple errors (i.e. DE-A, DE-WT, DE-BS), were done by one person and then just checked by another.

The general inconsistencies category (G-I) were done semi-automatically and then checked. The semi-automatic procedure was as follows: first finding similarly named entities in the training and test sets and then looking at their labels. By 'similarly named entities' we mean, e.g. a division of an organization having a geographical location in its name ("Pacific Division"), or a designation of a person from any country ("Czech ambassador").

Additionally, a document level context (DL-C) category was derived from the rule of not being present in any sentence level category (i.e. SL-C or SL-S).

2.4 Our diagnostic procedure

The next step, after the analysis of linguistic categories of errors, was to create additional diagnostic sets. The goal of this approach was to find, or create, more examples that reflect the most challenging linguistic properties; these can be sentence and document level dependencies and can also include a few ambiguous examples. These ambiguities are for instance names that contain words in common usage. We selected 65 examples

annotated class	agreement [%]	Kappa
SL-S	94.99	0.572
SL-C	69.64	0.389
DL-CR	78.00	0.554
DL-S	81.44	0.536
G-A	68.96	0.252
G-HC	74.46	0.340

Table 3: Inter-annotator statistics (agreement and Kappa) at the very first stage of the annotation procedure, before discussing each controversial example and the super-annotation stage. The statistics are calculated for those categories that were annotated by human annotators.

from Wikipedia articles per two groups of linguistic problems: sentence-level and document-level contexts.[2]

The first diagnostic set comprises sentences in which the properties of a language, general knowledge or a sentence structure are sufficient to identify a NE class. We use this Template Sentences (TS) to check whether a model will have the same quality after changing words, i.e. a name of an entity. For each sentence we prepared at least 2 extra entities with different lengths of words which are well suited to the context. For example in a sentence: *"Atlético's best years coincided with dominant Real Madrid teams."*, the football team *"Atlético"* can be replaced with *"Deportivo La Coruña"*.

The second batch of documents was a group of sentences in which a sentence context is not sufficient to designate a NE, so we need to know more about the particular NE, e.g. we need to look for its co-references in the document, or we require more context, e.g. a whole table of sports results, not only one row. (This particular case often occurs in the CoNLL 2003 set when referring to sports results.) We called this data set Document Context Sentences (DCS). In this data set we annotated NEs and their co-references that are also NEs. An example of such a sentence and its context is as follows: *"In 2003, Loyola Academy (X, ORG) opened a new 60-acre campus ... The property, once part of the decommissioned NAS Glenview, was purchased by Loyola (X,ORG) in 2001."* The second occurrence of the *"Loyola"* name is difficult to recognize as an organization without its first occurrence, i.e. *"Loyola Academy"*.

[2]Our prepared diagnostic data sets are available at https://github.com/applicaai/ner-resources

The other type of a diagnostic set is fairly simple. It is generated from random words and letters that are capitalized or not. Its purpose is just to check if a model over-fits a particular data set (in our case, the CoNLL 2003 set). A scrutinized model should not return any entities on those Random Sentences (RS). We generated 2 thousands of these pseudo-sentences.

3 Results

3.1 Annotation quality

In Table 4 we gathered our model's results for the standard CoNLL 2003 test set and the same set after the re-annotation and correction of annotation errors. We replaced only those annotations (gold standard) which we (all team members) were sure of. Those sentences in which the class of an entity occurrence was ambiguous were not corrected. This shows that the models are better than we thought they were, and so we corrected only the test set and left the inconsistencies.[3].

	Stanford	CMU	ELMO	FLAIR	BERT
ALL-O	88.13	89.78	92.39	92.83	91.62
ALL-C	88.73	90.39	93.21	**93.79**	92.33

MISC-C	79.37	77.58	82.47	**84.40**	81.10

Table 4: Results for selected models on the original (designated as ending '...-O') and re-annotated / corrected ('...-C') CoNLL 2003 test set concerning NE classes (ALL comprise PER, ORG, LOC, MISC). The given metric is a multilabel-F1 score (percentages).

3.2 Linguistic categories statistics

In the CoNLL 2003 test set, we chose as samples words and sentences in which at least one model made a mistake. The set of errors comprises 1101

[3]A small part of the data set of annotation corrections and also the debatable cases will be available at our github – https://github.com/applicaai/ner-resources. We decided not to open the whole data set, because it is the test set and the tuning models on this set would lead to unfair results. On the other hand, we could not perform the analysis on a validation set because it is rather poor with respect to different kinds of linguistic properties.

named entities. The results of each model on this set in terms of our linguistic categories are presented in Fig. 1, Fig. 2 and in Table 5.

Most mistakes were made by the Stanford and CMU models, 703 and 554 respectively. ELMO, FLAIR and BERT, which use contextualised language models, performed much better. These embedded features help the models to understand words in their context and thus resolve most problems with ambiguities.

The CMU model has most problems with sentence level context and ambiguity. This is probably due to the fact that this model uses non-contextualized embedded features (Fig. 2). The Stanford model fares the worst in terms of structured data (almost twice as many errors as the other models), which means that it is not good at defining an entity type within a very limited context (Tab. 5). The Stanford model's hand-crafted features do not store information about the probabilities of words which could represent a specific entity type. It generates much more errors than the other models.

	Stanford	CMU	ELMO	FLAIR	BERT
DE-WT	10	6	9	8	10
DE-BS	38	39	33	33	40
SL-S	46	21	13	16	11
SL-C	448	378	250	223	300
DL-CR	372	316	198	184	263
DL-S	202	107	97	100	117
DL-C	247	175	144	146	170
G-A	219	183	98	101	94
G-HC	72	68	65	59	65
G-I	19	20	21	20	20
Errors	703	554	395	370	472
Unique errors	235	93	23	12	79

Table 5: Number of errors for a particular model and a particular class of errors. The total number of annotated errors is 1101.

Modern techniques using contextualized language models like ELMO, FLAIR and BERT reduced a number of mistakes in SL-C category by more than 50% in comparison to the Stanford model. But they are unable to fix most errors in general problems related to inconsistency (G-I), general hard cases (G-HC) or word typos (DE-WT). See Figure 4 for more details.

Nevertheless, there are still a lot of common

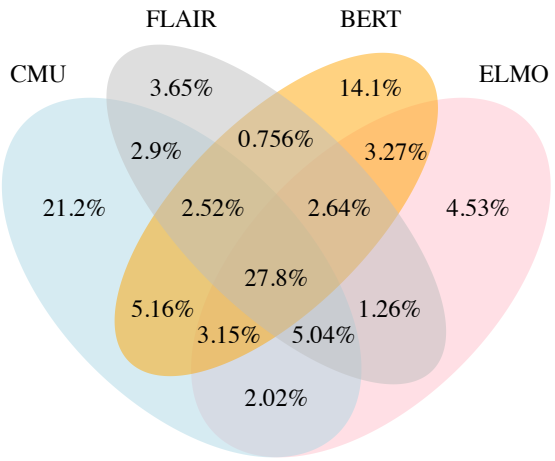

Figure 1: Venn diagram for errors in the CMU, FLAIR, BERT, ELMO models. The four models generate 794 errors and 221 are common to all of them. The Stanford model as the most error-prone is here not referred to.

problems (27.8%). In common errors (Fig. 3), SL-C (sentence level context) and DL-CR (document level co-reference) co-occur the most often. Thus, if a model also takes into account the context of a whole document, it can be of great benefit. Considering a document structure (DL-S) in modeling is also very important. This also can help to resolve a lot of ambiguity issues (G-A). Here is an example of such a situation: *"Pace outdistanced three senior finalists..."*, *"Pace"* is a person's surname, but one is able to find it out only when analysing the whole document and finding references to it in other sentences that directly point to the class of the named entity.

We must be aware of the fact that some problems cannot be resolved with this data set, not even in general. Those problems have roots in two main areas: data set annotation (word typos, bad segmentation, inconsistencies) and a complicated structure of a language. Generally in most languages it is easier to say what entity represents a real word instance than to define an exact entity type (especially when we use a metonymic sense of a word), e.g. 'Japan' can be a name of a country or of a sports team.

3.3 Diagnostic data sets

Looking at the models' results in our diagnostic data sets (Tab. 6), the first and most important observation is that we achieved significantly lower results than originally on the CoNLL 2003 test

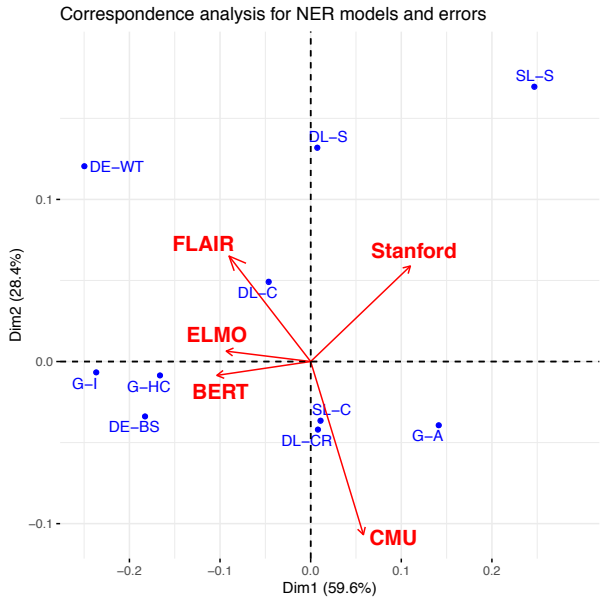

Figure 2: Correspondence analysis for the models' errors. ELMO, FLAIR and BERT are more affected by G-HC and G-I, FLAIR is also reduced with DL-C and DE-WT. See Table 5 for more details and Table 2 for names of categories.

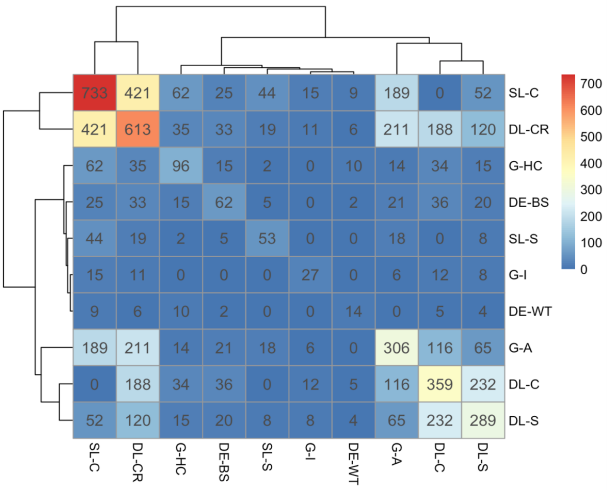

Figure 3: Heatmap for errors from the five considered models. 197 errors are common to all the models. In this figure we can see which linguistic categories tend to occur together.

set[4]. The reason for this is that diagnostic examples were selected for a broader range of topics (not only politics or sports). In particular, document context sentences (DCS) contain 364 unique entities of which only 47 appeared in an exact word form in the training data, and only 42 of them have the same entity type (organization, location or person) - the same type as in the CoNLL 2003

[4]We add statistics and a few examples from our diagnostic data sets in the supplementary materials.

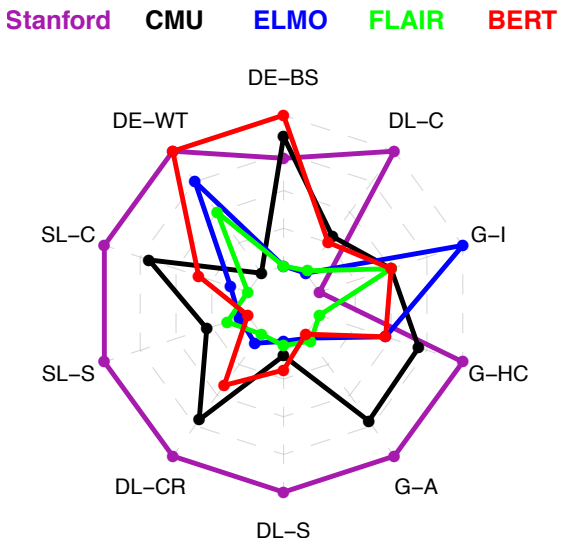

Figure 4: Radar plot with the strong and weak sides of NER models. A radius corresponds to a number of errors in a given linguistic category, the smaller the better. See Table 5 for more details.

training set. Additionally, those sentences are also difficult due to their linguistic properties (for some entities you must analyse a whole article to properly distinguish their type).

As far as the results of the diagnostic sets are concerned, we observed much better results for solutions using embeddings generated by the language models. It seems that by using ELMO embeddings we can outperform the FLAIR and BERT-Base models in case of sentences about general topics, in which the context of a whole sentence is more important than properties of words composing entities.

Moreover, when we tested all the models on random sentences (RS), this was not so good as we might have expected. All the models are very sensitive to words starting with or consisting of capital letters. Results from this diagnostic set could help to choose a model that must work properly on documents which were produced by the OCR engine with their many mistakes and misspellings.

Another interesting idea is to train or just test a model on some template sentences (TS). With such a data set we can test a model's ability to detect proper boundaries of an entity. We can do it by replacing a template entity with another one consisting of a different number of words. We could also adjust our models to a particular domain, e.g.to change entities with a PERSON type in an original data set to be more globally diversified, if we have to extract person names from the

whole world (Asian or Russian names).

	Stan-ford	CMU	ELMO	FLAIR	BERT
DCS (F1)	45.37	61.86	**76.36**	71.89	68.90
DCS (P)	43.66	58.07	73.11	69.35	59.06
DCS (R)	47.21	66.17	79.92	74.63	82.66

Table 6: Diagnostic data sets results for selected models: 'DCS' - Document Context Sentences, 'TS-O' - Template Sentences with original entities, 'TS-R' - Template Sentences with replaced entities, 'RS' - Random Sentences. F1=multilabel F1-score, P=Precision, R=Recall, No=number of returned entities (lower is better). In the RS data set there are 2000 strings pretending to be sentences.

4 Discussion

On the basis of our research, we can draw a number of conclusions that are not often addressed to in publications about new neural models, their achievements and architecture. The scope of any assessment of new methods and models should be broadened to the understanding of their mistakes and the reasons why these models perform well or poorly in concrete examples, contexts and word meanings. These issues are particularly important in text data sets, in which semantic meaning and linguistic syntax are very complex.

In our effort to define linguistic categories for problematic Named Entities and their statistics in the CoNLL 2003 test set, we were able to draw a few additional conclusions regarding data annotation and augmentation processes. Moreover, our categories are similar to the taxonomy defined in publication about errors analysis for Uyghur Named Tagger (Abudukelimu et al., 2018).

4.1 The annotation process

The annotation process is a very tedious and exhaustive task for a person involved. Errors in data sets are expected but what must be checked is their impact on generalizing a model, e.g. one can create entities in places where they do not occur and check the model's stability. There are some useful applications for detecting annotation errors (Ratner et al., 2017), (Graliński et al., 2019) and (Wisniewski, 2018) but they are not used very often. Obviously, an appropriate and exhaustive documentation for the data set creation and annotation process is crucial. All annotated entity types should be described in details and examples of border cases should be given. In our analysis of the CoNLL 2003 data set we did not find any documentation. We have made our own assumptions and tried to guess why some classes are annotated in a given way. However, the work was hard and required many discussions and extended reviews of literature.

Secondly, there is a need for extended data sets with a broadened annotation process, similar to that of our diagnostic sets. E.g. linguists can extend their work not only just to the labelling of items (sentences), but also to indicating the scope of context that is necessary to recognise an entity, and to extending annotations for difficult cases or adding sub-types of entities.

Our work on diagnostic data sets is an attempt to extend an annotation process by focusing only on specific use cases which are less represented in the original data set.

4.2 Extended context

A new model training process itself should consist of more augmentation of the data set. Currently, there is some work being done on this topic, e.g. a semi-supervised context change with cutting the neighbourhood around NEs using a sliding window (Clark et al., 2018). Other techniques could be a random change of the first letter (or whole words) of NEs so that the model would not be so vulnerable to capitalized letters in names or small changes in sentences (e.g. adding or removing a dot at the end of a sentence).

Furthermore, a sentence itself is not always sufficient to recognise a class of a NE. In these cases, in both training and test data sets, there should be more samples where there are indications of co-references that are important to recognise particular NEs. Then, the input of a model should comprise a sentence and embedded features (or any representation) of co-references or their contexts. E.g. *"Little was banned. Peter Little took part in the last match with Welsh team."* - in the first sentence, we are are not sure if it is a NE. Then *"Peter Little"* indicates the proper NE type. An

example of a model and data processing pipeline (i.e. memory of embeddings) that takes into consideration the same names in different sentences is to be found in (Akbik et al., 2019) and (Zhang et al., 2018).

Another important improvement is adding information about document layout or the structure of a text, e.g. a table, its rows and columns, and headings. In CoNLL 2003, there are many sports news, stock exchange reports or timetables where the structure of a text helps to understand its context, and thus to better recognise its NEs. Such a solution for another domaininvoice information extractionis elaborated on by (Katti et al., 2018) or (Liu et al., 2019). The solutions mentioned here combine character information with document image information in one architecture of a neural network.

The CoNLL 2003 test set is certainly too small to test the generalisation and stability of a model. Faced with this issue, we must find new techniques to prevent over-fitting. For instance, we could check a model's resistance to examples prepared in our diagnostics data sets, e.g. after changing a NE in a template sentence, the model should find the entity in the same place. We could also prepare small modifications to our original sentences, e.g. add or remove a dot at the end of an example and compare results (similarly to adversarial methods).

5 Concluding remarks

Mistakes are not all created equal. A comparison of models based on scores like F1 is rather simplistic. In this paper we defined 4 major and 11 minor linguistic categories of errors for NER problems. For the CoNLL 2003 data set and five important ML models (Stanford, CMU, ELMO, FLAIR, BERT-base) we re-annotated all errors with respect to the newly proposed ontology.

The presented analysis helps better understand a source of problems in recent models and also to better understand why some models are more reliable on one data set but less not on another.

Abstract

Document embeddings, created with methods ranging from simple heuristics to statistical and deep models, are widely applicable. Bag-of-vectors models for documents include the mean and quadratic approaches (Torki, 2018). We present evidence that quadratic statistics alone, without the mean information, can offer superior accuracy, fast document comparison, and compact document representations. In matching news articles to their comment threads, low-rank representations of only 3–4 times the size of the mean vector give most accurate matching, and in standard sentence comparison tasks, results are state of the art despite faster computation. Similarity measures are discussed, and the Frobenius product implicit in the proposed method is contrasted to Wasserstein or Bures metric from the transportation theory. We also shortly demonstrate matching of unordered word lists to documents, to measure topicality or sentiment of documents.

1 Introduction

Today, most computational models for natural language are based on distributional representations. Words are routinely represented by *word embeddings* (Mikolov et al., 2013), most commonly as fixed-dimensional real-valued vectors, such as GloVe (Pennington et al., 2014) and fastText (Mikolov et al., 2018). Even though there is extensive literature on using, e.g., character-level and other sub-word information (Lee et al., 2017; Radford et al., 2017; Mikolov et al., 2018) or non-Euclidean embedding spaces (Nickel and Kiela, 2017; Muzellec and Cuturi, 2018), the standard embeddings remain currently as the default building block for practical tools.

Most applications do not, however, care about individual words. Instead, we may be concerned about the meaning of sentences or retrieval of documents, or in general, units larger than words. Distributed representations can be built for these larger units as well. Although sentences and documents differ as linguistic concepts, computational models for them can be similar when they are considered as sequences or even (unordered) bags of words.

Document representations often build on word embeddings. Already the mean of the word vectors turns out to be a surprisingly good representation (Wieting et al., 2015b), and accounting for the importance of words by a weighting scheme improves it further (Arora et al., 2016; Gupta et al., 2019). Even though the bare mean clearly ignores information, it is very efficient to compute. On the other end of the spectrum, document embeddings are built with computationally extremely heavy deep learning models such as ELMo (Peters et al., 2018), ULMFiT (Howard and Ruder, 2018), and BERT (Devlin et al., 2018). Deep models produce rich representations, but the amount of data and computation needed for training make them prohibitive for many applications.[1]

Our work falls between these two extremes. With the understanding that mean vectors may miss important aspects of documents, we want to develop fast and easy-to-use tools. This rules out complex deep networks. Instead, we focus on using second-order interactions between words, building on *covariance* of the embeddings of individual words, following the recent works of Torki (2018) and Nikolentzos et al. (2017).

The motivation of the paper is on finding fast and accurate ways to compare documents, or, alternatively, documents and semantics spanned by word lists. We start by evaluating document sim-

[1] For example BERT takes 0.5 secs to process a sentence on a CPU (Nvidia blog, our experiments), and getting good document representations may require fine-tuning.

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 634–644
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

ilarity as pairwise similarities between words and show that this induces a compact approximative representation for the documents themselves. We relate the pairwise similarity to Wasserstein or Bures metric, used recently in various machine learning tasks (Arjovsky et al., 2017; Muzellec and Cuturi, 2018) and in quantum information theory (Bhatia et al., 2018).

The main result of these derivations is a practical document embedding strategy that builds on pre-trained word embeddings. The document embeddings are of relatively low dimension, larger than the word embeddings only by a small factor. They allow for efficient comparisons and are easy to implement and use in downstream tasks of document retrieval, sentence classification, etc. We demonstrate competitive performance against state-of-the-art methods in standard sentence similarity tasks (Conneau and Kiela, 2018), with a lower computational cost. We further demonstrate the approach in matching articles to their comment chains, and briefly in scoring moral sentiment and topicality defined by word lists.

2 Related work

Work on document representations has a long history in information retrieval. Sentence embeddings (Arora et al., 2016; Perone et al., 2018) is a related topic that has lately become more prominent, maybe because of the fast growth of social media platforms where communication is mostly done via short messages. For this paper, we treat sentences as short documents.

The mainline of research deals with building document vectors from pre-trained word vectors. The straightforward way averages over the word vectors. Wieting et al. (2015b) show that complex computations are not necessary for good document vectors. Instead, smart weighting under the averaging model is usually sufficient. On top of that work, weighting schemes and other heuristics have been proposed. The latest include common component removal (Arora et al., 2016), and the weighting schemes SIF (Arora et al., 2016), and P-SIF (Gupta et al., 2019), similar in idea to TF-IDF weighting. As alternatives to usage of pre-trained word embeddings, one can train directly document embeddings like skip-thought (ST) vectors (Kiros et al., 2015) basically generalizing the *word2vec* training method to sentences, or train the word embeddings and document embeddings together, but still within the bag-of-the-words averaging framework as is done with Paragraph Vectors (Le and Mikolov, 2014) and Doc2VecC (Chen, 2017).

Our core contributions are in the use of second-order information—covariance of the word vectors—for improving the representations. To our best knowledge, there is quite limited previous work in this direction. Torki (2018) used covariance matrices as (quite high-dimensional) representation for documents and Nikolentzos et al. (2017) represented documents with Gaussian distributions and used divergence metrics to compare the imposed distributions. We provide technical and computational analysis of the covariance approach, discuss similarity measures for the representations, including Frobenius and Wasserstein inner products, and show how low-rank approximations can then speed up the comparisons and make the representations more compact.

A completely different approach is taken by the deep learning community, with the use of universal language and transformer models such as ELMo (Peters et al., 2018), ULMFiT (Howard and Ruder, 2018), and BERT (Devlin et al., 2018). The accuracy of these deep learning models is state of the art, but the computational cost and need for training data are high. At the time of writing, there are no pre-trained models available for the Finnish language used in our experiments, and training such a base model would be costly as shown by Strubell et al. (2019).

3 Representations and similarities

Most applications compare word embeddings by the cosine similarity, $\cos(w_1, w_2) = \frac{w_1^T w_2}{|w_1||w_2|}$, where $w_1, w_2 \in \mathcal{R}^d$ are the embeddings (vectors). Cosine similarity is invariant to lengths of the vectors. Lengths typically do not encode semantics but relate to aspects like frequency of the word or homogeneity of its context.

Documents or sentences (later simply documents) are, in the absence of a sequence model, treated as bags of words. That is, methods for comparing documents are invariant to word order. We define for later purposes a *document matrix*,

$$D = \begin{bmatrix} \cdots & w_1 & \cdots \\ \cdots & w_2 & \cdots \\ \cdots & \cdots & \cdots \\ \cdots & w_n & \cdots \end{bmatrix} \in \mathcal{R}^{n \times d}, \qquad (1)$$

as a collection of word vectors. Although the representation as such is not order-invariant, order-invariant ways to compare documents can be derived for this representation. The simplest is the cosine similarity of means, $\cos(1^T D_1/n_1, 1^T D_2/n_2)$. Performance of document mean vectors in benchmarks is not quite a state of the art, but decent enough for many applications (Wieting et al., 2015b).

A refinement from the simple average is to reweigh the word vectors before averaging, either in a general way or by specializing into the current corpus. Term-frequency inverse-document-frequency (TF-IDF) weighting is the classic way. Later variations of weighting schemes are smooth inverse frequency (SIF) (Arora et al., 2016) and its derivative partition SIF (P-SIF) (Gupta et al., 2019). They use weighted mean with weights computed from corpus; SIF uses $\alpha/(\alpha + p(w))$, where $\alpha > 0$ controls the smoothing based on empirical probability $p(w)$ of word w. The precomputation of weights for the whole corpus makes SIF unusable in some cases where the whole corpus is not available or is extremely large, and prohibits online processing. The issue is even more severe with P-SIF that requires more elaborate preprocessing.

For further improvement within the mean vector framework, it should be possible to improve performance either by (a) computing word embeddings in a way that optimizes the document embeddings (still computed as word vector averages), or by (b) transformations of the document averages in a way that takes the current document corpus into account. An example of the former is the Doc2VecC embedding (Chen, 2017), and SIF (Arora et al., 2016) demonstrates the latter by removing variation common to the corpus by projecting away the main variation over documents.

Still, a third way to improve performance would be to expand the representation from average while maintaining order invariance for model simplicity. This leads to second-order representations discussed next.

4 Second-order document representations

Our motivation arises from an empirical observation that mean vectors are not necessarily efficient summaries of documents (Fig. 1). At least with the *word2vec* embeddings, the distribution of word

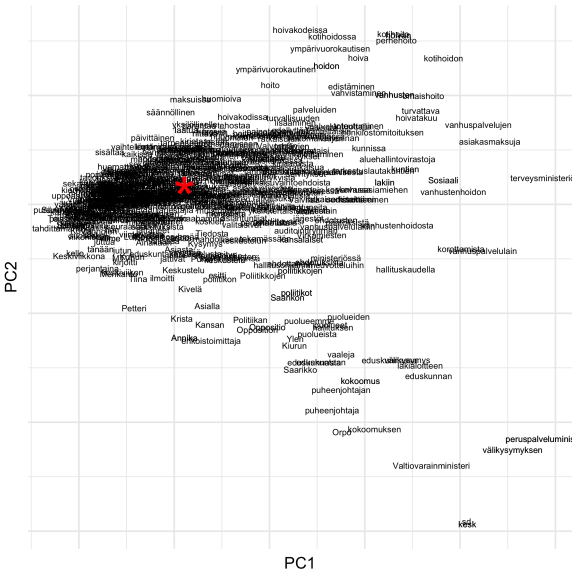

Figure 1: Words of a Finnish news article as *word2vec* vectors, projected to the 2D space of principal variation. The broad tail up right contains words related to health care and social services, especially those of seniors. The lower right tail is about politics. The mean vector (red star) makes a compromise between the tails, and is determined to a large degree by the numerous non-descriptive words projected closer to the origin. A representation that takes higher moments into account would catch the tails better. This structure seems to be typical to most of the documents in our corpora.

vectors (on the 2D-space of their principal variance) is strongly skewed, with a comet-like shape, often with more than one separate "tails". Mean is not an efficient statistic for such distribution, and it is an especially poor description of the tails that seem to carry the most descriptive words.

A representation based on higher-order moments would better catch the characteristics of the word vectors. Second moments, or covariance if centered to the means, would lose the asymmetry of the distributions, but the advantages compared to still higher-order moments are (relative) compactness and elegant algebra.

A question remains how second-order representations should be compared pairwise. A related worry is the computational efficiency, as the computational cost for naive second-order representations scales quadratically with the dimensionality of the embedding. Below, we first present an extension of cosine similarity to pairs of unordered collections of word vectors, and note how this induces a second-order representation for documents, and is interpretable as a Frobenius inner

product. We note a connection of this approach to existing work, compare to Bures and Wasserstein metric (later referred only as Wasserstein) and optimal transport theory, and later in the paper present empirical evidence of good performance of low-rank approximations of these representations.

4.1 Extending cosine similarity to documents

Using the notation of (1), let $A \in \mathcal{R}^{n\times d}, B \in \mathcal{R}^{m\times d}$ be the word vectors of two documents, sentences, or other unordered collections of words, with word counts (n, m) and embedding of dimensionality d.

The core of cosine similarity of single words a, b is the ordinary inner product $\cos(a, b) \propto a^T b$, with a normalization such that $\cos(a, a) = 1$ for any $a \neq 0$. We generalize this to similarities of word collections A and B, as the normalized square sum of all pairwise dot products:

$$\begin{aligned} Z(A,B)\, h^2(A,B) \equiv \\ \sum_{a,b}(a^T b)^2 = \sum_{a,b} ab^T\, ba^T \\ = \sum_a aB^T Ba^T = \sum_a \mathrm{Tr}(Ba^T aB^T) \\ = \mathrm{Tr}(BA^T AB^T) = \mathrm{Tr}(A^T AB^T B) \end{aligned}$$

with $Z(A, B)$ such that $h^2(A, A) = 1$ for any $A \neq 0$. The unnormalized trace structure appears so often later in the paper, that we define a shorter notation for it:

$$A * B \equiv [\mathrm{Tr}(BA^T AB^T)]^{1/2}. \quad (2)$$

The trace is interpretable as the *Frobenius inner product* of covariance-like but unnormalized matrices $C_A \equiv A^T A$ and $C_B \equiv B^T B$:

$$(A * B)^2 = \mathrm{Tr}(C_A^T C_B)\,. \quad (3)$$

With normalization, the similarity then becomes

$$h^2(A, B) = \frac{(A * B)^2}{(A * A)\,(B * B)} \equiv A' * B'\,, \quad (4)$$

where the last expression prenormalizes the word list matrices so that

$$A' \equiv A/(A * A)^{1/2}\,. \quad (5)$$

Finally, one can centralize word matrices before computing the similarity, $A_0 = A - 1^T m_A$, etc., without affecting the formalism:

$$h(A_0, B_0) = A_0' * B_0'\,. \quad (6)$$

Torki (2018) introduced a document representation named DoCoV and extended it in experiments to include mean vector gaining an increase in performance. This variant of the DoCoV representation is defined as $\mathrm{vec}(m_A, A_0^T A_0)$, where the vec operation concatenates the arguments and flattens the matrices row by row. This is similar to our cross product C_A but includes the mean. For computing similarities they used dot products

$$\begin{aligned} m_A^T m_B + vec(A_0^T A_0)^T\, vec(B_0^T B_0) \\ = m_A^T m_B + (A_0 * B_0)^2\,. \end{aligned}$$

We note that this is the similarity h^2 introduced above, summed to the cosine similarity of the means, but the normalization of the dot product by Torki (2018) is for the entire concatenated vectors, which is reasonable as long as mean and covariance are treated as commensurable. There is a unit inconsistency in the concatenation, for the covariance term is quadratic while the mean is not. Our reinterpretation and slight reformulation of the similarity as h^2 offers a way of substantially shrinking the document representations (Section 5), and including the mean does not seem empirically important.

4.2 Connection to transport theory

Wasserstein metric compares two (elliptic or gaussian) distributions defined by their means and covariances. It emerges in the optimal transport theory as a measure of minimum-path transport of the probability mass of distribution (m_A, C_A) to distribution (m_B, C_B):

$$\begin{aligned} \mathcal{W}^2((m_A, C_A), (m_B, C_B)) = \\ ||m_A - m_B||^2 + \\ \mathrm{Tr}\left(C_A + C_B - 2\left(C_A^{1/2}\, C_B\, C_A^{1/2}\right)^{1/2}\right)\,. \end{aligned}$$

For covariances computed from word vectors, $C_A = A^T A$, etc., we would like to have scale invariance similar to cosine or the Frobenius cosine above. But it is not clear how to obtain scale invariance in a principled way, for the scales of terms $\mathrm{Tr}\, C_A$ and $\mathrm{Tr}\, C_B$ vary differently from the scale of the cross term.

Within the context of their elliptical embeddings, Muzellec and Cuturi (2018) define a Bures or Wasserstein cosine by normalizing the sole

cross term[2]:

$$h_{\mathcal{W}}(C_A, C_B) = \frac{\operatorname{Tr}\left(C_A^{1/2} C_B C_A^{1/2}\right)^{1/2}}{[\operatorname{Tr} C_A]^{1/2} [\operatorname{Tr} C_B]^{1/2}} .$$

This form is surprisingly close to the "Frobenius cosine" of Eq. 4, and allows prenormalization of representations: First by applying the cyclic property of trace, and then moving normalizations to be computed first, we have

$$\begin{aligned} h_{\mathcal{W}}(C_A, C_B) &= \frac{\operatorname{Tr}\left(C_A^T C_B\right)^{1/2}}{[\operatorname{Tr} C_A]^{1/2} [\operatorname{Tr} C_B]^{1/2}} \\ &= \operatorname{Tr}\left(\left[\frac{C_A}{\operatorname{Tr} C_A}\right]^T \left[\frac{C_B}{\operatorname{Tr} C_B}\right]\right)^{1/2} . \end{aligned}$$

The difference to our similarity defined in Eq. 4 is only in the order of the outer square root and trace operators. If one denotes the eigenvalues of the suitably normalized matrix $C_A C_B$ by η_i^2, the Wasserstein cosine is equal to $\sum_i \eta_i$, while the Frobenius cosine equals to $(\sum_i \eta_i^2)^{1/2}$. The latter obviously gives more weight to "high-variance covariation" of C_A and C_B, that is, for larger eigenvalues. When only one eigenvalue is non-zero, the cosines are equal.

Matrix square root in the Wasserstein cosine, however, seems to require matrix diagonalization for every document comparison, which would be of computational complexity $O(d^3)$.

So although deriving anything equivalent to Frobenius cosine by starting from the Wasserstein metrics seems hard, similarities may be worth further investigation, either empirical or theoretical. An empirical comparison, presented in Figure 2, suggests that in practice the two cosines are quite closely related. Experiments later in the paper indicate better practical performance from the Frobenius cosine, in some applications. Frobenius cosine is notably faster to compute in practice, as shown in the next section.

[2]Or actually they have two separately normalized terms, one for means as ordinary cosine, and one for quadratics. We test the two-term version of our Frobenius product briefly in the experimental section and find that the mean term does not help performance there. The supplementary material of Muzellec and Cuturi (2018) easily leads to a similar conclusion with the Wasserstein cosine.

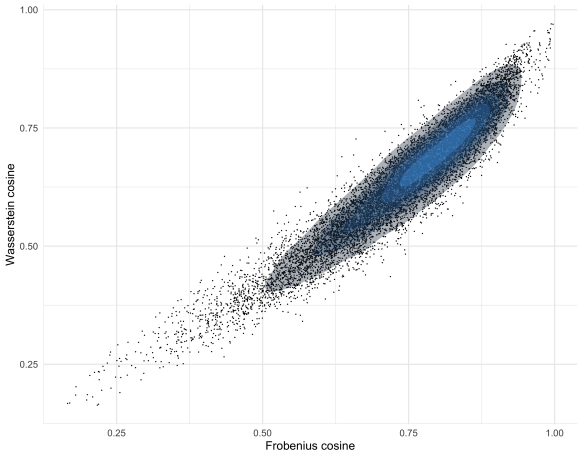

Figure 2: For our document collection of Finnish news articles and their comments, the Frobenius and Wasserstein cosines are closely related with correlation coefficient $r = 0.95$.

5 Computation and low-rank approximation

The Frobenius cosine of Eq. 4 can be computed by using word matrices A (of size $n \times d$) as document representations. Comparing these by pairwise vector inner products (Eq. 2) would have computationally cost of $O(n_A n_B d)$ — efficient for short word lists but not when lengths n approach or exceed d.

On the other hand, one can follow in the footsteps of Torki (2018) and represent documents as covariance-like inner products $A^T A$, which are of dimensionality $d(d+1)/2$. Torki (2018) named this method as DoCoV descriptor. In this case, the Frobenius complexity would then be $O(d^2)$, which for long documents is cheaper than a pairwise comparison of word lists, but still expensive compared to inner products of mean vectors, $O(d)$.

Key to low-order approximations is to note that the rows of the word lists A etc. do not need to represent words: Instead, any vectors $\hat{A}$ would give the same Frobenius product (and cosine) as long as the covariances are preserved, that is, $\hat{A}^T \hat{A} = A^T A$. If $\hat{A}$ is just an approximation of A, of, say, dimensionality $k \times d$ and of similar size for all documents, the pairwise Frobenius computation (Eq. 2) would be of complexity $O(k^2 d)$.

Our approximation and computation strategy is therefore to replace A with a suitable approximation $\hat{A}$, and compute the Frobenius inner product

without ever realizing the covariance matrices, by

$$\hat{A} * \hat{B} = \left(\sum_{kl} (\hat{A})^T_{k\cdot} (\hat{B})_{l\cdot} \right)^{1/2} . \quad (7)$$

For prenormalized approximations (Eq. 5), this is directly the desired similarity h^2 (as in Eq. 4).

We cannot optimize for approximation errors of pairwise Frobenius cosines, so we choose to optimize representations so that $A * A = \mathrm{Tr}(A^T A)$ is well preserved. Remembering that, for a symmetric matrix, trace is the sum of its eigenvalues, we may specifically choose a decomposition $H^T H$ of $A^T A$ such that dropping rows from H minimizes the approximation error in $\mathrm{Tr}(A^T A)$. The optimal H consists of the eigenvectors of $A^T A$ multiplied by square roots of their eigenvalues:

$$A^T A = U^T \Lambda^{\frac{1}{2}} \Lambda^{\frac{1}{2}} U = (U\Lambda^{\frac{1}{2}})^T (U\Lambda^{\frac{1}{2}}) \equiv H^T H .$$

Now $\mathrm{Tr}(A^T A) = \sum_i \lambda_i$, where λ are the diagonal of Λ, the eigenvalues. All eigenvalues of a positive semidefinite matrix are non-negative, so trace is best approximated with a $\hat{H}$ that contains the eigenvectors associated to largest eigenvalues (the square roots of the eigenvalues multiplied in):

$$\hat{A} = \hat{H} = \begin{bmatrix} \sqrt{\lambda_1} u_1 \\ \sqrt{\lambda_2} u_2 \\ \cdots \\ \sqrt{\lambda_3} u_k \end{bmatrix} \in \mathcal{R}^{k \times d} . \quad (8)$$

Let the SVD of the word list matrix be $A = U\Lambda' V^T$. Then $A^T A = V\Lambda' U^T U \Lambda' V^T = V\Lambda'^2 V^T$, the last form being the eigenvalue decomposition of $A^T A$. So the approximation $\hat{H}$ can be obtained directly from the SVD of the word list A, without computing the covariance matrix. This is relatively cheap for small ranks k, and can be scaled up for documents with very large n with stochastic methods (Halko et al., 2011). The complexity depends on the SVD algorithm chosen.

Note that analogously to the original word lists, the above approximation is applicable to centered word lists A_0, and the normalized counterparts A' and A'_0, as long as normalization of representations is done after approximation (to preserve $h^2(\hat{A}', \hat{A}') = 1$).

The Frobenius cosine can, therefore, be efficiently computed with Eq. 7 of complexity $O(k^2 d)$, if the documents are approximated by the first k principal vectors of the word list SVD. Savings, compared to full covariances, are of order k/d for space, and k^2/d for document comparison times.

6 Method summary

The pre-computation process for online comparison document comparison or search is as follows:

1. Choose suitable word embeddings for the corpus, defining factors being language and the domain.

2. Collect word vectors of each document into matrix A, as in Eq. 1.

3. Choose a rank k, typically 2–20. Compute the k-rank (SVD left side) approximation $\hat{A}_0$ of centered documents like in Eq. 8. Prenormalize (Eq. 5) and store $\hat{A}'_0$.

4. Compare documents by $\hat{A}'_0 * \hat{B}'_0$, using the pairwise dot products as in Eq. 7 for computation.[3]

Representations for new, upcoming documents repeat steps 2–3. (There is no global model to update or refer to.)

7 Experiments

To validate the proposed representations and the similarity h^2, we conducted two separate experiments and one demonstration. In the first one, proposed methods are compared to state-of-the-art sentence embedding models on the tasks of Facebook's SentEval library (Conneau and Kiela, 2018). The other experiment and the demonstration apply the techniques to news articles and their comments on three Finnish media sites. For the latter experiment, 88,986 articles with comments were gathered from the associated websites.

For English we use fastText (Mikolov et al., 2018) embeddings with $d = 300$, but note that similar results were achieved also with GloVe (Pennington et al., 2014) and Word2Vec (Mikolov et al., 2013). For Finnish, we use *word2vec* embeddings, provided by the Turku NLP group[4], since fastText does not provide adequate embeddings for Finnish.

[3] With rank $k = 1$, the similarity h^2 is equal to square of the cosine between directions of principal variation. The principal vectors have no well-defined polarity, so taking a square or absolute value of the cosine is important.

[4] Older version of the *fin-word2vec.bin* embeddings with dimension 300, linked from http://bionlp.utu.fi/finnish-internet-parsebank.html.

7.1 Textual similarity tasks

As an initial experiment on the quality of the second-order representations, we evaluated them with the standard unsupervised similarity tasks (STS12 - STS16) using SentEval library by Facebook (Conneau and Kiela, 2018).

We compare a few different low-rank approximations using our proposed method against the state-of-the-art unsupervised and semi-supervised methods in Table 1. We see that already at $k = 10$, the approximation reaches close to the accuracy of the full rank, within this dataset, while decreasing the size of representations significantly (here 300×10 vs. 300×300). It surpasses most of the other unsupervised methods and compares well with the semi-supervised methods. Interestingly, already the rank-1 approximation is better than the classical mean vector approach (Glove Avg in Table 1), while having the same computational complexity.

Our low-rank estimation is on par with the related unsupervised method, DoCoV, and the only model reaching clearly higher scores is the P-SIF + PSL by Gupta et al. (2019), which uses computationally relatively heavy reweighting.

Figure 3 demonstrates the validity of the low-rank approximation, by plotting the STS evaluation scores against the rank k of the approximation. The results are as expected: Using more components retains more information, and $k \approx 5 \ldots 10$ is roughly enough for all tasks. Contrary to the experiment of the next section, using too large k does not hurt performance (except nominally in some cases).[5]

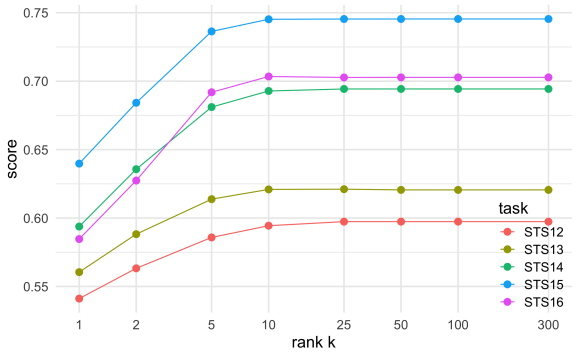

Figure 3: STS scores vs. rank k of the covariance approximation. Performance on these sentence tasks mostly saturates at $k = 5 \ldots 25$.

7.2 Comments vs. article

Many news sites contain a comment section associated with articles. It can be useful to compare articles to the comments, for example for moderation: If the discussion drifts too far from the original topic, human attention may be needed. In this experiment, we tried to find real article–comment pairs from a set in which half of the pairs were fake, as a proxy for the moderation task. It tests the semantic resolution of the similarity measures and has the convenience of known ground truth.

We crawled articles and their comment sections from three Finnish news sources: Yle (national broadcasting company), Uusi Suomi (news and blogging platform), and Iltalehti (a tabloid). Comments were concatenated to a single document (per article), retaining all article–comment pairs with at least 100 words on both sides. This gave 16,263, 18,548, and 9,682 pairs for Iltalehti, Uusi Suomi and Yle, respectively. The pairs were concatenated to sets of fake pairs of equal size, obtained by permuting the real pairs. We then rank the pairs according to decreasing similarity, and consider real pairs positive instances for retrieval measures. Figure 4 shows the ROC-like curves for our proposed h^2 of Eq. 7 (with rank $k = 4$), and two baselines based on document means, one computed directly from the word vectors and one after SIF weighting. The proposed method performs clearly better than average-based methods for all news sources, demonstrating the benefits of including second moments. It also outperforms the Wasserstein cosine $h_{\mathcal{W}}$ while having a clear advantage also in computation speed, and centering improves the results.

To see the effect of the rank, we ran the same test for various values of k and evaluated the recall at the selected value of precision (5% of fake pairs retrieved). All ranks $k > 0$ outperform the baseline of mean-vector cosine (horizontal line), except for Uusi Suomi at $k = 1$ (Figure 5). A bit unexpectedly, optimum is already at low values of k, which is nice from the computational perspective and suggests a regularization effect from SVD maybe worth of further study.

Finally, we wanted to see if adding a conventional mean term to the similarity computed with centralized second-order terms only helps with resolution, and ran the tests with various values of the weight α for the second-order term. One

[5] This may be because of the relative shortness of sentences here, vs. documents in the other experiment. The short sentences cannot even span a high-dimensional representation.

	Unsupervised					Semi-supervised			Ours		
Task	ST	Glove Avg	Glove tf-idf	DoCoV	P-SIF PSL	PSL Avg	Glove WR	PSL WR	Frob. $k = 1$	Frob. $k = 10$	Frob. $k = 300$

Table 1: Our method vs. other unsupervised and semi-supervised methods (from Gupta et al., 2019) on semantic textual similarity (STS) tasks, evaluated as Pearson correlations to human ground truth. ST stands for skip-thought vectors (Kiros et al., 2015), WR for SIF weighting combined with common component removal (Arora et al., 2016), and PSL for PARAGRAM-SL999 word vectors (Wieting et al., 2015a).

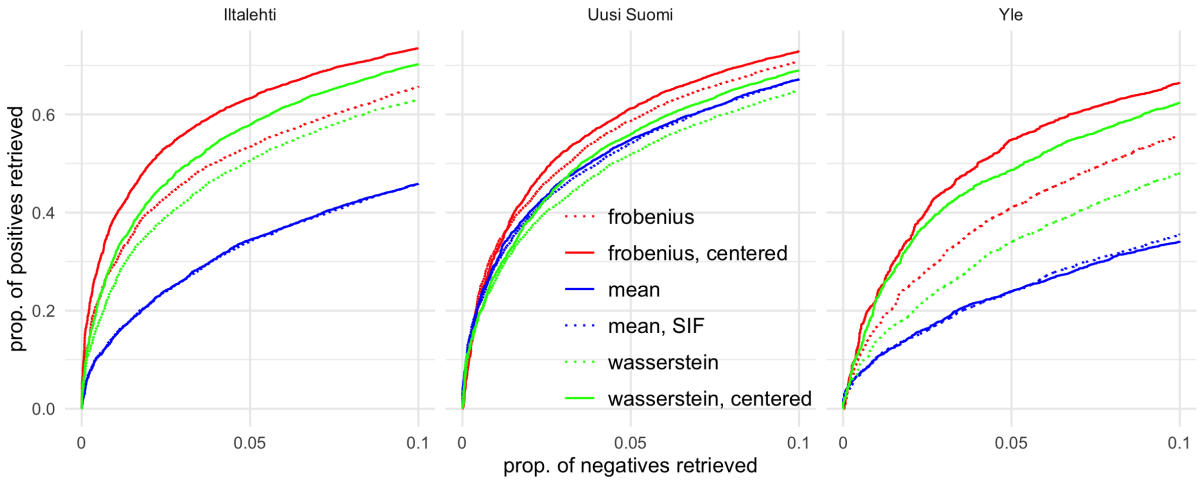

Figure 4: Fake vs. real pairs retrieved (ROC curves), in the article–comment matching tasks, for the three news sources, and for different matching methods. Cosine of mean vectors with original *word2vec* weights (blue; solid) and SIF weights (blue; dotted) perform practically identically. Quadratic approaches are all better, in general Frobenius (red) outperforming Wasserstein (green), and centered covariances (solid) outperforming non-centered ones (dotted). More fine-grained evaluations over k and mean-vector cosine mixing (Fig. 5 and 6) are run for 5% of the fake pairs retrieved (at the middle of x-axis).

source (Uusi Suomi) peaks around $\alpha = 0.5$, but for other sources, the performance increases monotonically with the weight of h^2. Apparently, mean vector is at least sometimes redundant if just low-rank second-order information is available.[6]

7.3 Media segmentation

Finally, the classic task of scoring documents for sentiment or topic by a word list is amenable to the application of the Frobenius similarity h^2. The target word list is usually just an unordered collection of words, although it may be weighted. Extensive sets of word lists are curated, for example, by LIWC. Likely, the semantics of such a list would sometimes be better operationalized by the suggested quadratic representation rather than by the list itself or its vectorized mean (with respect to an embedding).

As an example, we just present a single finding in Figure 7. The moral content of the comment chains of online news articles seems to vary by source, and climate change as a topic has differing effects, depending on the platform. The moral word lists were manually augmented and translated from the lists available from the developers of the Moral Foundations Theory (MFT)[7].

8 Conclusions

As already demonstrated by Torki (2018) and Nikolentzos et al. (2017), taking second moments of word vectors into document represen-

[6] The appendix of (Muzellec and Cuturi, 2018) gives similar impression for Wasserstein cosine: The performance is relatively flat over wide range of α and sometimes seems to increase monotonically.

[7] https://www.moralfoundations.org/othermaterials

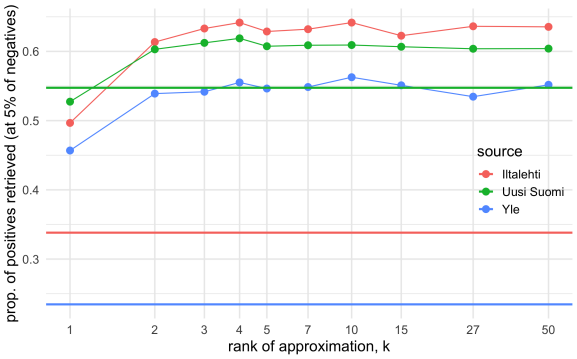

Figure 5: Frobenius recall of the article–comment matching task (proportion of real pairs retrieved when 5% of fake pairs are retrieved), as a function of rank k. For all news sources, performance saturates at rather low orders, $k = 2 \ldots 10$. Horizontal lines indicate recall with cosine of mean word vectors, which ignores second moments of the document.

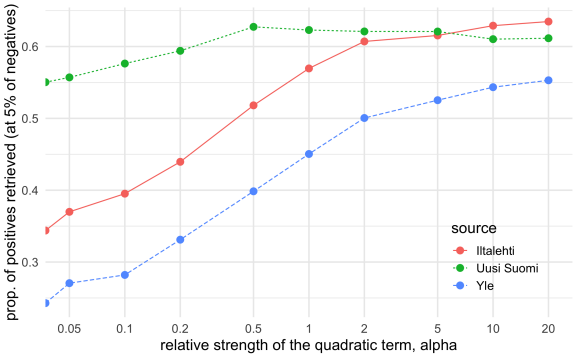

Figure 6: A recall measure on the article–comment matching task (proportion of real pairs retrieved when 5% of fake pairs are retrieved), when matching is with a mixture $\cos + \alpha h^2$ of ordinary cosine of means and centered Frobenius similarity (with rank $k = 3$). Adding mean information (smaller α) generally degrades performance except for one news source (*Uusi Suomi*) which peaks at $\alpha \approx 0.5$.

tations improves document matching. Surprisingly, the often-used mean vector seems to then become about irrelevant, a finding that needs to be replicated with other embeddings and larger experiments. There may exist efficient, ICA-like schemes relying on even higher moments to optimize the representations.

The second-order representations, and an associated similarity measure equivalent to the Frobenius inner product, can be derived by extending the Euclidean inner product into sets of words in a natural, pairwise manner. Empirically, the Frobenius similarity closely approximates Wasserstein similarity, familiar from transport theory, but allows efficient low-rank approximations of otherwise high-dimensional representations. The relationships of the two similarities may be worth further investigation, both theoretical and empirical.

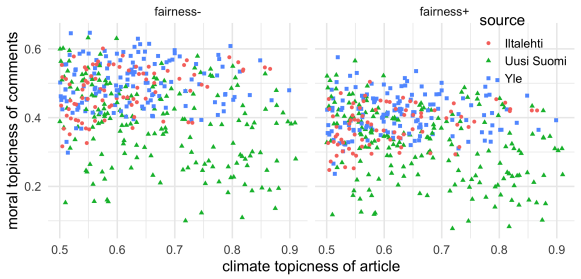

Figure 7: Moral sentiment of text, in the sense of the Moral Foundation Theory (Graham et al., 2013), has been measured by counting words appearing on a curated list (Garten et al., 2016). Moral word lists can also be related to documents with our h^2. On a blogging platform (*Uusi Suomi*), climate change as a prominent topic does not always rise moral comments at all (comments are probably technical). Points represent single article–comment pairs for articles of high topicality. Left: fairness, negative polarity; right: fairness, positive polarity.

Low-rank approximations are not only computationally useful, but also may sometimes have a regularizing effect that improves matching. Like mean vectors, second-order representations are useful as an alternative to traditional word-occurrence scoring, on quantifying sentiment and topicality of documents. Our experiments also show that rank-1 approximations are better representations of the documents than the mean vectors, while having the same representation size and computational complexity. There is an interesting contrast to the SIF preprocessing, where one step is to remove the corpus-wide largest component of variance to enhance the performance. While these two results are not contradictory, the combination is somewhat counter-intuitive.

Compared to other embedding methods, our approach requires only low precomputation effort and is local to document. The locality allows online processing that would be hard to implement with methods requiring preprocessing the corpus. If the online property is not needed, second-order representations are compatible with smart weighting schemes like SIF (Arora et al., 2016) or P-SIF (Gupta et al., 2019), and also with corpus-wide preprocessing schemes like projections and scalings.

Abstract

Supervised machine learning assumes the availability of fully-labeled data, but in many cases, such as low-resource languages, the only data available is partially annotated. We study the problem of Named Entity Recognition (NER) with partially annotated training data in which a fraction of the named entities are labeled, and all other tokens, entities or otherwise, are labeled as non-entity by default. In order to train on this noisy dataset, we need to distinguish between the true and false negatives. To this end, we introduce a constraint-driven iterative algorithm that learns to detect false negatives in the noisy set and downweigh them, resulting in a weighted training set. With this set, we train a weighted NER model. We evaluate our algorithm with weighted variants of neural and non-neural NER models on data in 8 languages from several language and script families, showing strong ability to learn from partial data. Finally, to show real-world efficacy, we evaluate on a Bengali NER corpus annotated by non-speakers, outperforming the prior state-of-the-art by over 5 points F1.

1 Introduction

Most modern approaches to NLP tasks rely on supervised learning algorithms to learn and generalize from labeled training data. While this has proven successful in high-resource scenarios, this is not realistic in many cases, such as low-resource languages, as the required amount of training data just doesn't exist. However, partial annotations are often easy to gather.

We study the problem of using partial annotations to train a Named Entity Recognition (NER) system. In this setting, all (or most) identified entities are correct, but not all entities have been identified, and crucially, there are no reliable examples of the negative class. The sentence shown in Figure 1 shows examples of both a gold and a partially annotated sentence. Such partially annotated data is relatively easy to obtain: for example, a human annotator who does not speak the target language may recognize common entities, but not uncommon ones. With no reliable examples of the negative class, the problem becomes one of estimating which unlabeled instances are true negatives and which are false negatives.

Oracle	1	1	0	0	1	1	1	1
Our model	1	0.6	0.01	0.03	0.8	1	1	0.4

Figure 1: This example has three entities: *Arsenal*, *Unai Emery*, and *Arsene Wenger*. In the *Partial* row, the situation addressed in this paper, only the first and last are tagged, and all other tokens are assumed to be non-entities, making *Unai Emery* a false negative as compared to *Gold*. Our model is an iteratively learned binary classifier used to assign weights to each token indicating its chances of being correctly labeled. The *Oracle* row shows optimal weights.

To address the above-mentioned challenge, we present Constrained Binary Learning (CBL) – a novel self-training based algorithm that focuses on iteratively identifying true negatives for the NER task while improving its learning. Towards this end, CBL uses constraints that incorporate background knowledge required for the entity recognition task.

We evaluate the proposed methods in 8 languages, showing a significant ability to learn from partial data. We additionally experiment with initializing CBL with domain-specific instance-weighting schemes, showing mixed results. In the process, we use weighted variants of popular NER models, showing strong performance in both non-neural and neural settings. Finally, we show experiments in a real-world setting, by employing non-speakers to manually annotate romanized Bengali text. We show that a small amount of non-speaker annotation combined with our method can outperform previous methods.

2 Related Work

The supervision paradigm in this paper, partial supervision, falls broadly under the category of semi-supervision (Chapelle et al., 2009), and is closely related to weak supervision (Hernández-González et al., 2016)[1] and incidental supervision (Roth, 2017), in the sense that data is constructed through some noisy process. However, all of the most related work shares a key difference from ours: reliance on a small amount of fully annotated data in addition to the noisy data.

Fernandes and Brefeld (2011) introduces a transductive version of structured perceptron for partially annotated sequences. However, their definition of partial annotation is labels removed at random, so examples from all classes are still available if not contiguous.

Fidelity Weighted Learning (Dehghani et al., 2017) uses a teacher/student model, in which the teacher has access to (a small amount) of high quality data, and uses this to guide the student, which has access to (a large amount) of weak data.

Hedderich and Klakow (2018), following Goldberger and Ben-Reuven (2017), add a noise adaptation layer on top of an LSTM, which learns how to correct noisy labels, given a small amount of training data. We compare against this model in our experiments.

In the world of weak supervision, Snorkel (Ratner et al., 2017; Fries et al., 2017), is a system that combines automatic labeling functions with data integration and noise reduction methods to rapidly build large datasets. They rely on high recall and consequent redundancy of the labeling functions. We argue that in certain realistic cases, high-recall candidate identification is unavailable.

We draw inspiration from the Positive-Unlabeled (PU) learning framework (Liu et al., 2002, 2003; Lee and Liu, 2003; Elkan and Noto, 2008). Originally introduced for document classification, PU learning addresses problems where examples of a single class (for example, sports) are easy to obtain, but a full labeling of all other classes is prohibitively expensive.

Named entity classification as an instance of PU learning was introduced in Grave (2014), which uses constrained optimization with constraints similar to ours. However, they only address the problem of named entity classification, in which mentions are given, and the goal is to assign a *type* to a named-entity (like 'location', 'person', etc.) as opposed to our goal of identifying and typing named entities.

Although the task is slightly different, there has been work on building 'silver standard' data from Wikipedia (Nothman et al., 2008, 2013; Pan et al., 2017), using hyperlink annotations as the seed set and propagating throughout the document.

Partial annotation in various forms has also been studied in the contexts of POS-tagging (Mori et al., 2015), word sense disambiguation (Hovy and Hovy, 2012), temporal relation extraction (Ning et al., 2018), dependency parsing (Flannery et al., 2012), and named entity recognition (Jie et al., 2019).

In particular, Jie et al. (2019) study a similar problem with a few key differences: since they remove entity surfaces randomly, the dataset is too easy; and they do not use constraints on their output. We compare against their results in our experiments.

Our proposed method is most closely aligned with the Constraint Driven Learning (CoDL) framework (Chang et al., 2007), in which an iterative algorithm reminiscent of self-training is guided by constraints that are applied at each iteration.

3 Constrained Binary Learning

Our method assigns instance weights to all negative elements (tokens tagged as O), so that false negatives have low weights, and all other instances have high weights. We calculate weights according to the confidence predictions of a classifier trained iteratively over the partially annotated data. We refer to our method as Constrained Binary Learning (CBL).[2]

We will first describe the motivation for this approach before moving on to the mechanics. We start with partially annotated data (which we call set T) in which some, but not all, positives are annotated (set P), and no negative is labeled. By default, we assume that any instance not labeled as positive is labeled as negative as opposed to unlabeled. This data (set N) is noisy in the sense that many true positives are labeled as negative (these are *false negatives*). Clearly, training on T as-is will result in a noisy classifier.

Two possible approaches are: **1)** find the false negatives and label them correctly, or **2)** find the false negatives and remove them. The former method affords more training data, but runs the risk of adding noise, which could be worse than the original partial annotations. The latter is more forgiving because of an asymmetry in the penalties: it is important to remove all false negatives in N, but inadvertently removing true negatives from N is typically not a problem, especially in NER, where negative examples dominate. Further, a binary model (only two labels) is sufficient in this case, as we need only detect entities, not type them.

We choose the latter method, but instead of removing false negatives, we adopt an instance-weighting approach, in which each instance is assigned a weight $v_i \geq 0$ according to confidence in the labeling of that instance. A weight of 0 means that the loss this instance incurs during training will not update the model.

With this in mind, CBL takes two phases: first, it learns a binary classifier λ using a constrained iterative process modeled after the CODL framework (Chang et al., 2007), and depicted in Figure 2. The core of

[2] Publication details (including code) can be found at cogcomp.org/page/publication_view/888

Require:
P : positive tokens
N : noisy negative tokens
C : constraints

1: $T = N \cup P$
2: $V \leftarrow$ Initialize T with weights (Optional)
3: **while** stopping condition not met **do**
4: $\quad \lambda \leftarrow \text{train}(T, V)$
5: $\quad \hat{T} \leftarrow \text{predict}(\lambda, T)$
6: $\quad T, V \leftarrow \text{inference}(\hat{T}, C)$
7: **end while**
8: return λ

Figure 2: Constrained Binary Learning (CBL) algorithm (phase 1). The core of the algorithm is in the while loop, which iterates over training on T, predicting on T and correcting those predictions.

the algorithm is the train-predict-infer loop. The training process (line 4) is weighted, using weights V. At the start, these can be all 1 (Raw), or can be initialized with prior knowledge. The learned model is then used to predict on all of T (line 5). In the inference step (line 6), we take the predictions from the prior round and the constraints C and produce a new labeling on T, and a new set of weights V. The details of this inference step are presented later in this section. Although our ultimate strategy is simply to assign weights (not change labels), in this inner loop, we update the labels on N according to classifier predictions.

In the second phase of CBL, we use the λ trained in the previous phase to assign weights to instances as follows:

$$v_i = \begin{cases} 1.0 & \text{if } x_i \in P \\ P_\lambda(y_i = \text{O} \mid x_i) & \text{if } x_i \in N \end{cases} \quad (1)$$

Where $P_\lambda(y_i = \text{O} \mid x_i)$ is understood as the classifier's confidence that instance x_i takes the negative label. In practice it is sufficient to use any confidence score from the classifier, not necessarily a probability. If the classifier has accurately learned to detect entities, then for all the false negatives in N, $P_\lambda(y_i = \text{O}|x_i)$ is small, which is the goal.

Ultimately, we send the original multiclass partially annotated dataset along with final weights V to a standard weighted NER classifier to learn a model. No weights are needed at test time.

3.1 NER with CBL

So far, we have given a high-level view of the algorithm. In this section, we will give more low-level details, especially as they relate to the specific problem of NER. One contribution of this work is the inference step (line 6), which we address using a constrained Integer Linear Program (ILP) and describe in this section. However, the constraints are based on a value we call the *entity ratio*. First, we describe the entity ratio, then we describe the constraints and stopping condition of the algorithm.

3.1.1 Entity ratio and Balancing

We have observed that NER datasets tend to hold a relatively stable ratio of entity tokens to total tokens. We refer to this ratio as b, and define it with respect to some labeled dataset as:

$$b = \frac{|P|}{|P| + |N|} \quad (2)$$

where N is the set of negative examples. Previous work has shown that in fully-annotated datasets the entity ratio tends to be about 0.09 ± 0.05, depending on the dataset and genre (Augenstein et al., 2017). Intuitively, knowledge of the gold entity ratio can help us estimate when we have found all the false negatives.

In our main experiments, we assume that the entity ratio with respect to the gold labeling is known for each training dataset. A similar assumption was made in Elkan and Noto (2008) when determining the c value, and in Grave (2014) in the constraint determining the percentage of OTHER examples. However, we also show in Section 4.8 that knowledge of this ratio is not strictly necessary, and a flat value across all datasets produces similar performance.

With a weighted training set, it is also useful to define the weighted entity ratio.

$$b = \frac{|P|}{|P| + \sum_{i \in N} v_i} \quad (3)$$

When training an NER model on weighted data, one can change the weighted entity ratio to achieve different effects. To make balanced predictions on test, the entity ratio in the training data should roughly match that of the test data (Chawla, 2005). To bias a model towards predicting positives or predicting negatives, the weighted entity ratio can be set higher or lower respectively. This effect is pronounced when using linear methods for NER, but not as clear in neural methods.

To change the entity ratio, we scale the weights in N by a scaling constant γ. Targeting a particular b^*, we may write:

$$b^* = \frac{|P|}{|P| + \gamma \sum_{i \in N} v_i} \quad (4)$$

We can solve for γ:

$$\gamma = \frac{(1 - b^*)|P|}{b^* \sum_{i \in N} v_i} \quad (5)$$

To obtain weights, v_i^*, that attain the desired entity ratio, b^*, we scale all weights in N by γ.

$$v_i^* = \gamma v_i \quad (6)$$

In the train-predict-infer loop, we balance the weights to a value near the gold ratio before training.

3.1.2 Constraints and Stopping Condition

We encode our constraints with an Integer Linear Program (ILP), shown in Figure 3. Intuitively, the job of the inference step is to take predictions ($\hat{T}$) and use knowledge of the task to 'fix' them.

In the objective function (Eqn. 8), token i is represented by two indicator variables y_{0i} and y_{1i}, representing negative and positive labels, respectively. Associated prediction scores C_0 and C_1 are from the classifier λ in the last round of predictions. The first constraint (Eqn. 9) encodes the fact that an instance cannot be both an entity and a non-entity.

The second constraint (Eqn. 10) enforces the ratio of positive to total tokens in the corpus to match a required entity ratio. $|T|$ is the total number of tokens in the corpus. b is the required entity ratio, which increases at each iteration. δ allows some flexibility, but is small.

Constraint 11 encodes that instances in P should be labeled positive since they were manually labeled and are by definition trustworthy. We set $\xi \geq 0.99$.

This framework is flexible in that more complex language- or task-specific constraints could be added. For example, in English and many other languages with Latin script, it may help to add a capitalization constraint. In languages with rich morphology, certain suffixes may indicate or contraindicate a named entity. For simplicity, and because of the number of languages in our experiments, we use only a few constraints.

After the ILP has selected predictions, we assign weights to each instance in preparation for training the next round. The decision process for an instance is:

$$v_i = \begin{cases} 1.0 & \text{If ILP labeled } x_i \text{ positive} \\ P_\lambda(y_i = \text{O} \mid x_i) & \text{Otherwise} \end{cases} \tag{7}$$

This is similar to Equation (1), except that the set of tokens that the ILP labeled as positive is larger than P. With new labels and weights, we start the next iteration.

The stopping condition for the algorithm is related to the entity ratio. One important constraint (Eqn. 10) governs how many positives are labeled at each round. This number starts at $|P|$ and is increased by a small value[3] at each iteration, thereby improving recall. Positive instances are chosen in two ways. First, all instances in P are constrained to be labeled positive (Eqn. 11). Second, the objective function ensures that high-confidence positives will be chosen. The stopping condition is met when the number of required positive instances (computed using gold unweighted entity ratio) equals the number of predicted positive instances.

4 Experiments

We measure the performance of our method on 8 different languages using artificially perturbed labels to simulate the partial annotation setting.

$$\max_{\mathbf{y}} \quad \sum_{i}^{|T|} C_{0i} y_{0i} + C_{1i} y_{1i} \tag{8}$$

$$\text{s.t.} \quad \forall i,\ y_{0i} + y_{1i} = 1 \tag{9}$$

$$b - \delta \leq \sum_i y_{1i}/|T| \leq b + \delta \tag{10}$$

$$\forall i,\ x_i \in P,\ \sum_i y_{1i} \geq \xi |P|, \tag{11}$$

Figure 3: ILP for the inference step

4.1 Data

We experiment on 8 languages. Four languages – English, German, Spanish, Dutch – come from the CoNLL 2002/2003 shared tasks (Tjong Kim Sang and De Meulder, 2003a,b). These are taken from newswire text, and have labelset of Person, Organization, Location, Miscellaneous.

The remaining four languages come from the LORELEI project (Strassel and Tracey, 2016). These languages are: Amharic (amh: LDC2016E87), Arabic (ara: LDC2016E89), Hindi (hin: LDC2017E62), and Somali (som: LDC2016E91). These come from a variety of sources including discussion forums, newswire, and social media. The labelset is Person, Organization, Location, Geo-political entity. We define train/development/test splits, taking care to keep a similar distribution of genres in each split. Data statistics for all languages are shown in Table 1.

4.2 Artificial Perturbation

We create partial annotations by perturbing gold annotated data in two ways: lowering recall (to simulate missing entities), and lowering precision (to simulate noisy annotations).

To lower recall, we replace gold named entity tags with O tags (for non-name). We do this by grouping named entity surface forms, and replacing tags on all occurrences of a randomly selected surface form until the desired amount remains. For example, if the token 'Bangor' is chosen to be untagged, then every occurrence of 'Bangor' will be untagged. We chose this slightly complicated method because the simplest idea (remove mentions randomly) leaves an artificially large diversity of surface forms, which makes the problem of discovering noisy entities easier.

To lower precision, we tag a random span (of a random start position, and a random length between 1 and 3) with a random named entity tag. We continue this process until we reach the desired precision. When both precision and recall are to be perturbed, the recall adjustment is made first, and then the number of random spans to be added is calculated by the entities that are left.

[3]The size of this value is related to how much we trust the ranking induced by prediction confidences. If we believed the ranking was perfect, we could take as many positives as we wanted and be finished in one round.

	Train			Test		
Lang.	b (%)	Tag	Tok	b (%)	Tag	Tok
English	16.6	23K	203K	17.3	5K	46K
Spanish	12.3	18K	264K	11.9	3K	51K
German	8.0	11K	206K	9.9	3K	51K
Dutch	9.5	13K	202K	8.3	4K	68K
Amharic	11.2	3K	52K	11.3	1K	18K
Arabic	12.6	4K	60K	10.2	931	16K
Hindi	7.38	4K	74K	7.53	1K	25K
Somali	11.2	4K	57K	11.9	1K	16K

Table 1: Data statistics for all languages, showing number of tags and tokens in Train and Test. The tag counts represent individual spans, not tokens. That is, "[Barack Obama]$_{\text{PER}}$" counts as one tag, not two. The b column shows the entity ratio as a percentage.

4.3 NER Models

In principle, CBL can use any NER method that can be trained with instance weights. We experiment with both non-neural and neural models.

4.3.1 Non-neural Model

For our non-neural system, we use a version of Cogcomp NER (Ratinov and Roth, 2009; Khashabi et al., 2018) modified to use Weighted Averaged Perceptron. This operates on a weighted training set $D_w = \{(x_i, y_i, v_i)\}_{i=1}^{N}$, where N is the number of training examples, and $v_i \geq 0$ is the weight on the ith training example. In this non-neural system, a training example is a word with context encoded in the features. We change only the update rule, where the learning rate α is multiplied by the weight:

$$\mathbf{w} = \mathbf{w} + \alpha v_i y_i (\mathbf{w}^T x_i) \tag{12}$$

We use a standard set of features, as documented in Ratinov and Roth (2009). In order to keep the language-specific resources to a minimum, we did not use any gazetteers for any language.[4] One of the most important features is Brown clusters, trained for 100, 500, and 1000 clusters for the CoNLL languages, and 2000 clusters for the remaining languages. We trained these clusters on Wikipedia text for the four CoNLL languages, and on the same monolingual text used to train the word vectors (described in Section 4.3.2).

4.3.2 Neural Model

A common neural model for NER is the BiLSTM-CRF model (Ma and Hovy, 2016). However, because the Conditional Random Field (CRF) layer calculates loss at the sentence level, we need a different method to incorporate token weights. We use a variant of the CRF that allows partial annotations by marginalizing over all possible sequences (Tsuboi et al., 2008).

[4]Separate experiments show that omitting gazetteers impacts performance only slightly.

When using a standard BiLSTM-CRF model, the loss of a dataset (D) composed of sentences (s) is calculated as:

$$\mathcal{L} = -\sum_{s \in D} \log P_\theta(\mathbf{y}^{(s)} | \mathbf{x}^{(s)}) \tag{13}$$

Where $P_\theta(\mathbf{y}^{(s)} | \mathbf{x}^{(s)})$ is calculated by the CRF over outputs from the BiLSTM. In the marginal CRF framework, it is assumed that $\mathbf{y}^{(s)}$ is necessarily partial, denoted as $\mathbf{y}_p^{(s)}$. To incorporate partial annotations, the loss is calculated by marginalizing over all possible sequences consistent with the partial annotations, denoted as $C(\mathbf{y}_p^s)$.

$$\mathcal{L} = -\sum_{s \in D} \log \sum_{\mathbf{y} \in C(\mathbf{y}_p^{(s)})} P_\theta(\mathbf{y} | \mathbf{x}^{(s)}) \tag{14}$$

However, this formulation assumes that all possible sequences are equally likely. To address this, Jie et al. (2019) introduced a way to weigh sequences.

$$\mathcal{L} = -\sum_{s \in D} \log \sum_{\mathbf{y} \in C(\mathbf{y}_p^{(s)})} q(\mathbf{y} | \mathbf{x}^{(s)}) P_\theta(\mathbf{y} | \mathbf{x}^{(s)}) \tag{15}$$

It's easy to see that this formulation is a generalization of the standard CRF if $q(.) = 1$ for the gold sequence $\mathbf{y}$, and 0 for all others.

The product inside the summation depends on tag transition probabilities and tag emission probabilities, as well as token-level "weights" over the tagset. These weights can be seen as defining a soft gold labeling for each token, corresponding to confidence in each label.

For clarity, define the soft gold labeling over each token x_i as $\mathbf{G}_i \in [0, 1]^L$, where L is the size of the labelset. Now, we may define $q(.)$ as:

$$q(\mathbf{y} | \mathbf{x}^{(s)}) = \prod_i G_i^{y_i}$$

Where $G_i^{y_i}$ is understood as the weight in $\mathbf{G}_i$ that corresponds to the label y_i.

We incorporate our instance weights in this model with the following intuitions. Recall that if an instance weight $v_i = 0$, this indicates low confidence in the label on token x_i, and therefore the labeling should not update the model at training time. Conversely, if $v_i = 1$, then this label is to be trusted entirely.

If $v_i = 0$, we set the soft labeling weights over x_i to be uniform, which is as good as no information. Since v_i is defined as confidence in the O label, the soft labeling weight for O increases proportionally to v_i. Any remaining probability mass is distributed evenly among the other labels.

To be precise, for tokens in N, we calculate values for $\mathbf{G}_i$ as follows:

$$G_i^O = \max(1/L, v_i)$$

$$G_i^{\text{non-}O} = \frac{1 - G_i^O}{L - 1}$$

For example, consider phase 1 of Constrained Binary Learning, in which the labelset is collapsed to two labels ($L = 2$). Assuming that the O label has index 0, then if $v_i = 0$, then $\mathbf{G}_i = [0.5, 0.5]$. If $v_i = 0.6$, then $\mathbf{G}_i = [0.6, 0.4]$.

For tokens in P (which have some entity label with high confidence), we always set $\mathbf{G}_i$ with 1 in the given label index, and 0 elsewhere.

We use pretrained GloVe (Pennington et al., 2014) word vectors for English, and the same pretrained vectors used in Lample et al. (2016) for Dutch, German, and Spanish. The other languages are distributed with monolingual text (Strassel and Tracey, 2016), which we used to train our own skip-n-gram vectors.

4.4 Baselines

We compare against several baselines, including two from prior work.

4.4.1 Raw annotations

The simplest baseline is to do nothing to the partially annotated data and train on it as is.

4.4.2 Instance Weights

Although CBL works with no initialization (that is, all tokens with weight 1), we found that a good weighting scheme can boost performance for certain models. We design weighting schemes that give instances in N weights corresponding to an estimate of the label confidence.[5] For example, non-name tokens such as *respectfully* should have weight 1, but possible names, such as *Russell*, should have a low weight, or 0. We propose two weighting schemes: frequency-based and window-based.

For the frequency-based weighting scheme, we observed that names have relatively low frequency (for example, *Kennebunkport*, *Dushanbe*) and common words are rarely names (for example *the*, *and*, *so*). We weigh each instance in N according to its frequency.

$$v_i^{\text{freq}} = freq(x_i) \tag{16}$$

where $freq(x_i)$ is the frequency of the i^{th} token in N divided by the count of the most frequent token. In our experiments, we computed frequencies over $P+N$, but these could be estimated on any sufficiently large corpus. We found that the neural model performed poorly when the weights followed a Zipfian distribution (e.g. most weights very small), so for those experiments, we took the log of the token count before normalizing.

For the window-based weighting scheme, noting that names rarely appear immediately adjacent to each other in English text, we set weights for tokens within a window of size 1 of a name (identified in P) to be 1.0, and for tokens farther away to be 0.

$$v_i^{\text{window}} = \begin{cases} 1.0 & \text{if } d_i \leq 1 \\ 0.0 & \text{otherwise} \end{cases} \tag{17}$$

where d_i is the distance of the i^{th} token to the nearest named entity in P.

Finally, we combine the two weighting schemes as:

$$v_i^{\text{combined}} = \begin{cases} 1.0 & \text{if } d_i \leq 1 \\ v_i^{\text{freq}} & \text{otherwise} \end{cases} \tag{18}$$

4.4.3 Self-training with Marginal CRF

Jie et al. (2019) propose a model based on marginal CRF (Tsuboi et al., 2008) (described in Section 4.3.2). They follow a self-training framework with cross-validation, using the trained model over all but one fold to update gold labeling distributions in the final fold. This process continues until convergence. They use a partial-CRF framework similar to ours, but taking predictions at face value, without constraints.

4.4.4 Neural Network with Noise Adaptation

Following Hedderich and Klakow (2018), we used a neural network with a noise adaptation layer.[6] This extra layer attempts to correct noisy examples given a probabilistic confusion matrix of label noise. Since this method needs a small amount of labeled data, we selected 500 random tokens to be the gold training set, in addition to the partial annotations.

As with our BiLSTM experiments, we use pretrained GloVe word vectors for English, and the same pretrained vectors used in Lample et al. (2016) for Dutch, German, and Spanish. We omit results from the remaining languages because the scores were substantially worse even than training on raw annotations.

4.5 Experimental Setup and Results

We show results from our experiments in Table 2. In all experiments, the training data is perturbed at 90% precision and 50% recall. These parameters are similar to the scores obtained by human annotators in a foreign language (see Section 5). We evaluate each experiment with both non-neural and neural methods.

First, to get an idea of the difficulty of NER in each language, we report scores from models trained on gold data without perturbation (*Gold*). Then we report results from an Oracle Weighting scheme (*Oracle Weighting*) that takes partially annotated data and assigns weights with knowledge of the true labels. Specifically, mislabeled entities in set N are given weight 0, and all other tokens are given weight 1.0. This scheme is free from labeling noise, but should still get lower scores than Gold because of the smaller number of entities. Since our method estimates these weights, we do not expect CBL to outperform the Oracle method. Next, we show results from all baselines. The bottom two sections are our results, first with no initialization (*Raw*), and CBL over that, then with *Combined Weighting* initialization, and CBL over that.

[5] All elements of P always have weight 1

CBL-Combined	Cogcomp	77.3	61.8	74.0	**72.4**	49.2	43.7	**58.2**	67.6	63.0
	BiLSTM-CRF	81.1	64.9	74.9	63.4	52.2	39.8	52.0	67.0	61.9

Table 2: F1 scores on English, German, Spanish, Dutch, Amharic, Arabic, Hindi, and Somali. Each section shows performance of both Cogcomp (non-neural) and BiLSTM (neural) systems. *Gold* is using all available gold training data to train. *Oracle Weighting* uses full entity knowledge to set weights on N. The next section shows prior work, followed by our methods. The column to the farthest right shows the average score over all languages. Bold values are the highest per column. On average, our best results are found in the uninitialized (*Raw*) CBL from BiLSTM-CRF.

4.6 Analysis

Regardless of initialization or model, CBL improves over the baselines. Our best model, *CBL-Raw BiLSTM-CRF*, improves over the *Raw Annotations BiLSTM-CRF* baseline by 11.2 points F1, and the *Self-training* prior work by 2.6 points F1, showing that it is an effective way to address the problem of partial annotation. Further, the best CBL version for each model is within 3 points of the corresponding *Oracle* ceiling, suggesting that this weighting framework is nearly saturated.

The *Combined* weighting scheme is surprisingly effective for the non-neural model, which suggests that the intuition about frequency as distinction between names and non-names holds true. It gives modest improvement in the neural model. The *Self-training* method is effective, but is outperformed by our best CBL method, a difference we discuss in more detail in Section 4.7. The *Noise Adaptation* method outperforms the *Raw annotations Cogcomp* baseline in most cases, but does not reach the performance of the *Self-training* method, despite using some fully labeled data.

It is instructive to compare the neural and non-neural versions of each setup. The neural method is better overall, but is less able to learn from the knowledge-based initialization weights. In the non-neural method, the difference between *Raw* and *Combined* is nearly 20 points, but the difference in the neural model is less than 3 points. *Combined* versions of the non-neural method outperform the neural method on 3 languages: Dutch, Arabic, and Hindi. Further, in the neural method, *CBL-Raw* is always worse than *CBL-Combined*. This may be due to the way that weights are used in each model. In the non-neural model, a low enough weight completely cancels the token, whereas in the neural model it is still used in training. Since the neural model performs well in the *Oracle* setting, we know that it can learn from hard weights, but it may have trouble with the subtle differences encoded in frequencies. We leave it to future work to discover improved ways of incorporating instance weights in a BiLSTM-CRF.

In seeking to understand the details of the other results, we need to consider the precision/recall tradeoff. First, all scores in the *Gold* row had higher precision than recall. Then, training on raw partially annotated data biases a classifier strongly towards predicting few entities. All results from the *Raw annotations* row have precision more than double the recall (e.g. Dutch Precision, Recall, F1 were: 91.5, 32.4, 47.9). In this context, the problem this paper explores is how to improve the recall of these datasets without harming the precision.

4.7 Difference from Prior Work

While our method has several superficial similarities with prior work, most notably Jie et al. (2019), there are some crucial differences.

Our methods are similar in that they both use a model trained at each step to assign a soft gold-labeling to each token. Each algorithm iteratively trains models using weights from the previous steps.

One difference is that Jie et al. (2019) use cross-validation to train, while we follow Chang et al. (2007) and retrain with the entire training set at each round.

	Avg F1		
Method \ b	10%	15%	Gold
Oracle Weighting	65.8	**65.9**	65.4
Raw annotations	40.9	40.9	40.9
Combined Weighting	59.9	**60.2**	**60.2**
CBL-Combined	62.4	62.3	**63.0**

Table 3: Experimenting with different entity ratios. Scores reported are average F1 across all languages. *Gold* b value refers to using the gold annotated data to calculate the optimal entity ratio. This table shows that exact knowledge of the entity ratio is not required for CBL to succeed.

However, the main difference has to do with the focus of each algorithm. Recall the discussion in Section 3 regarding the two possible approaches of **1**) find the false negatives and label them correctly, and **2**) find the false negatives and remove them. Conceptually, the former was the approach taken by Jie et al. (2019), the latter was our approach. Another way to look at this is as focusing on predicting correct tag labels ((Jie et al., 2019)) or focus on predicting O tags with high confidence (ours).

Even though they use soft labeling (which they show to be consistently better than hard labeling), it is possible that the predicted tag distribution is incorrect. Our approach allows us to avoid much of the inevitable noise that comes from labelling with a weak model.

4.8 Varying the Entity Ratio

Recall that the entity ratio is used for balancing and for the stopping criteria in CBL. In all our experiments so far, we have used the gold entity ratio for each language, as shown in Table 1. However, exact knowledge of entity ratio is unlikely in the absence of gold data. Thus, we experimented with selecting a default b value, and using it across all languages, with the Cogcomp model. We chose values of 10% and 15%, and report F1 averaged across all languages in Table 3.

While the gold b value is the best for *CBL-Combined*, the flat 15% ratio is best for all other methods, showing that exact knowledge of the entity ratio is not necessary.

5 Bengali Case Study

So far our experiments have shown effectiveness on artificially perturbed labels, but one might argue that these systematic perturbations don't accurately simulate real-world noise. In this section, we show how our methods work in a real-world scenario, using Bengali data partially labeled by non-speakers.

5.1 Non-speaker Annotations

In order to compare with prior work, we used the train/test split from Zhang et al. (2016). We removed all gold labels from the train split, romanized it[7] (Hermjakob et al., 2018), and presented it to two non-Bengali speaking annotators using the TALEN interface (Mayhew and Roth, 2018). The instructions were to move quickly and annotate names only when there is high confidence (e.g. when you can also identify the English version of the name). They spent about 5 total hours annotating, without using Google Translate. This sort of non-speaker annotation is possible because the text contains many 'easy' entities – foreign names – which are noticeably distinct from native Bengali words. For example, consider the following:

Num tokens	49K
Num sentences	2435
Num name tokens	2326
Entity ratio	4.66%
Num unique name tokens	664
Annotator 1 Prec/Rec/F1	84/34/48
Annotator 2 Prec/Rec/F1	79/28/42
Combined Prec/Rec/F1	83/32/47

Table 4: Bengali Data Statistics. The P/R/F1 scores are computed for the non-speaker annotator with respect to the gold training data.

- **Romanized Bengali**: ebisi'ra giliyyaana phinnddale aaja pyaalestaaina adhiinastha gaajaa theke aaja raate ekhabara jaaniyyechhena .
- **Translation**[8]: ABC's Gillian Fondley has reported today from Gaza under Palestine today.

The entities are Gillian Findlay, ABC, Palestine, and Gaza. While a fast-moving annotator may not catch most of these, 'pyaalestaaina' could be considered an 'easy' entity, because of its visual and aural similarity to 'Palestine.' A clever annotator may also infer that if Palestine is mentioned, then Gaza may be present.

Annotators are moving fast and being intentionally non-thorough, so the recall will be low. Since they do not speak Bengali, there are likely to be some mistakes, so the precision may drop slightly also. This is exactly the noisy partial annotation scenario addressed in this paper. The statistics of this data can be seen in Table 4, including annotation scores computed with respect to the gold training data for each annotator, as well as the combined score.

We show results in Table 5, using the BiLSTM-CRF model. We compare against other low-resource approaches published on this dataset, including two based on Wikipedia (Tsai et al., 2016; Pan et al., 2017), another based on lexicon translation from a high-resource language (Mayhew et al., 2017). These prior methods operate under somewhat different paradigms than

[7]This step is vitally important. We used `www.isi.edu/~ulf/uroman.html`

Train on Gold	71.6	70.2	70.9
Raw annotations	**73.0**	23.8	35.9
Combined Weighting	65.9	34.2	45.0
CBL-Raw	57.8	**47.3**	**52.0**
CBL-Combined	58.3	44.2	50.2

Table 5: Bengali manual annotation results. Our methods improve on state of the art scores by over 5 points F1 given a relatively small amount of noisy and incomplete annotations from non-speakers.

this work, but have the same goal: maximizing performance in the absence of gold training data.

Raw annotations is defined as before, and gives similar high-precision low-recall results. The *Combined Weighting* scheme improves over Raw annotations by 10 points, achieving a score comparable to the prior state of the art. Beyond that, *CBL-Raw* outperforms the prior best by nearly 6 points F1, although *CBL-Combined* again underwhelms.

To the best of our knowledge, this is the first result showing a method for non-speaker annotations to produce high-quality NER scores. The simplicity of this method and the small time investment for these results gives us confidence that this method can be effective for many low-resource languages.

6 Conclusions

We explore an understudied data scenario, and introduce a new constrained iterative algorithm to solve it. This algorithm performs well in experimental trials in several languages, on both artificially perturbed data, and in a truly low-resource situation.

Contextualized Cross-Lingual Event Trigger Extraction with Minimal Resources

Meryem M'hamdi , Marjorie Freedman and Jonathan May
Information Sciences Institute & Computer Science Department
University of Southern California (USC)
{meryem, mrf, jonmay}@isi.edu

Abstract

Event trigger extraction is an information extraction task of practical utility, yet it is challenging due to the difficulty of disambiguating word sense meaning. Previous approaches rely extensively on hand-crafted language-specific features and are applied mainly to English for which annotated datasets and Natural Language Processing (NLP) tools are available. However, the availability of such resources varies from one language to another. Recently, contextualized Bidirectional Encoder Representations from Transformers (BERT) models have established state-of-the-art performance for a variety of NLP tasks. However, there has not been much effort in exploring language transfer using BERT for event extraction.

In this work, we treat event trigger extraction as a sequence tagging problem and propose a cross-lingual framework for training it without any hand-crafted features. We experiment with different flavors of transfer learning from high-resourced to low-resourced languages and compare the performance of different multilingual embeddings for event trigger extraction. Our results show that training in a multilingual setting outperforms language-specific models for both English and Chinese. Our work is the first to experiment with two event architecture variants in a cross-lingual setting, to show the effectiveness of contextualized embeddings obtained using BERT, and to explore and analyze its performance on Arabic.

1 Introduction

Event trigger extraction, as defined the Automatic Content Extraction multilingual evaluation benchmark (ACE2005) (Walker, 2006), is a subtask of event extraction which requires systems to detect and label the lexical instantiation of an event, known as a *trigger*. As an example, in the sentence "John **traveled** to NYC for a meeting", **traveled** is a trigger of a *Movement-Transport* event. Trigger detection is typically the first step in extracting the structured information about an event (e.g. the time, place, and participant arguments; distinguishing between past, habitual, and future events). This definition of the task restricts it to events that can be triggered explicitly by actual words and makes it context-vulnerable: the same event might be expressed by different triggers and a specific trigger can represent different event types depending on the context.

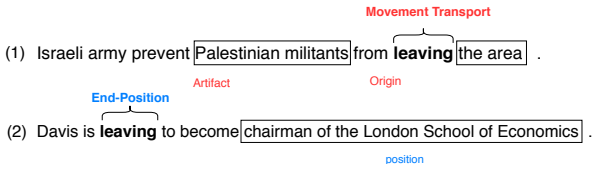

Figure 1: Examples of importance of context in trigger disambiguation.

Event trigger extraction is challenging as it involves understanding the context in order to be able to identify the event that the trigger refers to. Figure 1 shows two examples where context plays a crucial role in disambiguating the word sense of **leaving**, which is a trigger for a *Movement-Transport* event in the first sentence and for an *End-Position* event in the second sentence.

Due to the complexity of the task and the difficulty in constructing a standard annotation scheme, there exists limited labeled data, for only a few languages. The earliest work has focused mainly on English, for which there are relatively many annotated sentences, and relies extensively on language-specific linguistic tools to extract the lexical and syntactic features that need to be computed as a pre-requisite for the task (Ji and Grishman, 2008; Liao and Grishman, 2010; Hong et al., 2011; Li et al., 2013).

Simply generating annotated corpora for each

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 656–665
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

language of interest is not only costly and time-consuming, it is also not necessarily guaranteed to address the **great NLP divide**, where performance depends on the language, the ability to generate language-specific features, and the quality tools (in this case, syntactic parsers) available for each language. In an attempt to reduce the great NLP divide, we observe a tendency of practitioners drifting away from linguistic features and more towards continuous distributed features that can be obtained without hand-engineering, based simply on publicly available corpora. Recently, approaches have tried to overcome the limitation of traditional lexical features, which can suffer from the data sparsity problem and inability to fully capture the semantics of the words, by making use of sequential modeling methods including variants of Recurrent Neural Networks (RNN) and Convolutional Neural Networks (CNN), and/or Conditional Random Fields (CRF). (Chen et al., 2015; Liu et al., 2016; Nguyen et al., 2016; Sha et al., 2018; Liu et al., 2018b).

Existing approaches which take into consideration the cross-lingual aspect of event trigger extraction tend to either take inspiration from machine translation, distant supervision or multitasking. Machine translation is used by Liu et al. (2018a) to project monolingual text to parallel multilingual texts to model the confidence of clues provided by other languages. However, this approach suffers from error propagation of machine translation.

Another approach relies on multilingual embeddings, which can be pre-trained beforehand on large monolingual corpora, using no explicit parallel data, and bridging the gap between different languages by learning a way to align them into a shared vector space. The ability of these models to represent a common representation of words across languages makes them attractive to numerous downstream NLP applications. Multilingual Unsupervised and Supervised Embeddings (MUSE) is a framework for training cross-lingual embeddings in an unsupervised manner, which leads to competitive results, even compared to supervised approaches (Conneau et al., 2017). However, there is no prior work leveraging this kind of representation for cross-lingual event trigger extraction.

More recently, BERT, a deep bidirectional representation which jointly conditions on both left and right context (Devlin et al., 2019), was proposed, which unlike MUSE, provides *contextualized* word embeddings, and has been shown to achieve state-of-the-art performance on many NLP tasks. In particular, (Yang et al., 2019) propose a method based on BERT for enhancing event trigger and argument extraction by generating more labeled data. However, it has not been applied in the context of cross-lingual transfer learning.

In this paper, we investigate the possibility of automatically learning effective features from data while relying on zero language-specific linguistic resources. Moreover, we explore the application of multilingual embeddings to the event trigger extraction task in a **direct transfer of annotation scheme** where ground truth is only needed for one language and can be used to predict labels in other languages and **other boosted and joint multilingual schemes**. We perform a systematic comparison between training using monolingual versus multilingual embeddings and the difference in gain on performance with respect to different train/test language pairs. We evaluate our framework using two embedding approaches: type-based unsupervised embeddings (MUSE) and contextualized embeddings (BERT). For the latter, we demonstrate that our proposed model achieves a better (or comparable) performance for all languages compared to some benchmarks for event extraction on the ACE2005 dataset.

The main contributions of the paper can be summarized as follows:

(1) We apply different state-of-the-art NN architectures for sequence tagging on trigger extraction and compare them to feature-based baselines and multilingual projection based models.

(2) We achieve a better performance using contextualized word representation learning in event trigger extraction backed up with both quantitative and qualitative analysis.

(3) We evaluate the effectiveness of a multilingual approach using zero-shot transfer learning, targeted cross-lingual and joint multilingual training schemes.

(4) We investigate event trigger extraction performance when using Arabic.

2 Methodology

We treat trigger extraction as a sequence tagging problem for which we start by designing a ba-

sic state-of-the-art approach for sequence tagging based on bidirectional Long Short Term Memory (bi-LSTM) with word and character embeddings and a CRF layer on top of it. Then, we describe an approach that trains BERT with a CRF layer for the task. In both architectures, the input is in the form of BIO notation used to differentiate between the beginning (B), inside (I) and (O) for no associated trigger labels.

2.1 Bi-LSTM-Char-CRF networks

The Bi-LSTM-Char-CRF for sequence tagging model is a hierarchical neural network model based on three components: character-level using character embeddings, word-level using bi-LSTM over word embeddings and sequence-level using CRF. The architecture of the model is depicted in Figure 2.

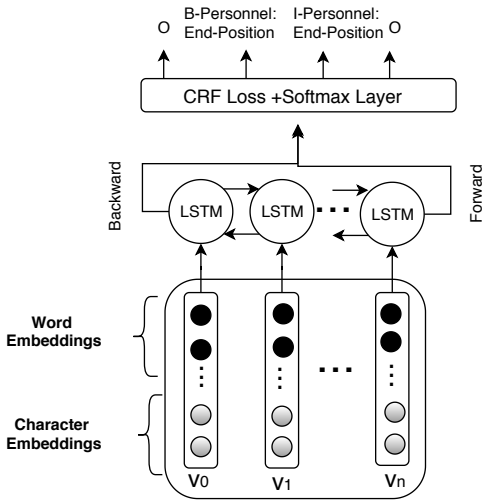

Figure 2: Bidirectional LSTM with character embeddings and CRF layer

2.1.1 Bi-LSTM networks

LSTMs (Hochreiter and Schmidhuber, 1997) are variants of RNNs that help learn long-range dependencies efficiently thanks to their use of memory and forget cells. Those cells help control the amount of the input to be retained/forgotten from previous states.

Given an input character or word embeddings representation x_t for a given time step t, we use bidirectional LSTMs by encoding features in their forward: $fh_i = \overrightarrow{LSTM}(x_i)$ and backward $bh_i = \overleftarrow{LSTM}(x_i)$ directions and concatenating them $h_i = [fh_i, bh_i]$ to capture information from both the past and future.

2.1.2 Character Embeddings

Character embeddings are used to capture orthographic patterns and to deal with out-of-vocabulary words, especially in the cross-lingual setting. We follow the same setup as Lample et al. (2016) to obtain character embeddings using bi-LSTM. Specifically, we concatenate both character and word-level features and use a bi-LSTM on top of that.

2.1.3 CRF Layer

The encoded character and word-level features are fed to a CRF layer to learn inter-dependencies between output trigger tags and find the optimal tag sequence. This layer simulates bi-LSTM in its use of past and future tags to predict the current tag. Following Lafferty et al. (2001), CRF layers define a transition matrix A and use a score A_{ij} to model the transition from the i^{th} state to the j^{th} for a pair of consecutive time steps. The scores $[f_\theta]_{i,t}$ of the matrix is the score output by the network with parameters θ, for the sentence $[x]_1^N$ and for the i^th tag, at the t^th word. The score of a sequence of tags $[y]_1^N$ for a particular sequence of words $[x]_1^N$ is the sum of transition scores and network scores which are computed efficiently using dynamic programming.

$$s([x]_1^N, [i]_1^N) = \sum_{t=1}^{N} ([A]_{[i]_{t-1},[i]_t} + [f_\theta]_{[i]_t,t}) \quad (1)$$

2.2 BERT-CRF

BERT is a multi-layer bidirectional transformer encoder, an extension to the original Transformer model (Vaswani et al., 2017). The input representation consists of a concatenation of WordPiece embeddings (Wu et al., 2016), positional embeddings, and the segment embedding. A special token ([CLS]) is inserted at the beginning of each sentence and another special token ([PAD]) is used to normalize the length of sentences (no ([SEP]) token is used in this case). The pre-trained BERT model provides a powerful contextualized representation which gives the state-of-the-art performance for many NLP tasks. We use BERT-CRF, which adds a CRF layer on top of BERT's contextualized embeddings layer.

3 Experimental Setup

3.1 Dataset

We evaluate our approach on the ACE2005 sentence-level event mention multilingual bench-

mark.[1] This dataset is annotated with 33 event subtypes which, when represented in BIO annotation, results in a 67-way labeling task. For a sound comparison, we use the same data split as the English baseline (as detailed in Section 3.3). To the best of our knowledge, there are no Arabic benchmark systems, so we produced our own split.[2] Statistics of the split for train, validation, and test for the three languages: English (EN), Chinese (ZH) and Arabic (AR) are included in Table 1.

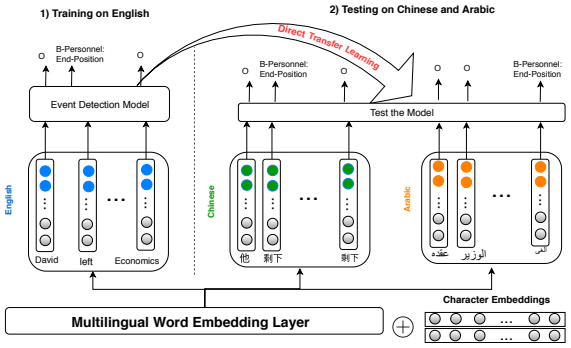

Figure 3: A zero-shot transfer learning architecture for cross-lingual event trigger extraction

3.2 Evaluation

We design different experiments for the evaluation of trigger extraction, where we train several language-specific and multilingual models using different embeddings and sequence labeling architectures. We evaluate the following training schemes:

- *Monolingual Baselines*: We train and fine-tune on EN, ZH or AR using monolingual FastText embeddings and testing on the trained language.
- *Zero-Shot learning experiments*: As depicted in Figure 3, we train and fine-tune on EN using multilingual embeddings (MUSE or BERT(multi)) and test on ZH and AR assuming no resources for those languages. To simplify experiments, we evaluate direct transfer only from EN since it is a high-resourced target language for learning projections needed in multilingual embeddings. We also believe AR and ZH are not good language-pair candidates, so we expect training on AR and testing on ZH and EN or training on ZH and testing on AR and EN would not lead to improvements.
- *Targeted cross-lingual experiments*: For each test language (ZH and AR), we train and fine-tune using multilingual embeddings on language pairs involving the test language in addition to EN to test to what extent adding training instances from the target language boosts the performance over zero-shot learning from EN only. When testing on EN, we train on EN+AR and EN+ZH.
- *Joint multilingual experiments*: We train and fine-tune on all languages (EN, ZH, and AR) using multilingual embeddings and testing on EN, ZH and AR. The hypothesis to be tested is whether a single language-independent model can work well across languages.

3.3 Baselines

We compare our methodology against different systems based on:

- Discrete Only: hand-crafted features only; *Ji's Cross-Entity'08* (Ji and Grishman, 2008); *Liao's Cross-Event'10* (Liao and Grishman, 2010); and *Li's Joint-Beam'13* (Li et al., 2013).
- Discrete + Continuous: using a combination of both linguistic features and trainable continuous features; *Chen's Dynamic CNN (DMCNN'15)* (Chen et al., 2015); *Nguyen's Joint RNN (JRNN'16)* (Nguyen et al., 2016); *Liu's Jointly Multiple Events (JMEE'18)* (Liu et al., 2018b); and *Zhang's Generative Adversarial Imitation Learning (GAIL'19)* (Zhang and Ji, 2018).
- Continuous Only: language-independent features only; *Feng's Hybrid Neural Network (HNN)'16* (Feng et al., 2016) and *Liu's Gated Multilingual Attention (GMLATT)'18* (Liu et al., 2018a).

For cross-lingual results, we include a comparison with ZH baselines; *Li's Maximum Entropy (MaxEnt)'13* (Li et al., 2013); *Chen's Rich-C'12* (Chen and Ng, 2012); *Feng's HNN'16* (Feng et al.,

2016); and *Hsi's Multi'16* (Hsi et al., 2016). More decriptions are included in Sections 5.1 and 5.2.

3.4 Hyper-parameters and Embeddings

We describe the hyper-parameters leading to the best attainable performance for each event trigger extraction architecture. They are selected based on random search and performance on the validation dataset. For Bi-LSTM-Char-CRF, we train character embeddings using a single bi-LSTM layer with 100 hidden units and use another single layer of bi-LSTM with 300 hidden units to train on the concatenated word and char embeddings. We use a dropout rate of 0.5. We optimize using Adam with learning rate of 0.01, weight decay rate of 0.9, $\beta_1 = 0.7$, $\beta_2 = 0.999$ and $\epsilon = 1\text{e}{-8}$.

For monolingual embeddings, we use 300-dimensional word embeddings for EN, ZH, and AR from fastText (Bojanowski et al., 2017). For multilingual experiments, we use MUSE library [3] to train unsupervised alignments from ZH and AR to EN resulting in a unified vector space for the three languages. We use the same training hyper-parameters across monolingual and multilingual training to ensure a fair comparison.

For BERT-CRF, we train monolingual EN and ZH using cased BERT-Base and BERT-ZH models[4] respectively and for all multilingual experiments, we use the recommended multi-cased BERT-Base model.[5] All models were trained using 12 layers with 768 hidden size and 12 self-attention heads and 110 Million parameters. We fine tune all BERT models with their default parameters. We use Adam with learning rate of 0.01, weight decay rate of 0.9, $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 1\text{e}{-6}$.

For all experiments, we use a batch size of 32 and limit the maximum sequence length of sentences to 128, padding or cutting otherwise. In the end, we report F1 for both trigger identification and classification tasks computed using the seqeval[6] framework for sequence labeling evaluation based on the CoNLL-2000 shared task, complying with previous work. Trigger classification doesn't assume the identification is correct but rather gives a stricter performance metric for measuring whether the trigger is not only identified but also correctly classified.

4 Results

Table 2 shows F1 scores of trigger identification and classification tested on EN, ZH and AR across two event architectures: Bi-LSTM-Char-CRF and BERT-CRF and using different embeddings and training schemes (fine-grained performance analysis based on precision, recall scores can be found in Appendix A).

4.1 Comparison with Feature-Based State-of-the-art

Before digging deeper into the comparison of our results with previous state-of-the-art methodology, it is worth comparing the different approaches taken by the prior work. For both EN and ZH, we observe that the best F1 scores over trigger identification and classification are obtained by Liu's JMEE in the first place and Feng's HNN with a close performance (with scores of 73.7% and 73.4% on trigger classification). For the multilingual case (ZH), it is clear that Feng's HNN is very competitive, whereas models relying on machine translation, namely Liu's GMLATT and Hsi's multi, lag behind the rest of models.

It is not surprising that a neural-based system outperforms other hand-crafted architectures since the former can capture richer sequence information beyond sentence-level than traditional NLP pre-processing such as dependency parsing and avoid errors propagated from such tools.

Table 2: Comparison of performance with different train/test language pairs using prior work baselines in the 1^{st} half and our method using Bi-LSTM-Char-CRF and BERT-CRF in the 2^{nd} half. †, + and ‡ denote baseline approaches using Discrete Only, Discrete + Continuous and Continuous Only features respectively, whereas * denotes our own approaches. A '-' designates that the experiment doesn't apply for that test language.

We observe that in general our language-independent (monolingual) Bi-LSTM-Char-CRF and BERT-CRF methods are on par with or outperform best attainable results. In particular, **BERT-CRF trained monolingually using BERT(Base) embeddings outperforms other baselines** for both EN and ZH, with F1-scores of 79.2 and 75.3 on trigger identification and classification, respectively, amounting to a 3.3% and 1.6% gain for EN. For ZH, we obtain F1-scores of 84.4% and 79.9%, amounting to an increase of 16.2% and 16.9% over the previous state-of-the-art. On the other hand, although results using Bi-LSTM-Char-CRF lag behind state-of-the-art for EN, incurring a loss of 10.5% over trigger classification, they are competitive for ZH, with scores of 86.6% and 69.5% and gains of 17.9% and 6.2% over Feng's HNN for trigger identification and classification respectively.

4.2 Comparison between MUSE and BERT Embeddings

We observe a significant difference in performance **in favor of BERT-CRF compared to Bi-LSTM-Char-CRF with a gain of 12.1%, 10.4%, and 13.9%** on the classification task. The better performance of BERT-CRF compared to Bi-LSTM-Char-CRF can be attributed to the fact that BERT is able to learn contextualized representation and long-range dependencies at different levels of granularity. Table 3 provides some examples where the surface form of the trigger is hard to dis-

ambiguate without context information. Reconsidering the second example from the introduction, we notice that a Bi-LSTM-Char-CRF fails to effectively associate it with position context clues.

4.3 Cross-lingual Event Trigger Extraction

In general, we observe that multilingual training leveraging multilingual embeddings provides a boost in performance for both event architectures, especially for EN and AR. More precisely, there is a **gain of 3.1% and 4.0% for EN and ZH respectively** on the identification performance of multilingual over monolingual models. We notice that AR benefits the most from multilingual training with an **improvement of 9.5% and 2.8%** on the classification score with BERT-CRF and Bi-LSTM-Char-CRF respectively. This supports our claim about the effectiveness of multilingual models which are efficient to train and are more robust than monolingual models.

Although F1-scores for **zero-shot transfer learning**(train: EN, test: ZH/AR) are not the best among multilingual experiments, they are still promising and exceed prior published work given the fact that no data from the target language was used to fine-tune. In particular, **training with EN using BERT-CRF was helpful for ZH** with a performance not far from monolingual performance. The same can be observed in the case of EN→ZH and EN→AR using MUSE. The lower performance of EN→AR using BERT-CRF raises questions about the quality of BERT(multi) embedding model training for Arabic.

Not surprisingly, training given a reasonable amount of language-specific resources from the test language under a **targeted cross-lingual scheme**(train: EN+ZH/EN+AR, test: EN/ZH/AR), boosts (with rare exceptions) the performance over both monolingual training and zero-shot learning: EN+AR>EN, EN+ZH>ZH>EN and EN+AR>EN>AR when testing on ZH, AR and even for EN for which we have a strong monolingual baseline.

When all languages are used to train **one single joint multilingual model** (train: All, test: EN/AR/ZH) we don't always notice improvements over monolingual models. To gain more insight into why multilingual training boosts performance over monolingual models, we include some examples of when EN is complementary to ZH and AR and without which the model fails to identify some events. In the Chinese example, there are only 12 "nearby" Chinese words to the trigger word 解散 (Jiěsàn) in ZH training data, whereas there are 4 times as many nearby words in EN (e.g. disband, dissolve, shut, cease, etc).

5 Related Work

Since this work is at the intersection of (i) event extraction and (ii) multilingual event extraction, we present previous work in relation to each domain separately in addition to (iii) a description of cross-lingual approaches for other tasks which motivate our current work.

5.1 Event Extraction in English

Previous works in event extraction on ACE2005 benchmark dataset are mostly focused on English and can be categorized based on the degree of hand-crafted features used and whether they are trained in a pipelined or joint fashion. While some systems such as Cross-Document (Ji and Grishman, 2008) and Cross-Event (Liao and Grishman, 2010) leverage document-level information to enhance the performance of event extraction in a pipelined fashion, others propose a more structured framework for joint training of both trigger labeling and argument extraction (Li et al., 2013).

Other approaches explore neural networks on top of linguistic features employing architectures like Dynamic Multi-Pooling CNNs (DM-CNN) (Chen et al., 2015) and bidirectional RNNs (JRNN) with manually crafted features (Nguyen et al., 2016). A joint approach was proposed by Liu et al. (2018b) to extract multiple events based on syntactic graph convolution network. More recently, Zhang and Ji (2018) propose an approach based on inverse reinforcement learning using Generative Adversarial Networks (GAN) to alleviate mistakes related to ambiguous labels making the model less vulnerable to biased, supervised datasets like ACE2005.

However, the majority of the described approaches involves to some degree the use of linguistic features. This is labor intensive and requires rich external resources, which are not necessarily available for low-resource languages.

5.2 Cross-lingual Event Extraction

Previous works for cross-lingual event extraction conducted in a semi-supervised way range from purely supervised approaches to those using ma-

Table 3: Examples of trigger extraction mislabeled by MUSE but correctly labeled by BERT and those missed/mislabeled with monolingual training only and corrected with multilingual BERT model.

chine translation techniques or word alignment data. Feng et al. (2016) propose a language-independent approach that doesn't require any linguistic feature engineering. However, this approach still requires equally abundant labeled data for different languages and implies the need to train a new model for each language independently.

Hsi et al. (2016) exploit both language-dependent and language-independent features in the form of universal features such as universal dependencies, limited bilingual dictionaries and aligned multilingual word embeddings to train a model with multiple languages. However, this work lags behind in terms of the neural approach used and doesn't investigate the effectiveness of leveraging multiple source languages.

Liu et al. (2018b) propose gated cross-lingual attention as a mechanism to exploit the inherent complementarity of multilingual data which helps with data scarcity and trigger disambiguation. However, this approach relies on machine translation which suffers from error propagation.

5.3 Cross-lingual Tasks

Cross-lingual embeddings are of practical usefulness in many tasks in natural language processing (NLP) and information extraction (IE). In each case, a model is trained on one language and transferred to unseen languages. Downstream applications on which they are applied include part-of-speech (POS) tagging (Cohen et al., 2011), cross-lingual document classification ((Klementiev et al., 2012); (Schwenk and Li, 2018)) named entity recognition (Xie et al., 2018). More recently, BERT was developed as an extension to the transformer architecture and achieved significant improvement in performance for many NLP tasks.

The gain in performance associated with multilingual training is what encouraged us to explore this methodology on event trigger extraction. To the best of our knowledge, there is no prior work adopting conventional or contextualized multilingual embeddings for event trigger detection.

6 Conclusion

In this work, we propose a cross-lingual approach for event trigger extraction using a direct transfer of annotation framework based on multilingual embeddings. Compared to previous approaches, our approach doesn't rely on hand-crafted linguistic features or machine translation.

We evaluate this approach using event trigger extraction architectures with type-based unsupervised embeddings (FastText and MUSE) and supervised embeddings tuned to the context (BERT). Our results for both English and Chinese show competitive performance with baselines on the ACE2005 benchmark even in the zero-shot learning scheme. Although results using MUSE are lower for English, they are on par with Chinese baselines and better for Arabic compared to BERT.

We observe a generous boost in performance when English is added to the target language, and when all languages are combined together to train one cross-lingual model, especially for Arabic. Our result are promising compared to both feature-based approaches and cross-lingual approaches based on machine translation.

Abstract

We propose a novel deep structured learning framework for event temporal relation extraction. The model consists of 1) a recurrent neural network (RNN) to learn scoring functions for pair-wise relations, and 2) a structured support vector machine (SSVM) to make joint predictions. The neural network automatically learns representations that account for long-term contexts to provide robust features for the structured model, while the SSVM incorporates domain knowledge such as transitive closure of temporal relations as constraints to make better globally consistent decisions. By jointly training the two components, our model combines the benefits of both data-driven learning and knowledge exploitation. Experimental results on three high-quality event temporal relation datasets (TCR, MATRES, and TB-Dense) demonstrate that incorporated with pre-trained contextualized embeddings, the proposed model achieves significantly better performances than the state-of-the-art methods on all three datasets. We also provide thorough ablation studies to investigate our model.

1 Introduction

Event temporal relation extraction aims at building a graph where nodes correspond to events within a given text, and edges reflect temporal relations between the events. Figure 1a illustrates an example of such graph for the text shown above. Different types of edges specify different temporal relations: the event **filed** is *SIMULTANEOUS* with **claiming**, **overruled** is *BEFORE* **claiming**, and **overruled** is also *BEFORE* **filed**. Temporal relation extraction is beneficial for many downstream tasks such as question answering, information retrieval, and natural language generation. An event graph can potentially be leveraged to help time-series forecasting and provide guidances for natural language generation. The CaTeRs dataset (Mostafazadeh et al., 2016) which annotates temporal and causal relations is constructed for this purpose.

A major challenge in temporal relation extraction stems from its nature of being a *structured*

*Both U.S. and British officials **filed** objections to the court's jurisdiction in 1995, **claiming** Security Council resolutions **imposed** on Lybia to force the suspects' extradition **overruled** a 1971 Convention which gives Libya the right to try the men.*

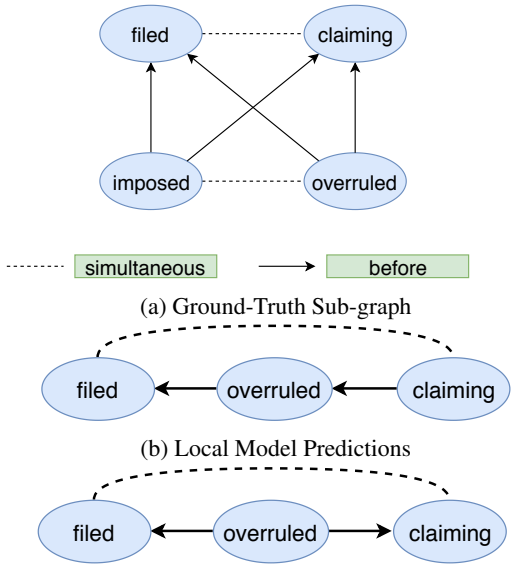

Figure 1: An illustration of a paragraph with its partial temporal graph. (a) shows the Ground-Truth temporal graph, in which case temporal relation *SIMULTANEOUS* and *BEFORE* are presented. (b) and (c) are the local and structured predictions, respectively, for three of the event pairs in (a). Local predictions are incompatible with temporal transitivity rule: **overruled** has to be *BEFORE* **claiming** if **overruled** is *BEFORE* **filed** and **filed** is *SIMULTANEOUS* with **claiming**. The structured model achieves coherence by reversing the temporal order between **claiming** and **overruled**.

prediction problem. Although a relation graph can be decomposed into individual relations on each event pair, any *local* model that is not informed by the whole event graph will usually fail to make globally consistent predictions, thus degrading the overall performance. Figure 1b gives an example where the *local model* classifies the relation between **overruled** and **claiming** incorrectly as it only considers pairwise predictions: graph temporal transitivity constraint is violated given the relation between **filed** and **claiming** is *SIMULTANEOUS*. In Figure 1c, the *structured model* changes the prediction of relation between **overruled** and **claiming** from *AFTER* to *BEFORE* to ensure compatibility of all predicted edge types.

Prior works on event temporal relation extraction mostly formulate it as a pairwise classification problem (Bethard, 2013; Laokulrat et al., 2013; Chambers, 2013; Chambers et al., 2014) disregarding the global structures. Bramsen et al. (2006a); Chambers and Jurafsky (2008); Do et al. (2012); Ning et al. (2018b,a) explore leveraging global *inference* to ensure consistency for all pairwise predictions. There are a few prior works that directly model global structure in the training process (Yoshikawa et al., 2009; Ning et al., 2017; Leeuwenberg and Moens, 2017). However, these structured models rely on hand-crafted features using linguistic rules and local-context, which cannot adequately capture potential long-term dependencies between events. In the example shown in Figure 1, **filed** occurs in much earlier context than **overruled**. Thus, incorporating long-term contextual information can be critical for correctly predicting temporal relations.

In this paper, we propose a novel deep structured learning model to address the shortcomings of the previous methods. Specifically, we adapt the structured support vector machine (SSVM) (Finley and Joachims, 2008) to incorporate linguistic constraints and domain knowledge for making joint predictions on events temporal relations. Furthermore, we augment this framework with recurrent neural networks (RNNs) to learn long-term contexts. Despite the recent success of employing neural network models for event temporal relation extraction (Tourille et al., 2017a; Cheng and Miyao, 2017; Meng et al., 2017; Meng and Rumshisky, 2018), these systems make pairwise predictions, and do not take advantage of problem structures.

We develop a joint end-to-end *training* scheme that enables the feedback from global structure to directly guide neural networks to learn representations, and hence allows our deep structured model to combine the benefits of both data-driven learning and knowledge exploitation. In the ablation study, we further demonstrate the importance of each global constraints, the influence of linguistic features, as well as the usage of contextualized word representations in the local model.

To summarize, our main contributions are:

- We propose a deep SSVM model for event temporal relation extraction.
- We show strong empirical results and establish new state-of-the-art for three event relation benchmark datasets.
- Extensive ablation studies and thorough error analysis are conducted to understand the capacity and limitations of the proposed model, which provide insights for future research on temporal relation extraction.

2 Related Work

Temporal Relation Data. Temporal relation corpora such as TimeBank (Pustejovsky et al., 2003) and RED (O'Gorman et al., 2016) facilitate the research in temporal relation extraction. The common issue in these corpora is missing annotation. Collecting densely annotated temporal relation corpora with all event pairs fully annotated has been reported to be a challenging task as annotators could easily overlook some pairs (Cassidy et al., 2014; Bethard et al., 2007; Chambers et al., 2014). TB-Dense dataset mitigates this issue by forcing annotators to examine all pairs of events within the same or neighboring sentences. Recent data construction efforts such as MATRES (Ning et al., 2018a) and TCR (Ning et al., 2018b) further enhance the data quality by using a multi-axis annotation scheme and adopting start-point of events to improve inter-annotator agreements. However, densely annotated datasets are relatively small both in terms of number of documents and event pairs, which restricts the complexity of machine learning models used in previous research.

Event Temporal Relation Extraction The series of TempEval competitions (Verhagen et al., 2007, 2010; UzZaman et al., 2013) attract many research interests in predicting event temporal relations. Early attempts (Mani et al., 2006; Verha-

gen et al., 2007; Chambers et al., 2007; Verhagen and Pustejovsky, 2008) only use local pairwise classification with hand-engineered features. Later efforts, such as ClearTK (Bethard, 2013), UTTime (Laokulrat et al., 2013), and NavyTime (Chambers, 2013) improve earlier work by feature engineering with linguistic and syntactic rules. A noteworthy work, CAEVO (Chambers et al., 2014), builds a pipeline with ordered sieves. Each sieve is either a rule-based classifier or a machine learning model; sieves are sorted by precision, i.e. decisions from a lower precision classifier cannot contradict those from a higher precision model.

More recently, neural network-based methods have been employed for event temporal relation extraction (Tourille et al., 2017a; Cheng and Miyao, 2017; Meng et al., 2017; Han et al., 2019a) which achieved impressive results. However, they all treat the task as a pairwise classification problem. Meng and Rumshisky (2018) considered incorporating global context for pairwise relation predictions, but they do not explicitly model the *output* graph structure for event temporal relation.

There are a few prior works exploring structured learning for temporal relation extraction (Yoshikawa et al., 2009; Ning et al., 2017; Leeuwenberg and Moens, 2017). However, their local models use hand-engineered linguistic features. Despite the effectiveness of hand-crafted features in previous research, the design of features usually fails to capture long-term context in the discourse. Therefore, we propose to enhance the hand-crafted features with contextual representations learned through RNN models and develop an integrated joint training process.

3 Methods

We adapt the notations from Ning et al. (2018a), where $\mathcal{R}$ denotes the set of all possible relations; $\mathcal{E}$ denotes the set of all event entities.

3.1 Deep SSVM

Our deep SSVM model adapts the SSVM loss as

$$\mathcal{L} = \sum_{n=1}^{l} \frac{1}{M^n} \big[\max\big(0, \Delta(\boldsymbol{y}^n, \hat{\boldsymbol{y}}^n) + S(\hat{\boldsymbol{y}}^n; \boldsymbol{x}^n) - S(\boldsymbol{y}^n; \boldsymbol{x}^n)\big)\big] + C||\Phi||^2, \quad (1)$$

where Φ denotes model parameters, n indexes instances, M^n is the number of event pairs in instance n. $\boldsymbol{y}^n, \hat{\boldsymbol{y}}^n$ denote the gold and predicted global assignments for instance n, each of

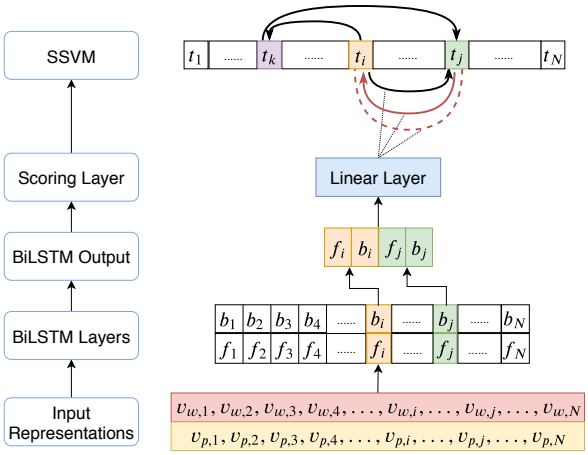

Figure 2: An overview of the proposed deep structured event relation extraction framework. The input representations consist of BERT representations ($v_{w,k}$) and POS tag embeddings ($v_{p,k}$). They are concatenated to pass through BiLSTM layers and classification layers to get pairwise local scores. Incompatible local pairwise prediction (denoted by red lines) is corrected by the SSVM layer. Edge notation follows Figure 1 and $t_1, ...t_N$ denote tokens in the input sentence.

which consists of M^n one hot vectors $\boldsymbol{y}^n_{i,j}, \hat{\boldsymbol{y}}^n_{i,j} \in \{0,1\}^{|\mathcal{R}|}$ representing true and predicted relation labels for event pair i, j respectively. $\Delta(\boldsymbol{y^n}, \hat{\boldsymbol{y}}^n)$ is a distance measurement between the gold and the predicted assignments; we simply use hamming distance. C is a hyper-parameter to balance the loss and the regularizer, and $S(\boldsymbol{y}^n; \boldsymbol{x}^n)$ is a pairwise scoring function to be learned.

The intuition behind the SSVM loss is that it requires the score of gold output structure $\boldsymbol{y}^n$ to be greater than the score of the best output structure under the current model $\hat{\boldsymbol{y}}^n$ with a margin $\Delta(\boldsymbol{y}^n, \hat{\boldsymbol{y}}^n)$[1], or else there will be some loss.

The major difference between our deep SSVM and the traditional SSVM model is the scoring function. Traditional SSVM uses a linear function over hand-crafted features to compute the scores, whereas we propose to use a RNN for estimation.

3.2 RNN-Based Scoring Function

We introduce a RNN-based pair-wise scoring function to learn features in a data-driven way and capture long-term context in the input. The local neural architecture is inspired by prior work in entity relation extraction such as Tourille et al. (2017b). As shown in Figure 2, the input layer consists of word representations and part-of-

[1]Note that if the best prediction is the same as the gold structure, the margin is zero.

speech (POS) tag embeddings of each token in the input sentence, denoted as $v_{w,k}$ and $v_{p,k}$ respectively.[2] The word representations are obtained via pre-trained BERT (Devlin et al., 2018)[3] model and are fixed throughout training, while the POS tag embeddings are tuned. The word and POS tag embeddings are concatenated to represent an input token, and then fed into a Bi-LSTM layer to get contextualized representations.

We assume the events are labeled in the text and use indices i and j to denote the tokens associated with an event pair $(i, j) \in \mathcal{EE}$ in the input sentences of length N. For each event pair (i, j), we take the forward and backward hidden vectors corresponding to each event, namely f_i, b_i, f_j, b_j to encode the event tokens. These hidden vectors are then concatenated to form the input to the final linear layer to produce a softmax distribution over all possible pair-wise relations, which we refer to as RNN-based **scoring function**.

3.3 Inference

The inference is needed both during training to obtain $\hat{\boldsymbol{y}}^n$ in the loss function (Equation 1), as well as during the test time to get globally compatible assignments. The inference framework is established by constructing a global objective function using scores from local model and imposing several global constraints: symmetry and transitivity as in Bramsen et al. (2006b); Chambers and Jurafsky (2008); Denis and Muller (2011); Do et al. (2012); Ning et al. (2017); Han et al. (2019b), as well as linguistic rules and temporal-causal constraints proposed by Ning et al. (2018a) to ensure global consistency. In this work, we incorporate the **symmetry**, **transitivity**, and **temporal-causal** constraints.

Objective Function. The objective function of the global inference maximizes the score of global assignments as specified in Equation 2[4].

$$\hat{y} = \arg\max \sum_{(i,j)\in\mathcal{EE}} \sum_{r\in\mathcal{R}} y^r_{i,j} S(y^r_{i,j}; \boldsymbol{x}) \quad (2)$$

$$\text{s.t. } y^r_{i,j} \in \{0, 1\}\,, \sum_{r\in\mathcal{R}} y^r_{i,j} = 1,$$

where $y^r_{i,j}$ is a binary indicator specifying if the global prediction is equal to a certain label $r \in \mathcal{R}$ and $S(y^r_{i,j}, \boldsymbol{x}), \forall r \in \mathcal{R}$ is the scoring function obtained from the local model. The output of the global inference $\hat{y}$ is a collection of optimal label assignments for all event pairs in a fixed context. The constraint following immediately from the objective function is that the global inference should only assign one label to each pair of sample inputs.

Symmetry and Transitivity constraint. The symmetry and transitivity constraints are used across all models and experiments in the paper. They can be specified as follows:

$$\forall (i, j), (j, k) \in \mathcal{EE}, y^r_{i,j} = y^{\bar{r}}_{j,i}, \text{ (symmetry)}$$

$$y^{r_1}_{i,j} + y^{r_2}_{j,k} - \sum_{r_3 \in Trans(r_1, r_2)} y^{r_3}_{i,k} \leq 1. \text{ (transitivity)}$$

Intuitively, the symmetry constraint forces two pairs with opposite order to have reversed relations. For example, if $r_{i,j}$ = *BEFORE*, then $r_{j,i}$ = *AFTER*. Transitivity constraint rules that if (i, j), (j, k) and (i, k) pairs exist in the graph, the label (relation) prediction of (i, k) pair has to fall into the transitivity set specifying by (i, j) and (j, k) pairs. The full transitivity table can be found in Ning et al. (2018a).

Temporal-causal Constraint. The temporal-causal constraint is used for the TCR dataset which is the only dataset in our experiments that contains causal pairs and it can written as:

$$y^c_{i,j} = y^{\bar{c}}_{j,i} \leq y^b_{i,j}, \ \forall (i, j) \in \mathcal{EE},$$

where c and $\bar{c}$ correspond to the label *CAUSES* and *CAUSED_BY*, and b represents the label *BEFORE*. This constraint specifies that if event i causes event j, then i has to occur before j. Note that this constraint only has 91.9% accuracy in TCR data (Ning et al., 2018a), but it can help improve model performance based on our experiments.

3.4 Learning

We develop a two-state learning approach to optimize the neural SSVM. We first train the local scoring function without feedback from global constraints. In other words, the local neural network model is optimized using only pair-wise relations in the first stage by minimizing cross-entropy loss. During the second stage, we switch to the global objective function in Equation 1 and

[2] Following the convention of event relation prediction literature (Chambers et al., 2014; Ning et al., 2018a,b), we only consider event pairs that occur in the same or neighboring sentences, but the architecture can be easily adapted to the case where inputs are longer than two sentences.

[3] We use pre-trained bert-base-uncased model from https://github.com/huggingface/pytorch-transformers.

[4] The objective function is specified on the instance level.

re-optimize the network to adjust for global properties[5]. We denote the local scoring model in the first stage as local model, and the final model as global model in the following sections.

4 Experimental Setup

In this section, we describe the three datasets that are used in the paper. Then we define the evaluation metrics. Finally, we provide details regarding our model implementation and experiments.

4.1 Data

Experiments are conducted on TB-Dense, MATRES and TCR datasets and an overview of data statistics are shown in Table 1. We focus on event relation, thus, all numbers refer to $\mathcal{EE}$ pairs[6]. Note that in all three datasets, event pairs are always annotated by their appearance order in text, i.e. given a labeled event pair (i, j), event i always appears prior to event j in the text. Following Meng et al. (2017), we augment event pairs with flipped-order pairs. That is, if a pair (i, j) exists, pair (j, i) is also added to our dataset with the opposite label. The augmentation is applied to training and development split, but test set remains unaugmented[7].

TB-Dense (Cassidy et al., 2014) is based on TimeBank Corpus but addresses the sparse-annotation issue in the original data by introducing the *VAGUE* label and requiring annotators to label all pairs of events/times in a given window.

MATRES (Ning et al., 2018b) is based on TB-Dense data, but filters out non-verbal events. The authors project events on multiple axes and only keep those in the main-axis. These two factors explain the large decrease of event pairs in Table 1. Start-point temporal scheme is adopted when outsourcing the annotation task, which contributes to the performance improvement of machine learning models built on this dataset .

TCR (Ning et al., 2018a) follows the same annotation scheme for temporal pairs in MATRES. It is also annotated with causal pairs. To get causal pairs, the authors select candidates based on EventCausality dataset (Do et al., 2011).

4.2 Evaluation Metrics

To be consistent with the evaluation metrics used in baseline models, we adopt two slightly different calculations of metrics.

Micro-average For all datasets, we compute the micro-average scores. For densely annotated data, the micro-average metric should share the same precision, recall and F1 scores. However, since VAGUE pairs are excluded in the micro-average calculations of TCR and MATRES for fair comparisons with the baseline models, the micro-average for precision, recall and F1 scores are different when reporting results for the two datasets.

Temporal Awareness (TE3) For TB-Dense dataset, TE3 evaluation scheme (UzZaman et al., 2013) is also adopted in previous research (Ning et al., 2017, 2018a). TE3 score not only takes into account of the number of correct pairs but also capture how "useful" a temporal graph is. We report this score for TB-Dense results only. For more details of this metric, please refer to the original paper (UzZaman et al., 2013).

4.3 Implementation Details

Since our work focuses on event relations, we build our models to predict relations between $\mathcal{EE}$ pairs only when conducting experiments. Thus, all micro-average F1 scores only consider $\mathcal{EE}$ pairs. Note that there are also time entities labeled in the TB-Dense denoted as $\mathcal{T}$. $\mathcal{ET}$ and $\mathcal{TT}$ pairs are

[5]We experiment with optimizing SSVM loss directly, but model performance degrades significantly. We leave further investigation for future work.

[6]For TCR, we also include causal pairs in the table.

[7]It is noted that if symmetric constraint is applied, scores for testing on augmented or unaugmented set are equal.

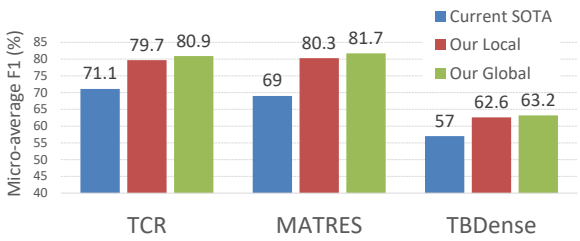

Figure 3: Model Performance (F1 Score) Overview. Our local and global models' performances are averaged over 3 different random seeds for robustness.

generally easier to predict using rule-based classifiers or date normalization technique (Do et al., 2012; Chambers et al., 2014; Mirza and Tonelli, 2016). To be consistent with the baseline models (Ning et al., 2018a,b) for TB-Dense data, we add $\mathcal{ET}$ and $\mathcal{TT}$ pairs for TE3 evaluation metric[8].

In the two-stage learning procedure, the local model is trained by minimizing cross-entropy loss with Adam optimizer. We use pre-trained BERT embedding with 768 dimensions as the input word representations and one-layer MLP as the classification layer. As for the structured learning stage, we observe performance boost by switching from Adam optimizer to SGD optimizer with decay and momentum[9]. To solve ILP in the inference process specified in Section 3.3, we leverage off-the-shelf solver provided by Gurobi optimizer, i.e. the best solutions from the Gurobi optimizer are inputs to the global training.

The hyper-parameters are chosen by the performance on the development set[10], and the best combination of hyper-parameters can be found in Table 2. We run experiments on 3 different random seeds and report the average results.

Note that for TCR data, we need a separate classifier for causal relations. Because of small amount of causal pairs, we simply build an independent final linear layer apart from the original linear layer in Figure 2. In other words, there are two final linear layers: only one of them is active when training temporal or causal pairs.

5 Results and Analysis

Figure 3 shows an overview of our model performance on three different datasets. As the chart illustrates, our RNN-based local models outperform state-of-the-art (SOTA) results and the global models further improve the performance over local models across all three datasets.

[8]We rely on annotated data to distinguish different pair types, i.e. $\mathcal{EE}$, $\mathcal{ET}$ and $\mathcal{TT}$ are assumed to be given.

[9]The weight decay in SGD is exactly the value C in Equation 1. We set the momentum in SGD as 0.9 in all datasets.

[10]We randomly select 4 documents from the training set as development set for TCR.

	Local Model			Global Model		
	P	**R**	**F1**	**P**	**R**	**F1**

Table 4: Model Performance Breakdown for MATRES. Again, we exclude VAGUE pairs in Micro-average score. * indicates global model outperforms local model with p-value < 0.05 per McNemar's test.

5.1 TCR

Detailed model performances for the TCR dataset are shown in Table 3. We only report model performance on temporal pairs. Both of our local and global models outperform the baseline. Our global model is able to improve overall model performance by more than 1.2% over our local model; per McNemar's test, this improvement is statistically significant (with p-value < 0.01).

5.2 MATRES

Detailed model performances for the MATRES dataset performances can be found in Table 4. Similar to TCR, both our local and structured models outperform this baseline and the global model is able to improve overall model performance by 1.4%; per McNemar's test, this improvement is statistically significant (with p-value < 0.05).

5.3 TB-Dense

Table 5 shows the breakdown performance for all labels as well as the improvement from local to

	Local Model			Global Model

Meng and Rumshisky (2018)						**57.0**
TE3 Metrics						
$\mathcal{EE}$ only	62.1	61.9	62.2	62.7	58.9	**62.5**
$+\mathcal{ET}, \mathcal{TT}$	58.6	63.6	61.0	59.0	64.0	61.4
Ning et al. (2018a)						52.1

Table 5: Model Performance Breakdown for TB-Dense (all values are percentage). Upper Table: for event pairs only, we adopt standard Micro-average score. Lower Table: TE3 refers to the temporal awareness score adopted by TE-3 Workshop. To make fair comparison with Ning et al. (2018a), we add CEAVO predictions on $\mathcal{ET}$ and $\mathcal{TT}$ pairs back into the calculation.

global model by adopting the two-stage structured learning method in TB-Dense dataset. Both our local and global models are able to outperform previous SOTA in micro-average metric (reported by Meng and Rumshisky (2018)) or in TE3 metric (results from Ning et al. (2018a)).

Per McNemar's test, the improvements from local to global model only has p-value $= 0.126$, so we are not able to conclude that the improvement is statistically significant. We think one of the reasons is the large share of VAGUE pairs (42.6%). VAGUE pairs make our transitivity rules less conclusive. For example, if $\mathcal{R}(e1, e2)$ = BEFORE and $\mathcal{R}(e2, e3)$ = VAGUE, $\mathcal{R}(e1, e3)$ can be any relation types. Moreover, this impact is magnified by our local model's prediction bias towards VAGUE pairs. As we can see in Table 5, the recall score for VAGUE pairs are much higher than other relation types, whereas precision score is moderate. Our global model leverages local output structure to enforce global prediction consistency, but when local predictions contain many VAGUE pairs, it introduces lots of noise too.

To make fair comparison between our model and the best reported TE3 F1 score from Ning et al. (2018a), we follow their strategy and add CAEVO system's predictions on $\mathcal{TT}$ and $\mathcal{ET}$ pairs in the evaluation. The scores are shown in Table 5. Our overall system outperforms the baseline over 10% for both micro-average and TE3 F1 scores.

5.4 Error Analysis

To understand why both the local and structured models make mistakes, we randomly sample 50 pairs from 345 cases where both models' predictions are incorrect among all 3 random seeds. We analyze these pairs qualitatively and categorize them into four cases as shown in Table 6, with each case (except other) paired with an example.

The first case illustrates that correct prediction requires broader contextual knowledge. For example, the gold label for **transition** and **discuss** is *BEFORE*, where the nominal event **transition** refers to a specific era in history that ends before **discuss** in the second sentence. Human annotators can easily infer this relation based on their knowledge in history, but it is difficult for machines without prior knowledge. We observe this as a very common mistake especially for pairs with nominal events. As for the second case shows that negation can completely change the temporal order. The gold label for the event pair **planned** and **plans** is *AFTER* because the negation token **no** postpones the event **planned** indefinitely. Our models do not pick up this signal and hence predict the relation as *VAGUE*.

Finally, "intention" events could make temporal relation prediction difficult (Ning et al., 2018b). Case 3 demonstrates that our models could ignore the "intention" tokens such as **aimed at** in the example and hence make an incorrect prediction *VAGUE* between **doubling** and **signed**, whereas the true label is *AFTER* because **doubling** is an intention that has not occurred.

6 Ablation Studies

Although we have presented strong empirical results, the isolated contribution of each component of our model has not been investigated. In this section, we perform a though ablation study to understand the importance of structured constraints, linguistic features, and the BERT representations.

6.1 Effect of the structured constraints

One of our core claims is that our learning benefits from modeling the structural constraints of event temporal graph. To study the contribution of structured constraints, we provide an ablation study on two constraints that are applied to all three datasets: Symmetry and Transitivity.

A straightforward ablation study on symmetric constraint is to remove it from our global inference

Case 1 (32%): Connection with broader context
The program also calls for coordination of economic reforms and joint improvement of social programs in the two countries, where many people have become impoverished during the chaotic post - Soviet **transition** to capitalism. Kuchma also planned to visit Russian gas giant Gazprom, most likely to **discuss** Ukraine's DLRS 1.2 billion debt to the company.
Case 2 (20%): Negation
Annan has **no** trip **planned** so far. Meanwhile, Secretary of State Madeleine Albright, Berger and Defense Secretary William Cohen announced **plans** to travel to an unnamed city in the us heartland next week, to explain to the American people just why military force will be necessary if diplomacy fails.
Case 3 (14%): Intention Axis
A major goal of Kuchma's four - day state visit was the signing of a 10-year economic program **aimed at doubling** the two nations' trade turnover, which fell to DLRS 14 billion last year, down DLRS 2.5 billion from 1996. The two presidents on Friday **signed** the plan, which calls for cooperation in the metallurgy, fuel, energy, aircraft building, missile, space and chemical industries.
Case 4: (34%) Other

Table 6: Error Categories and Examples in TB-Dense

step. However, even though we eliminate symmetric constraint explicitly in global inference, it is utilized implicitly in our data augmentation steps (Section 4.1). To better understand the benefits of the symmetry constraints, we study both the contribution of *explicitly* applying symmetry constraint in our SSVM as well as its *implicit* impact in data augmentation.

Hence, in this section, we view a pair with original order and flipped order as different instances for learning and evaluation. We denote the pairs with original order as "**forward**" data, their flipped-order counterparts as "**backward**" data, and their combinations as "**both-way**" data.

We train four additional models to study the impacts of symmetry and transitivity constraints: 1) local model trained on forward data; 2) global model with transitivity constraint trained on forward data; 3) local model trained on both-way data; 4) global model with transitivity constraint trained on both-way data, denoted as M_1, M_2, M_3, M_4 respectively. M_1 and M_2 are models that do not apply any symmetric property; M_3 and M_4 are models that utilize symmetric property implicitly.

Additionally, evaluation setup should be re-scrutinized if we remove the symmetry constraints. In the standard evaluation setup of prior works, evaluation is only performed on the pairs with their original order (forward data) in text. This evaluation assumes a model will work equally well for both forward and backward

Table 7: Ablation over global constraints: Symmetry and Transitivity. Test is conducted on forward test set and both-way test set, which are denoted as $\overrightarrow{Test}$ and $\overleftrightarrow{Test}$ respectively. The local models trained on forward data and both-way data are denoted as $\overrightarrow{L}$ and $\overleftrightarrow{L}$. Symmetry and Transitivity constraints are denoted as S and T. The results demonstrate that symmetry and transitivity constraints both improve model's performance.

data, which certainly holds when we explicitly impose symmetry constraints. However, as we can observe in the later analysis, this assumption fails when we remove symmetry constraints. To demonstrate the improvement of model robustness over backward data, we propose to test the model on both forward and both-way data. If a model is robust, it should perform well on both scenarios.

We summarize our analysis of the results in Table 7 (F1 scores) as follows:

- Impact of Transitivity: By comparing M_1 with M_2 and M_3 with M_4, the consistent improvements across all three datasets demonstrate the effectiveness of global transitivity constraints.
- Impact of Implicit Symmetry (data augmentation): Examining the contrast between M_1 and M_3 as well as M_2 and M_4, we can see significant improvements in both-way evaluation despite slight performance drops in forward evaluation. These comparisons imply that data augmentation can help improve model robustness. Note that Meng and Rumshisky (2018) leveraged this data augmentation trick in their model.
- Impact of Explicit Symmetry: By comparing the proposed model with M_4, the consistent improvements across all datasets demonstrate the benefit of using explicit symmetry property.
- Model Robustness: Although M_1 and M_2 show competitive results when evaluated on forward test data, their performance degrade

Table 8: Ablation study on linguistic feature usage. Additional linguistic features do not lead to significant improvement and even hurt performance in 2 out of 3 datasets. The results show that our proposed framework is semantic-rich and capable of avoiding the usage of additional linguistic feature.

significantly in the both-way evaluation. In contrast, the proposed model achieves strong performances in both test scenarios (best F1 scores except for one), and hence proves the robustness of our proposed method.

6.2 Effect of linguistic features

Previous research establish the success of leveraging linguistic features in event relation prediction. One advantage of leveraging contextualized word embedding is to provide rich semantic representation and could potentially avoid the usage of extra linguistic features. Here, we study the impact of incorporating linguistic features to our model by using simple features provided in the original datasets: token distance, tense and polarity of event entities. These features are concatenated with the Bi-LSTM hidden states before the linear layer (i.e. f_i, b_i, f_j, b_j in Figure 2). Table 8 shows the F1 scores of our local and global model using or not using linguistic features respectively. These additional features likely cause over-fitting and hence do not improve model performance across all three datasets we test. This set of experiments show that linguistic features do not improve the predicting power of our current framework.

6.3 Effect of BERT representations

In this section, we explore the impact of contextualized BERT representations under our deep SSVM framework. We replace BERT representations with the GloVe (Pennington et al., 2014) word embeddings. Table 9 shows the F1 scores of our local model and global model using BERT and GloVe[11] respectively. BERT improves the performance with a significant margin. Besides, even without BERT representations, our RNN-based local model and the deep structured global model still outperform (MATRES and TCR) or are comparable with (TB-Dense) current SOTA. These results confirm the improvements of our method.

[11]For GloVe model, additional linguistic features are used.

	previous SOTA	local- Glove	global- Glove	local- BERT	global- BERT
TB-Dense	57.0	56.6	57.0	62.6	**63.2**
MATRES	69.0	71.8	75.6	80.3	**81.7**
TCR	71.1	73.5	76.5	79.7	**80.9**

Table 9: Ablation over word representation: BERT vs GloVe. Although BERT representation largely contributes to the performance boost, our proposed framework remains strong and outperforms current SOTA approaches when GloVe is used.

7 Conclusion

In this paper, we propose a novel deep structured model based on SSVM that combines the benefits of structured models' ability to encode structure knowledge, and data-driven deep neural architectures' ability to learn long-range features. Our experimental results exhibit the effectiveness of this approach for event temporal relation extraction.

One interesting future direction is further leveraging commonsense knowledge, domain knowledge in temporal relation, and linguistics information to create more robust and comprehensive global constraints for structured learning. Another direction is to improve feature representations by designing novel neural architectures that better capture negation and hypothetical phrases as discussed in error analysis. We plan to leverage large amount of unannotated corpora to help event temporal relation extraction as well.

Investigating Entity Knowledge in BERT with Simple Neural End-To-End Entity Linking

Samuel Broscheit
Data and Web Science Group, University of Mannheim, Germany
broscheit@informatik.uni-mannheim.de

Abstract

A typical architecture for end-to-end entity linking systems consists of three steps: mention detection, candidate generation and entity disambiguation. In this study we investigate the following questions: (a) Can all those steps be learned jointly with a model for contextualized text-representations, i.e. BERT (Devlin et al., 2019)? (b) How much entity knowledge is already contained in pretrained BERT? (c) Does additional entity knowledge improve BERT's performance in downstream tasks? To this end, we propose an extreme simplification of the entity linking setup that works surprisingly well: simply cast it as a per token classification over the entire entity vocabulary (over $700K$ classes in our case). We show on an entity linking benchmark that (i) this model improves the entity representations over plain BERT, (ii) that it outperforms entity linking architectures that optimize the tasks separately and (iii) that it only comes second to the current state-of-the-art that does mention detection and entity disambiguation jointly. Additionally, we investigate the usefulness of entity-aware token-representations in the text-understanding benchmark GLUE, as well as the question answering benchmarks SQUAD V2 and SWAG and also the EN-DE WMT14 machine translation benchmark. To our surprise, we find that most of those benchmarks do not benefit from additional entity knowledge, except for a task with very small training data, the RTE task in GLUE, which improves by 2%.

1 Introduction

The goal of entity linking is, given a knowledge base (KB) and unstructured data, e.g. text, to detect mentions of the KB's entities in the unstructured data and link them to the correct KB entry. The entity linking task is typically implemented by the following steps:

- Mention detection (MD): text spans of potential entity mentions are identified,
- Candidate generation (CG): entity candidates for each mention are retrieved from the KB,
- Entity disambiguation (ED): (typically) a mix of useful coreference and coherence features together with a classifier determine the entity link.

Durrett and Klein (2014) were the first to propose jointly modelling MD, CG and ED in a graphical model and could show that each of those steps are interdependent and benefit from a joint objective. Other approaches only model MD and ED jointly (Nguyen et al., 2016; Kolitsas et al., 2018), thus these architectures depend on a CG step after mention detection. Hachey et al. (2013); Guo et al. (2013); Durrett and Klein (2014) showed the influence of CG on entity linking, because it can be the coverage bottleneck, when the correct entity is not contained in the candidates for ED. Yamada et al. (2016, 2017) use a precomputed set of entity candidates published by Pershina et al. (2015) for their experiments on the CoNLL03/AIDA benchmark dataset (Hoffart et al., 2011), and due to this their experiments are comparable across studies with regards to the CG step. MD has a similar impact on entity linking performance, as it determines the upper bound of linkable mentions.

BERT (Devlin et al., 2019) is a deep self-attention-based architecture which is pretrained on large amounts of data with a language modelling objective. This model provides very rich linguistic text-representations that have been shown to be very useful for many NLP tasks. Since its appearance, BERT is being analyzed and applied in various domains (Beltagy et al., 2019; Lee et al., 2019). A recent study found that BERT automatically learns the NLP pipeline (Tenney et al., 2019),

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 677–685
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

i.e. a stack of increasingly higher level linguistic functions. Zhang et al. (2019) investigated injecting entity knowledge from noisy[1] automatic entity linking into the pretraining of BERT and they could show that this improves relation extraction.

In this study we investigate the following questions:

(a) Can BERT's architecture learn all entity linking steps jointly? We propose an extreme simplification of entity linking and cast it as a per token classification over the entire entity vocabulary, thus solving MD, CG and ED simultaneously (see Fig. 1). The entity vocabulary is based on the $700K$ top most frequent entities in English Wikipedia and the training data was derived from English Wikipedia texts. We first trained BERT-base-uncased on English Wikipedia (dubbed BERT+Entity) and then fine-tuned and evaluated it on an entity linking benchmark. We found that this worked surprisingly well for entity linking, even if we do not have any supervision on mention-spans, i.e. BIO tags. An error analysis with validation data revealed that only 3% of errors are purely due to span errors, while most errors are due to wrong *Nil* predictions which often coincided with entities being infrequent.

(b) How much entity knowledge is already contained in pretrained BERT? To investigate this question, we froze BERT and only trained the entity classifier of BERT+Entity on Wikipedia (dubbed Frozen-BERT+Entity), i.e. the resulting entity classifier is adjusted for entity mentions for which plain BERT already does assign distinct token representations, such that correct entity classification is possible. Then we fine-tuned and evaluated Frozen-BERT+Entity on an entity linking benchmark. We find that the performance of Frozen-BERT+Entity is 6% below BERT+Entity, showing that BERT+Entity has learned additional entity knowledge.

(c) Does additional entity knowledge improve BERT's performance in downstream tasks? Due to training BERT+Entity with a per token classification, the model is forced to assign distinct entity specific features to each token of an entity mention. Downstream tasks could exploit this, if additional entity information is necessary for them. We evaluated BERT+Entity in the natural language understanding benchmark GLUE (Wang et al., 2018), the question answering (QA) benchmarks SQUAD V2 (Rajpurkar et al., 2018) and SWAG (Zellers et al., 2018), and the machine translation benchmark EN-DE WMT14. We confirm the finding from Zhang et al. (2019) that additional entity knowledge is not beneficial for the GLUE benchmark. To our surprise, we also find that additional entity knowledge is neither helpful for the two QA datasets nor for machine translation. The only exception is the RTE task in GLUE in which BERT+Entity improves 2%. This dataset has just 0.5-2% of the training data of the two larger natural language inference datasets in GLUE.

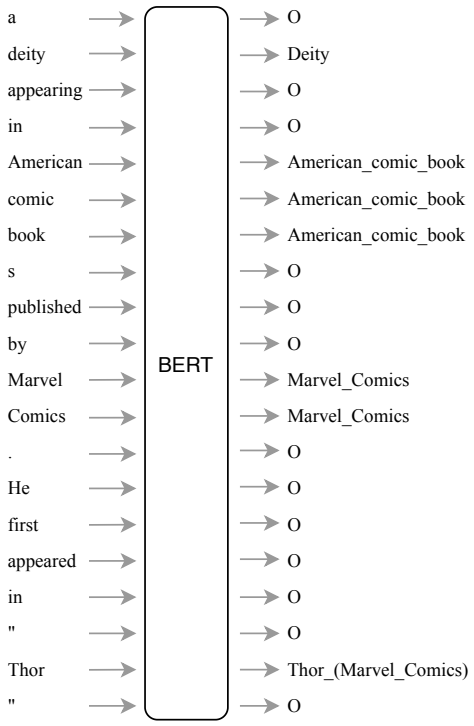

Figure 1: Illustrating the simple neural end-to-end entity linking setup. BERT+Entity predicts entity links per token, where "O" denotes a *Nil* prediction. The example shows how context can help to link *"Thor"* to *Thor_(Marvel_Comics)*.

Our contributions are: We are the first to study the latter questions. We are also the first to propose a fully neural model, that does MD, CG and ED all in one model, i.e. performing entity linking without any pipeline or any heuristics. We are also the first to propose to model entity linking as a token classification and show that this seems to be a viable option. We also uncover that there is a lack of tasks that evaluate additional entity knowledge in pretrained language models.

[1]TagMe's performance on various benchmark datasets ranges from 37% to 72%. F1 (Kolitsas et al., 2018)

2 Related Work

Entity Linking Durrett and Klein (2014) is the work that is closest to our approach, although not neural. In their approach they model interactions between the MD, CG and ED tasks jointly. They find that the joint objective is beneficial, such that each task improves. They also note that there is no natural order of the tasks and they should interact freely. Their approach to CG is to learn to generate queries to the KB. Nguyen et al. (2016) also propose jointly modelling MD and ED with a graphical model and show that it improves ED performance and is more robust. Kolitsas et al. (2018) recently published their study in which they propose the first neural model to learn MD and ED jointly. Their proposed method is to overgenerate mentions and prune them with a mention-entity dictionary. The ED step reasons over the remaining mentions if and to what they link to. However, modern approaches for solving natural language tasks operate on neural text-representations, and the approaches discussed so far only yield entity-links. Yamada et al. (2016, 2017) was the first to investigate neural text representations and entity linking, but their approach is limited to ED.

Pretrained Language Models ULMFIT (Howard and Ruder, 2018), ELMO (Peters et al., 2018), BERT (Devlin et al., 2019) and GPT-2 (Radford et al., 2019) are modern language models that are very deep and wide (for NLP) and are pretrained on large amounts of data. They provide very rich text representations that have shown to improve many NLP tasks by just replacing the static word embeddings with deep contextualized word embeddings. As Peters et al. (2019) show, further training the deep language models alongside the model that uses the embeddings as input can be helpful, for which the term "finetuning" is used. The current trend in research is to investigate all aspects of these language models, seeking insights in their inner workings (Tenney et al., 2019), or their application to various domains (Beltagy et al., 2019; Lee et al., 2019). In this study, we investigate the factual information in form of entities that is contained in BERT, seeking to understand to what degree this information is already identifiable in BERT and if the entity knowledge can be improved.

3 End-To-End Neural Entity-Linking

In this section we describe the BERT+Entity, which is a is straightforward extension of BERT, however, as with the original BERT, the main challenge lies in designing the training scheme, i.e. in our case the creation of the training data. Our goal for the experiments is to evaluate, if we can learn candidate generation, thus a desiderata is to make the entity vocabulary as large as possible to be comparable to other studies. The text data and the entity linking annotations are derived from Wikipedia by exploiting intra-Wikipedia links. This yields the challenge that the annotations for entity links from Wikipedia are assumed to be incomplete, i.e. not every entity mention in Wikipedia is linked, which we hypothesize can be detrimental during training.

3.1 Model

Our model is based on BERT, which is a deep self-attention-based architecture (Vaswani et al., 2017) that was trained on large amounts of text. Its training objective is two-fold: (a.) predict missing tokens from sentences, and (b.) classify if a second sentence was an adjacent sentence. The input and output token vocabulary are sub-words, i.e. the vocabulary is computed from the training data by determining the $30K$ most frequent character sequences, excluding spaces. Devlin et al. (2019) made several pretrained BERT models publicly available. They differ in size — i.e. token embedding size and self-attention layer depth — and whether the token vocabulary is cased or uncased. BERT+Entity is a straightforward extension on top of BERT, i.e. we initialize BERT with the publicly available weights from the BERT-base-uncased model and add an output classification layer on top of the architecture. Given a contextualized token, the classifier computes the probability of an entity link for each entry in the entity vocabulary. Formally, let d be BERT's token embedding size, and $E \in \mathbb{R}^{|KB| \times d}$ the entity classification layer, with $|KB|$ being the number of entities in the KB, V is the sub-word vocabulary, $c_i = BERT(h)[i]$ is the i-th contextualized token computed by BERT from context $h = [v_1, v_2, ..., v_{i-1}, v_i, v_{i+1}, ..., v_m]$ with each $v \in V$. Consequently, the probability $p(j|v, h)$ of word v — which is the i-th token in context h — linking to entity j is computed by $\sigma(E_j c_i)$, where σ is the sigmoid function.

3.2 Training Data

The entity vocabulary and training data are derived from English Wikipedia texts[2]. We used an extended version of WikiExtractor[3] to extract the text spans that are associated with an internal Wikipedia link to use as annotation, e.g. in the sentence *"The first Thor was all about introducing Asgard"*, the text span *"Thor"* links to *https://en.wikipedia.org/wiki/Thor_(film)*. BERT is originally trained with sentences. However, for entity linking, a larger context can help to disambiguate entity mentions, which is why we select text fragments of such a length, that they span multiple sentences. For later use we collect (m, e) tuples of entities e and their mention m. This yields a set M of potentially linkable strings and also lets us compute the conditional probability $p(e|m)$ based on the $\#(m, e)$ counts.

Handling incomplete annotation A challenge in using the Wikipedia links as annotation is that most entities do not have all their mentions annotated, i.e. often only the first appearance in an article is linked. We hypothesize that learning a classifier on such skewed data would yield a skewed model. Our approach to counter missing annotations is two-fold: (i) We only select text fragments that contain a minimum count of annotated Wikipedia links. (ii) To account for unlinked mentions in the fragments we use a Trie-based matcher[4] to annotate all occurrences of linkable strings that we collected in M. As entity links we annotate all possible entities this mention could link to but only with the conditional probability $p(e|m)$, with the goal that the model remembers a context independent entity prior. One issue is that due to the incomplete annotation, the $\#(e, m)$ counts yield $p(Nil|\text{"}\textit{United States}\text{"}) > 0$, i.e. the mention *"United States"* has a large non-zero probability to link to nothing. Based on the assumption that the mentions of the most popular entities should always link to something, we compute the average of the probability of linking to *Nil* for the $k = 1000$ most frequent entities

$$\bar{p}_{Nil} = \frac{1}{k} \sum_{j} \frac{\#(m_j, Nil)}{\#m_i}.$$

and use $\#(m_i, Nil) - \frac{\bar{p}_{Nil}}{(1-\bar{p}_{Nil})} * \#(m_i, e_*)$ to discount $\#(m_i, Nil)$ such that $p(Nil|\text{"}\textit{United States}\text{"}) \approx 0$, i.e. the model should always link "United States" and mentions of less frequent entities get an increase in probability to link to something.

4 Entity Linking Experiments

In the experiments we want to investigate how the simple neural end-to-end entity linking model BERT+Entity performs, i.e. if it learns something additional on-top of BERT. Additionally, we investigated if the entity-aware token-representations are useful for downstream tasks. We also discuss the main engineering challenges training with such a large entity vocabulary.

4.1 Data

Wikipedia We report two settings which differ in size of the entity vocabulary, size of the fragments and minimum number of entities per fragments. The first setting was the initial study, and the second one is a follow up study in which we changed settings that potentially could improve entity linking performance.

Setting I: We keep the $700K$ top most frequent entities from the $\approx$ $6M$ entities in Wikipedia, i.e. we chose the entity vocabulary as large as it was technically feasible with regards to memory and training speed. To put it into context, the CoNLL03/AIDA entity linking benchmark contains $23,5K$ entities in 1300 documents. We are missing 30 entities from CoNLL03/AIDA that only appear less than 10 times in the Wikipedia training data. We chunk the Wikipedia texts into fragments with a length of 110 tokens and an overlap of 20 tokens with the previous and following fragment. We only keep fragments that contain at least 1 infrequent linked entity or at least 3 frequent ones. This yields $8,8M$ training instances from which we take 1000 each for validation and testing.

Setting II: We keep the $500K$ top most frequent entities, which is comparable to the entity vocabulary of Kolitsas et al. (2018) and we have to add ≈ 1000 entities from CoNLL03/AIDA to the entity vocabulary to be able to evaluate our model on that benchmark. We increase the fragment size to 250 tokens and keep fragments that contain at least 1 linked entity but keep at most 500 fragments per entity. This yields $2,4M$ training instances from which we take 500 each for validation and testing.

[4]https://github.com/vi3k6i5/flashtext

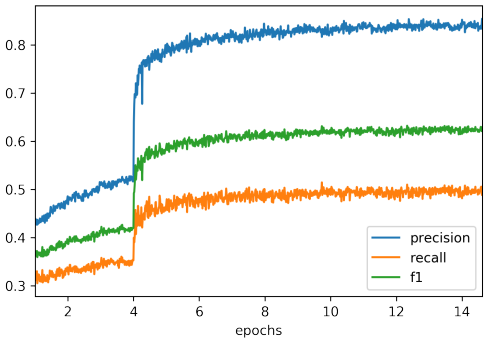

Figure 2: Per token classification InKB scores on the validation data during training on the Wikipedia dataset in Setting II for 40 days. The jump at the 4-th epoch happens when we switch from training Frozen-BERT+Entity to BERT+Entity, i.e. when we start fine-tuning BERT.

Entity Linking Benchmark To evaluate on a commonly used benchmark dataset we use CoNLL03/AIDA. It is the biggest manually annotated ED dataset. It contains 946 documents in training, 216 in validation (testa/AIDA-VALID) and 231 in test (testb/AIDA-TEST).

4.2 Training

We use a multi-class classification over the entity vocabulary, i.e. the label y vector for one token v_i is defined by

$$y_{ij} = p(j|v_i), \text{ for } j \in \{1, .., ||KB||\}.$$

However, computing the loss over the whole entity vocabulary would be infeasible, because the entity mention vocabulary is very large and the gradients for the entity classifier would exceed our GPU memory. Thus, to improve memory efficiency and increase convergence speed, we use negative sampling. After sampling text fragments for a batch b, we collected the set $N+_b$ of all true entities — according to the annotations discussed in Sec. 3.2 — that occurred in those text fragments. Ideally we would update the representations of those entities that do not occur in the set $N+_b$ which the model is erroneously the most confident about. To achieve this, we first performed a prediction for the text fragments in the current batch and collected for each token the top k predicted entities. We aggregated the entities' logits over the whole batch and sorted the entities by their aggregated logits into the list N_b- and removed from it any entity contained in N_b+. We join $N_b = N_b+ \cup N_b-$ and truncate N_b- such that $|N_b|$ equals a given maximum size. Each label vector y_i for token c_i from fragment C in batch b was now defined over the entities in N_b. Thus, we only predict over the corresponding subset of the entity embedding table, i.e. $\hat{E} = E(N_b)$. The loss for one fragment C in batch b was computed by

$$L = \frac{1}{|N_b| * |C|} \sum_{i}^{|C|} \sum_{j}^{|N_b|} -[y_{ij} \cdot \log \sigma(\hat{E}_j c_i) + (1 - y_{ij}) \cdot \log(1 - \sigma(\hat{E}_j c_i))].$$

For training on Wikipedia we used Adam (Kingma and Ba, 2015) with mini batch size 10, gradient accumulation over 4 batches, maximum label size 10240, the learning rate for BERT was $5e$-5 and for the entity classifier 0.01. In Setting I we train the model for 4 epochs, one epoch took five days with two TitanXp/1080Ti. In the first 1.5 epochs we train Frozen-BERT+Entity and then BERT+Entity. In Setting II we train the model for 14 epochs and one epoch took three days. In the first 3 epochs we train Frozen-BERT+Entity and then BERT+Entity.

For training on CoNLL03/AIDA we used Adam (Kingma and Ba, 2015) with mini batch size 10, gradient accumulation over 4 batches, maximum label size 1024, learning rates for BERT $5e$-5, dropout in BERT 0.2, and we freeze the token embeddings, the first two layers of BERT and the entity classifier. We train the remaining parameters for up to 30 epochs and perform early stopping according to strong match (see next Section). One epoch took seven minutes with one TITAN Xp/1080 Ti.

4.3 Performance Metrics

We compute the Micro InKB Precision, Recall and F1 metrics and we only consider entities as true, if they are in our KB. We compute a strong match, i.e. every token in the gold annotated span has to be classified correctly. We also report a weak match, which we define as at least one token in the gold annotated span having to link to the correct entity. This setting accounts for annotation inconsistencies, e.g. when the model and the annotation do not agree on which mention *"U.S. army"* or *"U.S."* to annotate (can be either way). We also report strong ED Precision@1, i.e. we ignore *Nil* predictions of the model and only evaluate the top ranked entity only for spans that have a gold entity.

		AIDA/testa			AIDA/testb		
		strong F1	weak F1	ED	strong F1	weak F1	ED
Kolitsas et al. (2018) indep. baseline		75.7	76.0	-	73.3	73.9	-
Kolitsas et al. (2018)		86.6	87.2	92.4	82.6	83.2	89.1
BERT		63.3	66.6	67.6	49.6	52.4	52.8
Setting I	Frozen-BERT+Entity	76.8	79.6	80.6	64.7	68.0	68.6
	BERT+Entity	82.8	84.4	86.6	74.8	76.5	78.8
Setting II	Frozen-BERT+Entity	76.5	80.1	79.6	67.8	71.9	67.8
	BERT+Entity	86.0	87.3	92.3	79.3	81.1	87.9

Table 1: Comparing entity linking results on CoNLL03/AIDA. *strong F1* and *weak F1* denote InKB F1 scores. *ED* is Precision@1 for InKB. Kolitsas et al. (2018) also study a neural model, however, they only model MD and ED. The independent baseline shows how their model performs when they use mentions detected by Stanford NLP. In Frozen-BERT+Entity BERT is not trained and only the entity classifier on-top is trained.

4.3.1 Results

In Table 1 we compare our results to the most recent results by Kolitsas et al. (2018) who studied a neural approach that does joint modelling of MD and ED, but not CG. They also provide a baseline in which they show how their classifier performs when MD and ED are independent, i.e. linking mentions detected by Stanford NLP.

For the reported results denoted only with BERT, the entity classifier is trained from scratch on CoNLL03/AIDA and BERT is finetuned. This shows the lower bound on this dataset, i.e. the amount of information that we can learn with BERT only from the CoNLL03/AIDA training data. Note, that this cannot generalize to entities that are not contained in training. The difference between BERT and Frozen-BERT+Entity shows the amount of entity knowledge that plain BERT already had, which it transferred in the entity classifier during training on Wikipedia. Finally, BERT+Entity is the proposed model, in which both BERT and the entity classifier have been trained on Wikipedia.

4.3.2 Discussion

Comparing BERT+Entity and Frozen-BERT+Entity we see that there is a significant amount of entity knowledge that BERT+Entity learns additionally to Frozen-BERT+Entity, i.e. training BERT+Entity increases the scores between 6%-10% depending on the score and dataset. However, it should also be noted that Frozen-BERT+Entity already shows an increase of 13%-16% over BERT, thus it already learns for many entities distinct features that enable the entity classifier to identify them. The improvement of Frozen-BERT+Entity in contrast to BERT on CoNLL03/AIDA shows that this pretraining generalizes to validation and test data. We can also observe that Setting II improves by a large margin over Setting I and comes very close to the results of Kolitsas et al. (2018). We conjecture that the biggest impact on the performance from changing the training from Setting I to Setting II, was due to the downsampling of the training data in favor of less frequent entities. This reduction of training data in Setting II — caused by capping the maximum amount of examples per entity — enabled us to run more epochs in less time, which might have improved the representations of less frequent entities.

Reason for error	#

RTE	accuracy	71.48	73.64
WNLI	accuracy	56.33	56.33
SQUAD V2	matched/mismatched	76.89/73.83	76.36/73.46
SWAG	accurracy	80.70	80.76
WMT14 EN-DE	BLEU	22.51	22.20

Table 3: Experiments on downstream tasks with BERT+Entity trained in Setting I. The first group are the GLUE tasks, then followed by SQUAD V2 and SWAG (for which only the dev set results are reported), and the results for machine translation WMT14 EN-DE.

When we compare BERT+Entity with the two results from Kolitsas et al. (2018), we observe that BERT+Entity improves over the baseline that models MD, CG and ED independently, and that BERT+Entity comes second to the current state-of-the-art in end-to-end entity linking. What can also be observed is that the performance of all models drops from AIDA/testa to AIDA/testb. For BERT+Entity, however, the drop is more severe, obviously the model overfits to some patterns in the training data that are present in the validation data, but not in the test data. We hypothesize that this might be due to some sport specific documents that make roughly $1/4$ of the dataset's mentions. However, without spoiling the test-set we cannot know for sure.

In Table 2 we performed an error analysis for the experiments for Setting I to learn what kind of strong precision errors are responsible for the performance of BERT+Entity. The largest source of errors was that BERT+Entity did predict *Nil* instead of an entity. We hypothesized that most of the *no prediction* errors are because those entities have only a low frequency in the training data, i.e. this could be solved by increasing the model size and improving the training time. Another source of error we observed was that the context size was too small due to the fragment size. A surprisingly positive result from the error analysis was that in only 3% a wrong span caused the error. Motivated by the observations we devised the follow-up experiment Setting II (see Section 4.1) in which we changed some of the settings to potentially solve the observed issues.

5 Downstream Tasks Experiments

In this section we discuss the downstream task results. We performed evaluations on the natural language understand task GLUE, the question answering tasks SQUAD V2 and SWAG and the machine translation benchmark EN-DE WMT14. We found that only in one of the subtasks of GLUE —the natural language inference tasks RTE— BERT+Entity performs better than BERT, for all other we can observe no such effect. The reported results are for Setting I, however, we repeated the experiments with Setting II and observed the same outcomes.

5.1 Model

For the tasks GLUE, SQUAD V2 and SWAG we extend hugginface's implementation[5] and concatenate the outputs of BERT and BERT+Entity (dubbed BERT+Entity-Ensemble) or two BERTs (dubbed BERT-BERT-Ensemble). For EN-DE WMT14 we use BERT (dubbed BERT-2Seq) or BERT+Entity (dubbed BERT+Entity-2Seq) as encoder and use a Transformer decoder by adapting fairseqs Pytorch Seq2Seq Transformer implementation (Ott et al., 2019).

[5]https://github.com/huggingface/pytorch-pretrained-BERT

5.2 Training

For the GLUE benchmark, SQUAD and SWAG we train the BERT+Entity-Ensemble and BERT-BERT-Ensemble for 3 epochs and use the default hyper-parameters from the implementation. The models BERT-2Seq and BERT+Entity-2Seq we train for 4 epochs, with Adam as optimizer and learning rate $5e$-5, max 1000 tokens per batch, clip gradient norm 0.1, dropout 0.2, label smoothing 0.1, and we keep the encoders BERT and BERT+Entity fixed for the first epoch and then train it together with the decoder.

5.3 Results

We find that the additional entity knowledge is not helpful in the evaluated tasks. The results in Table 3 show that, except for RTE, there seems to be no advantage in having additional entity knowledge. The question is, if this is (a) due to the entity overlap in training and testing such that also an entity unaware model can learn the necessary model, or (b) the entities are too scarce in the training data to make a difference, or (c) the tasks themselves do not require entity knowledge, i.e. other textual cues are enough. We leave those questions for future research.

6 Conclusion

In this study we investigated an extremely simplified approach to entity linking that worked surprisingly well and allowed us to investigate entity knowledge in BERT. Even when there is a gap to the current state-of-the-art in entity linking, we hypothesize that this gap can be closed with larger hardware capacity to scale up the model size and effective training time. Apart from that, the model is the first that performs entity linking without any pipeline or any heuristics, compared to all prior approaches. We found that with our approach we can learn additional entity knowledge in BERT that helps in entity linking. However, we also found that almost none of the downstream tasks really required entity knowledge, which is an interesting observation and an open question for future research.

jessy@austin.utexas.edu

Abstract

Implicit discourse relations are not only more challenging to classify, but also to annotate, than their explicit counterparts. We tackle situations where training data for implicit relations are lacking, and exploit domain adaptation from explicit relations (Ji et al., 2015). We present an unsupervised adversarial domain adaptive network equipped with a reconstruction component. Our system outperforms prior works and other adversarial benchmarks for unsupervised domain adaptation. Additionally, we extend our system to take advantage of labeled data if some are available.

1 Introduction

Discourse relations capture the relationship between units of text—e.g., sentences and clauses—and are an important aspect of text coherence. While some relations are expressed explicitly with a discourse connective (e.g., "for example", "however"), relations are equally often expressed implicitly without an explicit connective (Prasad et al., 2008); in these cases, the relation needs to be inferred.

Resources for implicit discourse relations are scarce compared to the explicit ones, since they are harder to annotate (Miltsakaki et al., 2004). For example, among corpora annotated with discourse relations such as Arabic (Al-Saif and Markert, 2010), Czech (Poláková et al., 2013), Chinese (Zhou and Xue, 2015), English (Prasad et al., 2008), Hindi (Oza et al., 2009), and Turkish (Zeyrek et al., 2013), only the Chinese, English and Hindi corpora include implicit discourse relations (Prasad et al., 2014). In this low-resource scenario, Ji et al. (2015) proposed training with explicit relations via unsupervised domain adaptation, viewing explicit relations as a source domain with labeled training data, and implicit relations as a target domain with no labeled data. The domain gap between explicit and implicit relations is acknowledged by prior observations that the two types of discourse relations are linguistically dissimilar (Sporleder and Lascarides, 2008; Rutherford and Xue, 2015).

We present a new system for the unsupervised domain adaptation setup on the Penn Discourse Treebank (Prasad et al., 2008). Our system is based on Adversarial Discriminative Domain Adaptation (Tzeng et al., 2017), which decouples source domain training and representation mapping between source and target. We improve this framework by proposing a reconstruction component to preserve the discriminability of target features, and incorporating techniques for stabler training on textual data.

Experimental results show that even with a simple architecture for representation learning, our unsupervised domain adaptation system outperforms prior work by 1.4-2.3 macro F1, with substantial improvements on Temporal and Contingency relations. It is also superior to DANN (Ganin et al., 2016), an adversarial framework widely used in NLP (Chen et al., 2018; Gui et al., 2017; Zhang et al., 2017; Fu et al., 2017; Joty et al., 2017; Xu and Yang, 2017), by 5.7 macro F1.

Finally, we extend the system to incorporate in-domain supervision as it is sometimes feasible resource-wise to build a seed corpus that may not be large enough to train a fully supervised system. We simulate this scenario by enabling the system to jointly optimize over a varying number of labeled examples of implicit relations. Our system consistently outperforms two strong baselines.

2 Related Work

Sporleder and Lascarides (2008) and Rutherford

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 686–695
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

and Xue (2015) observed that explicit and implicit relations are linguistically dissimilar, warranting an unsupervised domain adaptation approach in Ji et al. (2015). They used a marginalized denoising autoencoder to obtain generalized feature representations across the source and target domains with a linear SVM as the classification model. Our system improves upon this work using an adversarial network; we further generalize our network to semi-supervised settings.

To supplement the training data of implicit discourse relations, prior works have used weak supervision from sentences with discourse connectives (Marcu and Echihabi, 2002; Sporleder and Lascarides, 2008; Braud and Denis, 2014; Ji et al., 2015), by analyzing connectives (Zhou et al., 2010a,b; Biran and McKeown, 2013; Rutherford and Xue, 2015; Braud and Denis, 2016; Wu et al., 2017), using a multi-task framework with other corpora (Lan et al., 2013; Liu et al., 2016; Lan et al., 2017), or utilizing cross-lingual data (Wu et al., 2016; Shi et al., 2017). The important distinction between this work and the research above is that these are supervised systems that used all of the annotated *implicit* annotation from PDTB during training, while exploring non-PDTB corpora for additional, noisy discourse cues; on the contrary, our main goal is to assume no labeled training data for implicit discourse relations.

Unsupervised domain adaptation with adversarial networks has become popular in recent years; this type of approach generates a representation for the target domain with the goal that the discriminator unable to distinguish between the source and target domains. Prior works proposed both generative approaches (Liu and Tuzel, 2016; Bousmalis et al., 2017; Sankaranarayanan et al., 2018; Russo et al., 2018) and discriminative approaches (Ganin et al., 2016; Tzeng et al., 2015, 2017). The discriminative DANN algorithm from Ganin et al. (2016) is frequently used in NLP tasks (Chen et al., 2018; Gui et al., 2017; Zhang et al., 2017; Fu et al., 2017; Joty et al., 2017; Xu and Yang, 2017). Our method builds upon Adversarial Discriminative Domain Adaptation (Tzeng et al., 2017), shown to outperform DANN in visual domain adaptation but has not been used in NLP tasks. The key differences between the two are discussed in Section 3.

Qin et al. (2017) adopted adversarial strategies to supervised implicit discourse classification. They train an adversarial model using implicit discourse relations with and without expert-inserted connectives. Note again that theirs is a fully supervised system using signals in addition to the implicit relation annotations themselves, while our main focus is unsupervised domain adaptation that does not train on implicit relations.

3 Model Architecture

To classify discourse relations, our system takes a pair of sentence arguments x as input, and outputs the discourse relation y between these two arguments. With unsupervised domain adaptation, we have examples (X_s, Y_s) from the source domain, i.e., explicit discourse relations, and unlabeled examples (X_t) from a target domain, i.e., implicit discourse relations.

We use ADDA (Tzeng et al., 2017) as our underlying framework for domain adaptation. ADDA first learns a discriminative representation for the classification task in the source domain, then learns a representation for the target domain that mimics the distribution of the source domain. The key insight here is asymmetric mapping, where the target representation is "updated" until it matches with the source, a process more similar to the original Generative Adversaial Networks (Goodfellow et al., 2014) than joint training as in DANN (Ganin et al., 2016). Intuitively, since ADDA learns distinct feature encoders for the source and target domains instead of using a shared encoder, the same network doesn't have to handle instances from different domains.

Summarized in Figure 1, we first pre-train a source encoder M_s and source classifier C (Section 3.1), then train the target encoder M_t (initialized with M_s) and discriminator D in an adversarial way, to minimize the domain discrepancy distance between the target representation distribution $M_t(X_t)$ and that of the source $M_s(X_s)$ (Section 3.2). Eventually, the target feature space is trained to match the source, and the source classifier C can be directly used on the target domain.

3.1 Base encoder and classifier

The source and target **encoders** M_s and M_t follow the same architecture; M_t is initialized to be M_s during adaptation. The encoders encode relation arguments into latent representations, and then feeds the representations into a **classifier** C to predict the discourse relation.

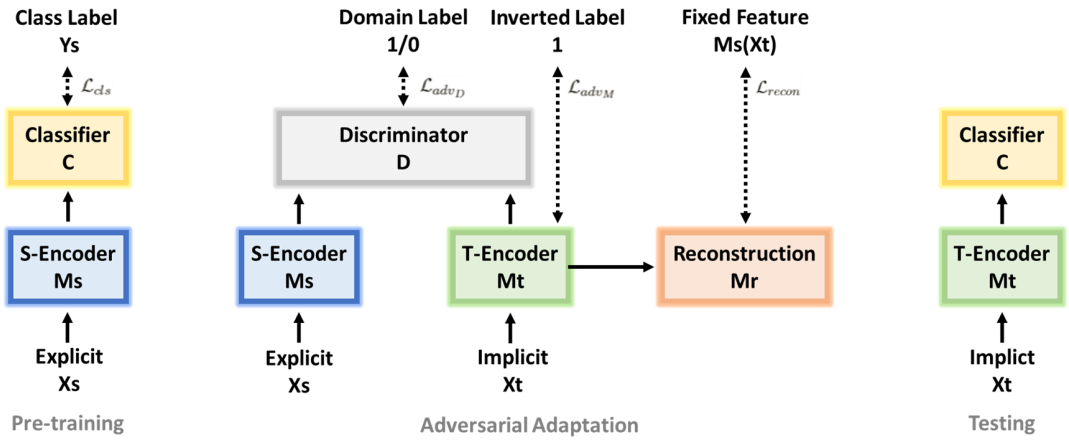

Figure 1: The framework of our proposed adversarial domain adaptation model, containing the pre-training stage, the adversarial adaptation stage, and the testing stage. The dashed box shows the supervised component.

Encoder The encoder generates a representation for each argument with an inner-attention Bidirectional LSTM (Yang et al., 2016) shared between the two arguments. Then, the representations of the two arguments are concatenated to form the final representation, shown in Figure 2.

Specifically, we encode each word in an argument into its word embeddings, which are fed into a BiLSTM, to get the hidden representations z_i using a fully-connected layer W_c on top of the concatenated hidden states $h_i = [\overrightarrow{h_i}, \overleftarrow{h_i}]$. We then apply an attention mechanism to induce a distribution of weights over all tokens in the argument; the final argument representation Arg is a weighted sum of z_i based on the attention weights α_i:

$$
\begin{aligned}
z_i &= W_c h_i + b_c \\
u_i &= tanh(W_w h_i + b_w) \\
\alpha_i &= \frac{exp(u_i^T u_w)}{\sum_i exp(u_i^T u_w)} \\
Arg &= \sum_i \alpha_i z_i
\end{aligned} \tag{1}
$$

Where W_c, b_c, W_w, b_w, u_w are model parameters.

Classifier The classifier consists of a single fully-connected layer on top of the encoder, finished with a softmax classification layer.

The source encoder M_s and the classifier C are trained using a supervised loss:

$$
\begin{aligned}
&\min_{M_s, C} \mathcal{L}_{cls}(X_s, Y_s) = \\
&\mathbb{E}_{(x_s, y_s)} - \sum_k \mathbb{1}[k = y_s] \log C(M_s(x_s))
\end{aligned} \tag{2}
$$

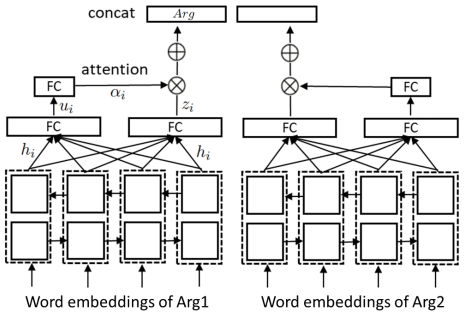

Figure 2: Neural structure of inner-attention BiLSTM to encode relation argument pairs.

3.2 Unsupervised adversarial domain adaptation

We then learn a target encoder M_t to generate features for the target data which can be classified with classifier C, without assuming labels Y_t in the target domain. This is achieved by training a domain discriminator D, which classifies whether a feature is from the source or the target domain, and the target encoder M_t, that produces features similar to the source domain features and tries to fool the discriminator to predict the incorrect domain label.

The discriminator D is optimized according to a standard supervised loss:

$$
\begin{aligned}
&\min_D \mathcal{L}_{adv_D}(X_s, X_t, M_s, M_t) = \\
&\quad - \mathbb{E}_{x_s}[\log D(M_s(x_s))] \\
&\quad - \mathbb{E}_{x_t}[\log (1 - D(M_t(x_t)))]
\end{aligned} \tag{3}
$$

D consists of two fully-connected layers on top of the encoder, finished with a softmax classification layer.

The target encoder M_t is optimized according to a standard GAN loss with inverted labels:

$$\min_{M_t} \mathcal{L}_{adv_M}(X_s, X_t, D) = -\mathbb{E}_{x_t}[\log D(M_t(x_t))] \quad (4)$$

Spectral normalization To stabilize the training of the discriminator, we employ spectral normalization, a weight normalization technique (Miyato et al., 2018), which controls the Lipschitz constant of the discriminator function by constraining the spectral norm of each layer. Spectral normalization is easy to implement without tuning any hyper-parameters and has a small additional computational cost.

Label smoothing We utilize label smoothing (Szegedy et al., 2016) to regularize the classifier during pre-training, which prevents the largest logit from becoming much larger than all others, and therefore prevents overfitting and makes the classifier, trained in the source domain, more adaptable.

For a source domain training example x_s with ground-truth label y_s and ground-truth distribution $q(k|x_s)$, the classifier computes the classification probability over relation classes as $p(k|x_s)$ for $k \in \{1...K\}$. With label smoothing, we replace the ground-truth label distribution $q(k|x_s)$ in the standard cross-entropy loss as a linear combination of $q(k|x_s)$ and a uniform distribution over classes $u(k) = 1/K$.

$$\min_{M_s,C} \mathcal{L}_{cls}(X_s, Y_s) = -\sum_k q'(k) \log\left(p(k)\right)$$
$$q'(k|x_s) = (1-\epsilon)\mathbb{1}[k = y_s] + \epsilon/K \quad (5)$$

Reconstruction loss In order to classify the target representations using the source classifier, the target encoder is trained to produce representations that mimic the source domain representations in the adversarial training stage. Since there is no supervised loss applied in this stage, the target encoder may lose its ability to produce discriminative features that are helpful during classification. We propose a reconstruction loss to preserve the discriminability of the target encoder when adversarially adapting its features.

Since we initialize the target encoder with the source encoder, the initial representation (before domain adaptation) of a target instance x_t is the representation of *target* instances produced by the *source* encoder $M_s(x_t)$ (which is then fixed). After training, $M_t(x_t)$ adapts to the source domain and becomes dissimilar to $M_s(x_t)$. The reconstruction loss encourages the target encoder to produce features that can be reconstructed back to $M_s(x_t)$ (Figure 3).

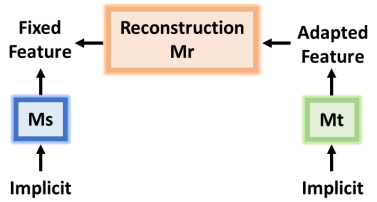

Figure 3: The reconstruction loss component augmenting our unsupervised adversarial domain adaptor.

For a target example x_t, we learn a reconstruction mapping M_r that maps the target representation $M_t(x_t)$ to $M_s(x_t)$:

$$x_t \rightarrow M_t(x_t) \rightarrow M_r(M_t(x_t)) \approx M_s(x_t) \quad (6)$$

The target encoder M_t and the reconstruction mapping M_r are optimized jointly with a reconstruction loss:

$$\min_{M_t,M_r} \mathcal{L}_{recon}(X_t, M_s) = \mathbb{E}_{x_t}[||M_r(M_t(x_t)) - M_s(x_t)||_2^2] \quad (7)$$

M_r consists of three fully-connected layers on top of the encoder.

Unsupervised objective For unsupervised domain adaptation, our full objective is:

$$\begin{aligned}\mathcal{L}^{unsup}(X_s, Y_s, X_t, M_s, M_t, D) = & \\ \min_{M_s,C} \mathcal{L}_{cls}(X_s, Y_s) + & \\ \min_{D} \mathcal{L}_{adv_D}(X_s, X_t, M_s, M_t) + & \\ \min_{M_t} \mathcal{L}_{adv_M}(X_s, X_t, D) + & \\ \min_{M_t,M_r} \mathcal{L}_{recon}(X_t, M_s) & \quad (8)\end{aligned}$$

3.3 Training

Summarized in Algorithm 1, the training procedure consists of three stages: pre-training, adversarial adaptation, and testing. During pre-training, we train the source encoder M_s and the classifier C according to Eq.(2). In the adversarial adaptation stage, we alternately train the discriminator D, target encoder M_t, and reconstruction mapping

Algorithm 1: Adversarial Adaptation

Input: explicit sentences with labels $\{x_s, y_s\}$
implicit sentences without labels $\{x_t\}$
Notations: source encoder M_s, classifier C,
target encoder M_t,
reconstruction mapping M_r,
domain discriminator D

1 Train M_s, C through Eq.(2) with $\{x_s, y_s\}$;
2 Initialize M_t as M_s;
3 **Repeat**
4 Train D through Eq.(3) with $\{x_s, x_t\}$ and train M_t through Eq.(4) with $\{x_t\}$;
5 Train M_t, M_r through Eq.(7) with $\{x_t\}$;
Output: M_t and C for relation prediction

M_r according to Eq.(3), Eq.(4), Eq.(7). Finally, we test the model using the target encoder M_t and classifier C. The steps (lines 4 and 5) in the Repeat loop execute once in one iteration, and we optimized the model in two-step units.

4 Unsupervised Domain Adaptation Experiments

We first evaluate our model for the default task: unsupervised domain adaptation from explicit discourse relations to implicit discourse relations.

4.1 Settings

Data We train and test our model on the PDTB, following the experimental setup of Ji et al. (2015). The test examples are implicit relation instances from PDTB sections 21-22. The explicit training set consists of explicit examples from sections 02-20 and 23-24, and the explicit development set consists of the explicit examples from sections 00-01. The implicit training set and the implicit development set consist of examples from the same sections as the explicit sets. Evaluation is done for the first-level relations—Temporal, Comparison, Contingency, and Expansion. Table 1 summarizes the statistics of the four top-level implicit and explicit discourse relations in the PDTB.

Training Details We early-stopped training for both stages before total convergence if the macro F1 on the development set does not improve. During pre-training (Line 1 in Algorithm 1), we train and validate the model on the explicit training and development set. Early stopping happened after around 20 epochs. During adversarial adaptation (lines 4 and 5 in Algorithm 1), we train the model on the explicit and implicit training sets *without relation labels* Y_t, and validate on the implicit development set[1]. Early stopping happened after around 5 epochs (with lines 4 and 5 executed once in each epoch).

	Explicit		Implicit		
Relation	Train	Dev	Train	Dev	Test
Temporal	2904	288	704	68	54
Contingency	2792	181	3622	276	287
Comparison	4674	366	2104	146	191
Expansion	5342	450	7394	556	651

Table 1: The number of examples of the four top level discourse relations in PDTB 2.0.

Model configuration The hyperparameters, as well as the number of fully connected layers for the classifier C, discriminator D and the reconstruction mapping M_r, are all set according to the performance on the development sets. We first set the hyper-parameters of the encoders M_s, M_t and classifier C based on development performance during the pre-training stage. Then, we set the hyper-parameters of D and M_r based on development performance of the adaptation stage.

We use GloVe (Pennington et al., 2014) for word embeddings with dimension 300. The maximum argument length is set to 80. The encoder contains an inner-attention BiLSTM with dimension 50, producing a representation with dimension 200 for each example. The discriminator D consists of 2 hidden layers with 200 and 200 neurons on each layer. The reconstruction mapping M_r contains 3 hidden layers with 120, 15 and 120 neurons on each layer. The label smoothing parameter ϵ is 0.1. We use Adam (Kingma and Ba, 2015) with learning rate 1e-4 for the base encoder and classifier, and 1e-6 for the adversarial domain adapter. We use SGD optimizer with learning rate 1e-2 for the reconstruction component. All the models were implemented using PyTorch (Paszke et al., 2017) and adapted from Conneau et al. (2017).

4.2 Systems

We experiment with three settings:

Implicit → Implicit A supervised implicit discourse relation classifier using the base encoder and classifier, optimizing the standard cross-entropy loss, using the full implicit training and

[1]Using a development set in the target domain is common in unsupervised domain adaptation (Ganin et al., 2016; Liu and Tuzel, 2016; Tzeng et al., 2017; Bousmalis et al., 2017; Russo et al., 2018)

	Temporal	Contingency	Comparison	Expansion	Macro F_1
Implicit → Implicit	25.53	41.02	30.35	65.38	40.57
Explicit → Implicit	22.22	22.35	23.06	57.86	31.37
+Domain Adaptation	30.62	42.71	25.00	52.23	37.64
+Spectral Normalization	30.20	45.42	21.90	58.72	39.06
+Label Smoothing	**31.58**	46.40	24.64	58.03	40.16
+Reconstruction	31.25	**48.04**	25.15	59.15	**40.90**
(Ji et al., 2015)	19.26	41.39	25.74	68.08	38.62
+weak supervision	20.35	42.25	**26.32**	**68.92**	39.46
DANN	26.19	34.20	25.74	54.70	35.21

Table 2: Per-class and macro average F1 (%) of unsupervised domain adaptation from explicit to implicit relations.

development sets. This model does not use the explicit relations.

Explicit → Implicit A discourse relation classifier using the explicit training set and implicit development set, optimizing the standard cross-entropy loss. This serves as a baseline without any domain adaptation.

Domain adaptation Our full adaptation model trained on the explicit training set, and adapted to the implicit training set without relation labels. We perform ablation study with different extensions describe in Section 3: spectral normalization, label smoothing, and reconstruction loss.

For *benchmarking*, we train an unsupervised domain adaptation system using **DANN** (Ganin et al., 2016), which jointly learns domain-invariant representations and the classifier and is often used in NLP (c.f. Section 2). We use the same encoder, classifier and discriminator structures, with parameters tuned on the implicit development data. The system is optimized using Adam with learning rate 2e-4 and the adaptation parameter 0.25, chosen between 0.01 and 1 on a logarithmic scale.

4.3 Results

To evaluate our model, we train four-way classifiers and report **per-class and macro F1 scores**. Table 2 tabulates the experimental results for unsupervised domain adaptation.

We also show reported results from Ji et al. (2015). Even though they trained four binary classifiers (instead of doing multi-class classification), it is the only prior work exploring unsupervised domain adaptation for implicit discourse relation classification. We include two settings: their best system with labeled data from PDTB explicit relations only (and an implicit development set), and their system with additional weak supervision from non-PDTB sources.[2]

Our full system achieves the best average F1 measure, a 9.53% absolute increase from Explicit → Implicit. It also performs 2.28% better than Ji et al. (2015)'s model trained without weak supervision, and 1.44% better than their model trained with weak supervision. The full system achieved an average F1 comparable to the supervised Implicit → Implicit, while Ji et al. (2015)'s models did not. Comparing with DANN, our system achieved superior performance for 3 of the 4 relations, showing that training target representations and the classifier in two stages outperforms doing both jointly.

The largest improvements from the Explicit → Implicit baseline are from Temporal (from 22.22 to 31.25) and Contingency (from 22.35 to 48.04) relations. Our system performs ∼11% better for Temporal, and ∼6% better for Contingency, than Ji et al. (2015)'s binary classifiers. The Comparison and Expansion relations improved by about 2% from the baseline, a smaller improvement compared to the other two relations. Our Comparison performance is comparable with Ji et al. (2015)'s model without weak supervision.

Notably, the performance for Expansion dropped after domain adaptation (without extensions) by about 5%. We suspect that this is because the distributions of Expansion among other relations are very different (33% for explicit and 53% for implicit, c.f. Table 1). By applying Spectral Normalization, the performance improved and surpassed Explicit → Implicit.

Component-wise, Spectral Normalization helps two of the four relations (Contingency and Expansion), but hurts the performance of Comparison.

[2]The weakly labeled data includes sentences extracted from 1000 CNN articles, with explicit discourse connectives but without annotated discourse relations.

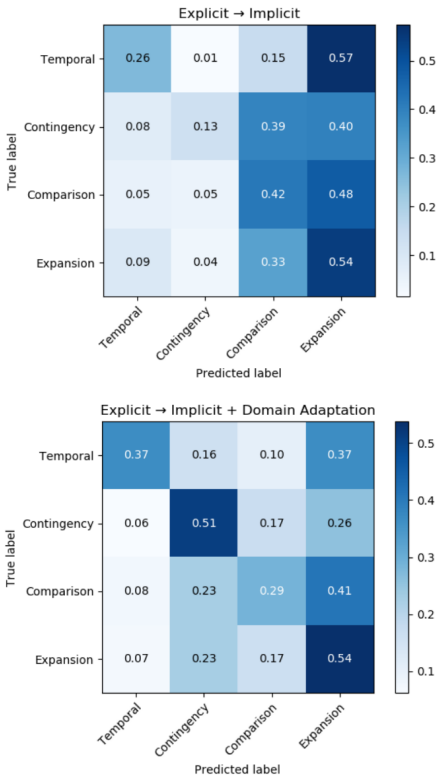

Figure 4: Normalized confusion matrices before and after unsupervised domain adaptation.

Label smoothing improves performance for all relations except Expansion; applying the reconstruction loss improves performance for all relations except Temporal. Overall, the best result on this task is to incorporate all components.

Error analysis Figure 4 shows the normalized confusion matrices before and after unsupervised domain adaptation. Before adaptation, Temporal and Contingency relations are often misclassified as Expansion, which is substantially improved after adaptation. The improvement in F score for Comparison is milder due to lower precision and higher recall, which is also reflected in the matrices. Finally, the drop of performance in Expansion adaptation can be traced through increased confusion between Expansion and Contingency.

5 How about a little supervision?

We have so far presented an unsupervised domain adaptation system that is not trained on any labels Y_t in the target domain. However, it is sometimes feasible to have some seed annotation that can be used to improve prediction. Hence we extend the model with an optional supervised component. We evaluate this extension by gradually adding labeled examples of implicit discourse relations, simulating situations when different numbers of labeled examples are available.

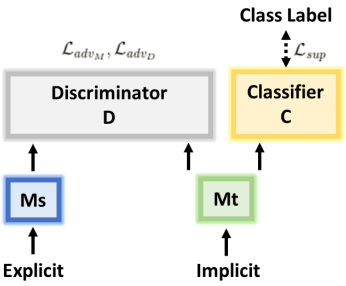

Figure 5: An extension component to incorporate supervision with our unsupervised adversarial domain adaptor.

5.1 Incorporating supervision

We extend the model with a supervised component, where a subset $X_t^L \subseteq X_t$ has labels Y_t^L. Illustrated in Figure 5, we jointly optimize the target encoder M_t and the classifier C according to an additional supervised loss:

$$\min_{M_t,C} \mathcal{L}_{sup}(X_t^L, Y_t^L) = \mathbb{E}_{(x_t^L, y_t^L)} - \sum_k \mathbb{1}[k = y_t^L] \log C(M_t(x_t^L)) \quad (9)$$

Effectively, we encourage the target encoder to jointly extract more discriminative features for all target examples (X_t), and learning target domain representations close to the source.

The full objective incorporates supervision of the in-domain labels by adding $\mathcal{L}_{sup}(X_t^L, Y_t^L)$ to the unsupervised objective:

$$\mathcal{L}^{sup}(X_s, Y_s, X_t, M_s, M_t, D) = \mathcal{L}^{unsup}(X_s, Y_s, X_t, M_s, M_t, D) + \min_{M_t,C} \mathcal{L}_{sup}(X_t^L, Y_t^L) \quad (10)$$

5.2 Data and settings

We synthesize the labeled target subset (X_t^L, Y_t^L) $(X_t^L \subseteq X_t)$ by randomly extracting subsets from the implicit training set and get their labels. The sizes of this subset range from 1382 to 13824 with a stepsize of 1382. Note that we use the entire implicit training set (X_t without relation labels Y_t) in the adversarial adaptation process as unlabeled data in the target domain, and the sampled labeled data is used in the supervised component only.

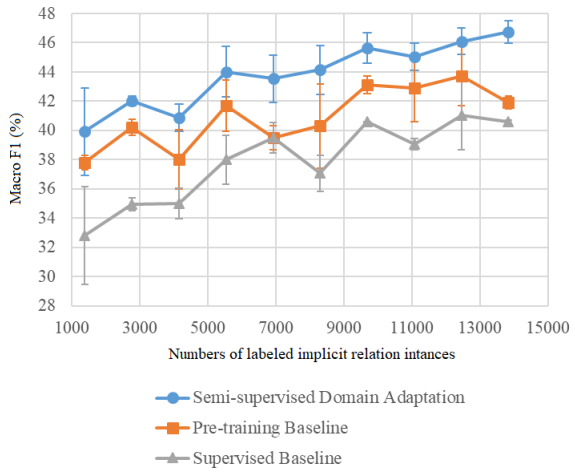

Figure 6: The average F1 (%) with varying numbers of labeled implicit relation training data.

We use the same hyper-parameters as the unsupervised experiment, except that we tune the learning rate on the implicit development set.

5.3 Systems

We compare three settings:

Supervised baseline The encoder and classifier trained on the sampled implicit instances (X_t^L, Y_t^L), optimizing Eq.(9).

Pre-training baseline Our model with the supervised component, but without the domain adaptation component. This setting is equivalent to pre-training on the explicit instances then fine-tuning on the sampled implicit instances. This is trained on the explicit training set (X_s, Y_s), plus the sampled implicit instances (X_t^L, Y_t^L), optimizing Eq.(5) and Eq.(9).

Semi-supervised domain adaptation Our full model with both the supervised and adaptation components, optimizing Eq.(10). The supervised component uses the sampled implicit instances (X_t^L, Y_t^L) for training.

5.4 Results

Since the added training data is randomly sampled, we average the performance across 3 different runs. Figure 6 shows the average F1 measure (y-axis) of the above three supervised systems, with varying numbers of labeled implicit relation training data (x-axis). Standard errors are also shown in the graph.

Our full system outperforms both the supervised baseline and the pre-training baseline, regardless of the amount of labeled target data. This evaluation also reveals that the pre-training baseline also improves upon the supervised baseline across the board, which means that the performance of implicit relation classification can be improved with pre-training on explicit relations.

Finally, the macro F1 of our system using full supervision is 47.50. Since we focus on domain adaptation and used very simple encoders, we do not attempt to achieve state-of-the-art (e.g., Dai and Huang (2018), Bai and Zhao (2018)). However this performance is on-par with many recent work using multi-task or GANs, including Lan et al. (2017) (47.80), Qin et al. (2017) (44.38, Reproduced results on four-way classification), and Liu et al. (2016) (44.98). These results confirm that our framework generalizes well with respect to the amount of supervision in the target domain.

6 Conclusion

Our work tackles implicit discourse relation classification in a low resource setting that is flexible to the amount of supervision. We present a new system based on the adversarial discriminative domain adaptation framework (Tzeng et al., 2017) for unsupervised domain adaptation from explicit discourse relation to implicit discourse relation. We propose a reconstruction loss to preserve the discriminability of features during adaptation, and we generalize the framework to make use of possibly available seed data by jointly optimizing it with a supervised loss. Our system outperforms prior work and strong adversarial baselines on unsupervised domain adaptation, and works effectively with varying amount of supervision.

Abstract

Remarkable success has been achieved in the last few years on some limited machine reading comprehension (MRC) tasks. However, it is still difficult to interpret the predictions of existing MRC models. In this paper, we focus on extracting evidence sentences that can explain or support the answers of multiple-choice MRC tasks, where the majority of answer options cannot be directly extracted from reference documents.

Due to the lack of ground truth evidence sentence labels in most cases, we apply distant supervision to generate imperfect labels and then use them to train an evidence sentence extractor. To denoise the noisy labels, we apply a recently proposed deep probabilistic logic learning framework to incorporate both sentence-level and cross-sentence linguistic indicators for indirect supervision. We feed the extracted evidence sentences into existing MRC models and evaluate the end-to-end performance on three challenging multiple-choice MRC datasets: MultiRC, RACE, and DREAM, achieving comparable or better performance than the same models that take as input the full reference document. To the best of our knowledge, this is the first work extracting evidence sentences for multiple-choice MRC.

1 Introduction

Recently, there have been increased interests in machine reading comprehension (MRC). In this work, we mainly focus on multiple-choice MRC (Richardson et al., 2013; Mostafazadeh et al., 2016; Ostermann et al., 2018): given a document and a question, the task aims to select the correct answer option(s) from a small number of answer options associated with this question. Compared to extractive and abstractive MRC tasks (e.g., (Rajpurkar et al., 2016; Kočiskỳ et al., 2018; Reddy et al., 2019)) where most questions can be answered using spans from the reference documents, the majority of answer options cannot be directly extracted from the given texts.

Existing multiple-choice MRC models (Wang et al., 2018b; Radford et al., 2018) take as input the entire reference document and seldom offer any explanation, making interpreting their predictions extremely difficult. It is a natural choice for human readers to use sentences from a given text to explain why they select a certain answer option in reading tests (Bax, 2013). In this paper, as a preliminary attempt, we focus on exacting ***evidence sentences*** that entail or support a question-answer pair from the given reference document.

For extractive MRC tasks, information retrieval techniques can be very strong baselines to extract sentences that contain questions and their answers when questions provide sufficient information, and most questions are factoid and answerable from the content of a single sentence (Lin et al., 2018; Min et al., 2018). However, we face unique challenges to extract evidence sentences for multiple-choice MRC tasks. The correct answer options of a significant number of questions (e.g., 87% questions in RACE (Lai et al., 2017; Sun et al., 2019)) are not extractive, which may require advanced reading skills such as inference over multiple sentences and utilization of prior knowledge (Lai et al., 2017; Khashabi et al., 2018; Ostermann et al., 2018). Besides, the existence of misleading wrong answer options also dramatically increases the difficulty of evidence sentence extraction, especially when a question provides insufficient information. For example, in Figure 1, given the reference document and question *"Which of the following statements is true according to the passage?"*, almost all the tokens in

* This work was done when H. W. and K. S. were at Tencent AI Lab, Bellevue, WA.

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 696–707
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

the wrong answer option B *"In 1782, Harvard began to teach German."* appear in the document (i.e., sentence S_9 and S_{11}) while the question gives little useful information for locating answers. Furthermore, we notice that even humans sometimes have difficulty in finding pieces of evidence when the relationship between a question and its correct answer option is implicitly indicated in the document (e.g., *"What is the main idea of this passage?"*). Considering these challenges, we argue that extracting evidence sentences for multiple-choice MRC is at least as difficult as that for extractive MRC or factoid question answering.

Given a question, its associated answer options, and a reference document, we propose a method to extract sentences that can potentially support or explain the (question, correct answer option) pair from the reference document. Due to the lack of ground truth evidence sentences in most multiple-choice MRC tasks, inspired by distant supervision, we first extract *silver standard* evidence sentences based on the lexical features of a question and its correct answer option (Section 2.2), then we use these noisy labels to train an evidence sentence extractor (Section 2.1). To denoise imperfect labels, we also manually design sentence-level and cross-sentence linguistic indicators such as *"adjacent sentences tend to have the same label"* and accommodate all the linguistic indicators with a recently proposed deep probabilistic logic learning framework (Wang and Poon, 2018) for indirect supervision (Section 2.3).

Previous extractive MRC and question answering studies (Min et al., 2018; Lin et al., 2018) indicate that a model should be able to achieve comparable end-to-end performance if it can accurately predict the evidence sentence(s). Inspired by the observation, to indirectly evaluate the quality of the extracted evidence sentences, we only keep the selected sentences as the new reference document for each instance and evaluate the performance of a machine reader (Wang et al., 2018b; Radford et al., 2018) on three challenging multiple-choice MRC datasets: MultiRC (Khashabi et al., 2018), RACE (Lai et al., 2017), and DREAM (Sun et al., 2019). Experimental results show that we can achieve comparable or better performance than the same reader that considers the full context. The comparison between ground truth evidence sentences and automatically selected sentences indicates that there is still room for improvement.

Our primary contributions are as follows: 1) to the best of our knowledge, this is the first work to extract evidence sentences for multiple-choice MRC; 2) we show that it may be a promising direction to leverage various sources of linguistic knowledge for denoising noisy evidence sentence labels. We hope our attempts and observations can encourage the research community to develop more explainable MRC models that simultaneously provide predictions and textual evidence.

2 Method

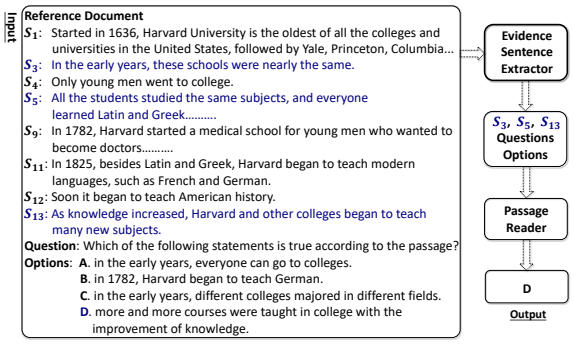

Figure 1: An overview of our pipeline. The input instance comes from RACE (Lai et al., 2017).

We will present our evidence sentence extractor (Section 2.1) trained on the noisy training data generated by distant supervision (Section 2.2) and denoised by an existing deep probabilistic logic framework that incorporates different kinds of linguistic indicators (Section 2.3). The extractor is followed by an independent neural reader for evaluation. See an overview in Figure 1.

2.1 Evidence Sentence Extractor

We use a multi-layer multi-head transformer (Vaswani et al., 2017) to extract evidence sentences. Let W_w and W_p be the word (subword) and position embeddings, respectively. Let M denote the total number of layers in the transformer. Then, the m-th layer hidden state h^m of a token is given by:

$$h^m = \begin{cases} W_w + W_p & \text{if } m = 0 \\ \text{TB}(h^{m-1}) & \text{if } 1 \leq m \leq M \end{cases} \quad (1)$$

where TB stands for the Transformer Block, which is a standard module that contains MLP, residual connections (He et al., 2016) and LayerNorm (Ba et al., 2016).

Compared to classical transformers, pre-trained transformers such as GPT (Radford et al., 2018)

and BERT (Devlin et al., 2018) capture rich world and linguistic knowledge from large-scale external corpora, and significant improvements are obtained by fine-tuning these pre-trained models on a variety of downstream tasks. We follow this promising direction by fine-tuning GPT (Radford et al., 2018) on a target task. Note that the pre-trained transformer in our pipeline can also be easily replaced with other pre-trained models, which however is not the focus of this paper.

We use (X, Y) to denote all training data, (X_i, Y_i) to denote each instance, where X_i is a token sequence, namely, $X_i = \{X_i^1, \ldots, X_i^t\}$ where t equals to the sequence length. For evidence sentence extraction, X_i contains one sentence in a document, a question, and all answer options associated with the question. Y_i indicates the probability that sentence in X_i is selected as an evidence sentence for this question, and $\sum_{i=1}^{N} Y_i = 1$, where N equals to the total number of sentences in a document. GPT takes as input X_i and produces the final hidden state h_i^M of the last token in X_i, which is further fed into a linear layer followed by a softmax layer to generate the probability:

$$P_i = \frac{\exp(W_y h_i^M)}{\sum_{1 \le i \le N} \exp(W_y h_i^M)} \quad (2)$$

where W_y is weight matrix of the output layer. We use Kullback-Leibler divergence loss $\mathrm{KL}(Y||P)$ as the training criterion.

We first apply distant supervision to generate noisy evidence sentence labels (Section 2.2). To denoise the labels, during the training stage, we use deep probabilistic logic learning (DPL) – a general framework for combining indirect supervision strategies by composing probabilistic logic with deep learning (Wang and Poon, 2018). Here we consider both sentence-level and cross-sentence linguistic indicators as indirect supervision strategies (Section 2.3).

As shown in Figure 2, during training, our evidence sentence extractor contains two components: a probabilistic graph containing various sources of indirect supervision used as a supervision module and a fine-tuned GPT used as a prediction module. The two components are connected via a set of latent variables indicating whether each sentence is an evidence sentence or not. We update the model by alternatively optimizing GPT and the probabilistic graph so that they reach an agreement on latent variables. After training, only the fine-tuned GPT is kept to make predictions for a new instance during testing. We provide more details in Appendix A and refer readers to Wang and Poon (2018) for how to apply DPL as a tool in a downstream task such as relation extraction.

2.2 Silver Standard Evidence Generation

Given correct answer options, we use a distant supervision method to generate the *silver standard* evidence sentences.

Inspired by Integer Linear Programming models (ILP) for summarization (Berg-Kirkpatrick et al., 2011; Boudin et al., 2015), we model evidence sentence extraction as a maximum coverage problem and define the value of a selected sentence set as the sum of the weights for the unique words it contains. Formally, let v_i denote the weight of word i, $v_i = 1$ if word i appears in the correct answer option, $v_i = 0.1$ if it appears in the question but not in the correct answer option, and $v_i = 0$ otherwise.[1]

We use binary variables c_i and s_j to indicate the presence of word i and sentence j in the selected sentence set, respectively. $\mathrm{Occ}_{i,j}$ is a binary variable indicating the occurrence of word i in sentence j, l_j denotes the length of sentence j, and L is the predefined maximum number of selected sentences. We formulate the ILP problem as:

$$\max \sum_i v_i c_i \quad s.t. \sum_j s_j \le L \quad (3)$$

$$s_j\ \mathrm{Occ}_{ij} \le c_i, \forall i, j \quad \sum_j s_j\ \mathrm{Occ}_{ij} \ge c_i, \forall i \quad (4)$$

$$c_i \in \{0, 1\}\ \forall i \quad s_j \in \{0, 1\}\ \forall j$$

2.3 Linguistic Indicators for Indirect Supervision

To denoise the imperfect labels generated by distant supervision (Section 2.2), as a preliminary attempt, we manually design a small number of sentence-level and cross-sentence linguistic indicators incorporated in DPL for indirect supervision. We briefly introduce them as follows and detail all indicators in Appendix A.3 and implementation details in Section 3.2.

We assume that a sentence is more likely to be an evidence sentence if the sentence and the question have similar meanings, lengths, coherent entity types, same sentiment polarity, or the

[1] We do not observe a significant improvement by tuning parameters v_i on the development set.

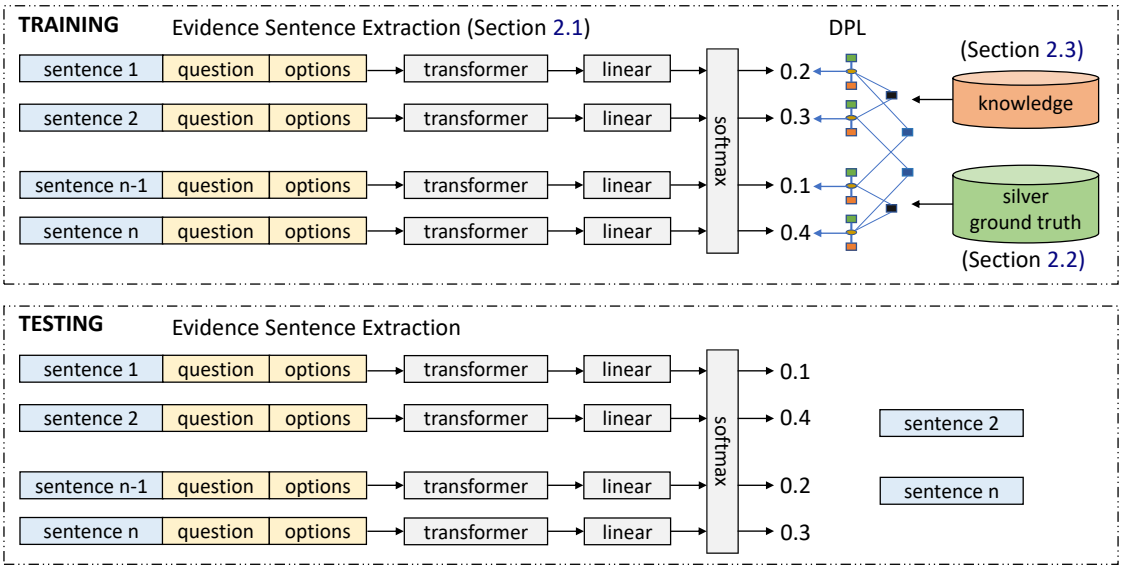

Figure 2: Deep probabilistic logic (DPL) framework for evidence sentence extraction. During testing, we only use trained evidence sentence extractor for prediction.

sentence is true (i.e., entailment) given the question. We assume that a good evidence sentence should be neither too long nor too short (i.e., $5 \leq$ # of tokens in sentence ≤ 40) considering informativeness and conciseness, and an evidence sentence is more likely to lead to the prediction of the correct answer option (referred as "reward"), which is motivated by our experiments that machine readers take as input the silver (or gold) standard evidence sentences achieve the best performance except for human performance on three multiple-choice machine reading comprehension datasets (Table 2, Table 3, and Table 4 in Section 3). We rely on both lexical features (e.g., lengths and entity types) and semantic features based on pre-trained word/paraphrase embeddings and external knowledge graphs to measure the similarity of meanings. We use existing models or resources for reward calculation, sentiment analysis and natural language inference.

For cross-sentence indicators, we consider that the same set of evidence sentences are less likely to support multiple questions and two evidence sentences that support the same question should be within a certain distance (i.e., evidence sentences for the same question should be within window size 8 (in sentences)). We also assume that adjacent sentences tend to have the same label. We will have more discussions about these assumptions in the data analysis (Section 3.6).

3 Experiments

3.1 Datasets

We use the following three latest multiple-choice machine reading comprehension datasets for evaluation. We show data statistics in Table 1.

MultiRC (Khashabi et al., 2018): MultiRC is a dataset in which questions can only be answered by considering information from multiple sentences. A question may have multiple correct answer options. Reference documents come from seven different domains such as elementary school science and travel guides. For each document, questions and their associated answer options are generated and verified by turkers.

RACE (Lai et al., 2017): RACE is a dataset collected from English language exams designed for middle (RACE-Middle) and high school (RACE-High) students in China, carefully designed by English instructors. The proportion of questions that requires reasoning is 59.2%.

DREAM (Sun et al., 2019): DREAM is a dataset collected from English exams for Chinese language learners. Each instance in DREAM contains a multi-turn multi-party dialogue, and the correct answer option must be inferred from the dialogue context. In particular, a large portion of questions require multi-sentence inference (84%) and/or commonsense knowledge (34%).

Dataset	# of documents			# of questions			Average # of sentences per document
	Train	Dev	Test	Train	Dev	Test	Train + Dev + Test
MultiRC	456	83	332	5,131	953	3,788	14.5 (Train + Dev)
DREAM	3,869	1,288	1,287	6,116	2,040	2,041	8.5
RACE	25,137	1,389	1,407	87,866	4,887	4,934	17.6

Table 1: Statistics of multiple-choice machine reading comprehension and question answering datasets.

3.2 Implementation Details

We use spaCy (Honnibal and Johnson, 2015) for tokenization and named entity tagging. We use the pre-trained transformer (i.e., GPT) released by Radford et al. (2018) with the same pre-processing procedure. When GPT is used as the neural reader, we set training epochs to 4, use eight P40 GPUs for experiments on RACE, and use one GPU for experiments on other datasets. When GPT is used as the evidence sentence extractor, we set batch size 1 per GPU and dropout rate 0.3. We keep other parameters default. Depending on the dataset, training the evidence sentence extractor generally takes several hours.

For DPL, we adopt the toolkit from Wang and Poon (2018). During training, we conduct message passing in DPL iteratively, which usually converges within 5 iterations. We use Vader (Gilbert, 2014) for sentiment analysis and ParaNMT-50M (Wieting and Gimpel, 2018) to calculate the paraphrase similarity between two sentences. We use the knowledge graphs (i.e., triples in ConceptNet v5.6 (Speer and Havasi, 2012; Speer et al., 2017)) to incorporate commonsense knowledge. To calculate the natural language inference probability, we first fine-tune the transformer (Radford et al., 2018) on several tasks, including SNLI (Bowman et al., 2015), SciTail (Khot et al., 2018), MultiNLI (Williams et al., 2018), and QNLI (Wang et al., 2018a).

To calculate the probability that each sentence leads to the correct answer option, we sample a subset of sentences and use them to replace the full context in each instance, and then we feed them into the transformer fine-tuned with instances with full context. If a particular combination of sentences $S = \{s_1, \ldots, s_n\}$ leads to the prediction of the correct answer option, we reward each sentence inside this set with $1/n$. To avoid the combinatorial explosion, we assume evidence sentences lie within window size 3. For another neural reader Co-Matching (Wang et al., 2018b), we use its default parameters. For DREAM and RACE, we set L, the maximum number of silver standard evidence sentences of a question, to 3. For MultiRC, we set L to 5 since many questions have more than 5 ground truth evidence sentences.

3.3 Evaluation on MultiRC

Since its test set is not publicly available, currently we only evaluate our model on the development set (Table 2). The fine-tuned transformer (GPT) baseline, which takes as input the full document, achieves an improvement of 2.2% in macro-average F1 ($F1_m$) over the previous highest score, 66.5%. If we train our evidence sentence extractor using the ground truth evidence sentences provided by turkers, we can obtain a much higher $F1_m$ 72.3%, even after we remove nearly 66% of sentences in average per document. We can regard this result as the supervised upper bound for our evidence sentence extractor. If we train the evidence sentence extractor with DPL as a supervision module, we get 70.5% in $F1_m$. The performance gap between 70.5% and 72.3% shows there is still room for improving denoising strategies.

3.4 Evaluation on RACE

As we cannot find any public implementations of recently published independent sentence selectors, we compare our evidence sentence extractor with InferSent released by Conneau et al. (2017) as previous work (Htut et al., 2018) has shown that it outperforms many state-of-the-art sophisticated sentence selectors on a range of tasks. We also investigate the ***portability*** of our evidence sentence extractor by combing it with two neural readers. Besides the fine-tuned GPT baseline, we use Co-Matching (Wang et al., 2018b), another state-of-the-art neural reader on the RACE dataset.

As shown in Table 3, by using the evidence sentences selected by InferSent, we suffer up to a 1.9% drop in accuracy with Co-Matching and up to a 4.2% drop with the fine-tuned GPT. In comparison, by using the sentences extracted by our sentence extractor, which is trained with DPL as a

Amazon Turker Performance (Lai et al., 2017)	-	-	-	85.1	69.4	73.3
Ceiling Performance (Lai et al., 2017)	-	-	-	95.4	94.2	94.5

Table 3: Accuracy (%) of various settings on the RACE dataset. ESE_{DS}: evidence sentence extractor trained on the silver standard evidence sentences extracted from the rule-based distant supervision method.

supervision module, we observe a much smaller decrease (0.1%) in accuracy with the fine-tuned GPT baseline, and we slightly improve the accuracy with the Co-Matching baseline. For questions in RACE, introducing the content of answer options as additional information for evidence sentence extraction can narrow the accuracy gap, which might be due to the fact that many questions are less informative (Xu et al., 2018). Note that all these results are compared with 59% reported from Radford et al. (2018), if compared with our own replication (56.8%), sentence extractor trained with either DPL or distant supervision leads to gain up to 2.1%.

Since the problems in RACE are designed for human participants that require advanced reading comprehension skills such as the utilization of external world knowledge and in-depth reasoning, even human annotators sometimes have difficulties in locating evidence sentences (Section 3.6). Therefore, ***a limited number of evidence sentences might be insufficient for answering challenging questions***. Instead of removing "non-relevant" sentences, we keep all the sentences in a document while adding a special token before and after the extracted evidence sentences. With DPL as a supervision module, we see an improvement in accuracy of 0.9% (from 58.9% to 59.8%).

For our current supervised upper bound (i.e., assuming we know the correct answer option, we find the silver evidence sentences from rule-based distant supervision and then feed them into the fine-tuned transformer, we get 72.8% in accuracy, which is quite close to the performance of Amazon Turkers. However, it is still much lower than the ceiling performance. To answer questions that require external knowledge, ***it might be a promising direction to retrieve evidence sentences from external resources***, compared to only considering sentences within a reference document for multiple-choice machine reading comprehension tasks.

3.5 Evaluation on DREAM

See Table 4 for results on the DREAM dataset. The fine-tuned GPT baseline, which taks as input the full document, achieves 55.1% in accuracy on the test set. If we train our evidence sentence extractor with DPL as a supervision module and feed the extracted evidence sentences to the fine-tuned GPT, we get test accuracy 57.7%. Similarly, if we train the evidence sentence extractor only with silver standard evidence sentences extracted from the rule-based distant supervision method, we obtain test accuracy 56.3%, i.e., 1.4% lower than that with full supervision. Experiments demonstrate the effectiveness of our evidence sentence extractor with denoising strategy, and the usefulness of evidence sentences for dialogue-based machine reading comprehension tasks in which reference documents are less formal compared to those in RACE and MultiRC.

3.6 Human Evaluation

Extracted evidence sentences, which help neural readers to find correct answers, may still fail to convince human readers. Thus we evaluate the quality of extracted evidence sentences based on human annotations (Table 5).

Dataset	Silver Sentences	Sentences by ESE_{DPL}
RACE-M	59.9	57.5
MultiRC	53.0	60.8

Table 5: Macro-average F1 compared with human annotated evidence sentences on the dev set (silver sentences: evidence sentences extracted by ILP (Section 2.2); sentences by ESE_{DPL}: evidence sentences extracted by ESE trained on silver stand ground truth, GT: ground truth evidence sentences).

MultiRC: Even trained using the noisy labels, we achieve a macro-average F1 score 60.8% on MultiRC, indicating the learning and generalization capabilities of our evidence sentence extractor, compared to 53.0%, achieved by using the noisy silver standard evidence sentences guided by correct answer options.

RACE: Since RACE does not provide the ground truth evidence sentences, to get the ground truth evidence sentences, two human annotators annotate 500 questions from the RACE-Middle development set.[2] The Cohen's kappa coefficient between two annotations is 0.87. For negation questions which include negation words (e.g., *"Which statement is not true according to the passage?"*), we have two annotation strategies: we can either find sentences that can directly imply the correct answer option; or the sentences that support the wrong answer options. During annotation, for each question, we use the strategy that leads to fewer evidence sentences.

We find that even humans have troubles in locating evidence sentences when the relationship between a question and its correct answer option is implicitly implied. For example, a significant number of questions require the understanding of the entire document (e.g., *"what's the best title of this passage"* and *"this passage mainly tells us that _"*) and/or external knowledge (e.g., *"the writer begins with the four questions in order to _"*, *"The passage is probably from _"* , and *"If the writer continues the article, he would most likely write about_"*). For 10.8% of total questions, at least one annotator leave the slot blank due to the challenges mentioned above. 65.2% of total questions contain at least two evidence sentences, and

[2]Annotations are available at https://github.com/nlpdata/evidence.

70.9% of these questions contain at least one adjacent sentence pair in their evidence sentences, which may provide evidence to support our assumption *adjacent sentences tend to have the same label* in Section 2.3.

The average and the maximum number of evidence sentences for the remaining questions is 2.1 and 8, respectively. The average number of evidence sentences in the full RACE dataset should be higher since questions in RACE-High are more difficult (Lai et al., 2017), and we ignore 10.8% of the total questions that require the understanding of the whole context.

3.7 Error Analysis

We analyze the predicted evidence sentences for instances in RACE for error analysis. Tough with a high macro-average recall (67.9%), it is likely that our method extracts sentences that support distractors. For example, to answer the question *"You lost your keys. You may call _"*, our system mistakenly extracts sentences *"Please call 5016666"* that support one of the distractors and adjacent to the correct evidence sentences *"Found a set of keys. Please call Jane at 5019999."* in the given document. We may need linguistic constraints or indicators to filter out irrelevant selected sentences instead of simply setting a hard length constraint such as 5 for all instances in a dataset.

Besides, it is possible that there is no clear sentence in the document for justifying the correctness of the correct answer. For example, to answer the question *"What does "figure out" mean ?"*, neither *"find out"* nor the correct answer option appears in the given document as this question mainly assesses the vocabulary acquisition of human readers. Therefore, all the extracted sentences (e.g., *"sometimes... sometimes I feel lonely, like I'm by myself with no one here."*, *"sometimes I feel excited, like I have some news I have to share!"*) by our methods are inappropriate. A possible solution is to predict whether a question is answerable following previous work (e.g., (Hu et al., 2019)) on addressing unanswerable questions in extractive machine reading comprehension tasks such as SQuAD (Rajpurkar et al., 2018) before to extract the evidence sentences for this question.

4 Related Work

4.1 Sentence Selection for Machine Reading Comprehension and Fact Verification

Previous studies investigate paragraph retrieval for factoid question answering (Chen et al., 2017; Wang et al., 2018c; Choi et al., 2017; Lin et al., 2018), sentence selection for machine reading comprehension (Hewlett et al., 2017; Min et al., 2018), and fact verification (Yin and Roth, 2018; Hanselowski et al., 2018). In these tasks, most of the factual questions/claims provide sufficient clues for identifying relevant sentences, thus often information retrieval combined with filters can serve as a very strong baseline. For example, in the FEVER dataset (Thorne et al., 2018), only 16.8% of claims require composition of multiple evidence sentences. For some of the cloze-style machine reading comprehension tasks such as CBT (Hill et al., 2016), Kaushik and Lipton (2018) demonstrate that for some models, comparable performance can be achieved by considering only the last sentence that usually contains the answer. Different from above work, we exploit information in answer options and use various indirect supervision to train our evidence sentence extractor, and previous work can actually be a regarded as a special case for our pipeline. Compared to Lin et al. (2018), we leverage rich linguistic knowledge for denoising imperfect labels.

Several work also investigate content selection at the token level (Yu et al., 2017; Seo et al., 2018), in which some tokens are automatically skipped by neural models. However, they do not utilize any linguistic knowledge, and a set of discontinuous tokens has limited explanation capability.

4.2 Machine Reading Comprehension with External Linguistic Knowledge

Linguistic knowledge such as coreference resolution, frame semantics, and discourse relations is widely used to improve machine comprehension (Wang et al., 2015; Sachan et al., 2015; Narasimhan and Barzilay, 2015; Sun et al., 2018) especially when there are only hundreds of documents available in a dataset such as MCTest (Richardson et al., 2013). Along with the creation of large-scale reading comprehension datasets, recent machine reading comprehension models rely on end-to-end neural models, and it primarily uses word embeddings as input. However, Wang et al. (2016); Dhingra et al. (2017,

2018) show that existing neural models do not fully take advantage of the linguistic knowledge, which is still valuable for machine reading comprehension. Besides widely used lexical features such as part-of-speech tags and named entity types (Wang et al., 2016; Liu et al., 2017; Dhingra et al., 2017, 2018), we consider more diverse types of external knowledge for performance improvements. Moreover, we accommodate external knowledge with probabilistic logic to potentially improve the interpretability of MRC models instead of using external knowledge as additional features.

4.3 Explainable Machine Reading Comprehension and Question Answering

To improve the interpretability of question answering, previous work utilize interpretable internal representations (Palangi et al., 2017) or reasoning networks that employ a hop-by-hop reasoning process dynamically (Zhou et al., 2018). A research line focuses on visualizing the whole derivation process from the natural language utterance to the final answer for question answering over knowledge bases (Abujabal et al., 2017) or scientific word algebra problems (Ling et al., 2017). Jansen et al. (2016) extract explanations that describe the inference needed for elementary science questions (e.g., *"What form of energy causes an ice cube to melt"*). In comparison, the derivation sequence is less apparent for open-domain questions, especially when they require external domain knowledge or multiple-sentence reasoning. To improve explainability, we can also check the attention map learned by neural readers (Wang et al., 2016), however, attention map is learned in end-to-end fashion, which is different from our work.

A similar work proposed by Sharp et al. (2017) also uses distant supervision to learn how to extract informative justifications. However, their experiments are primarily designed for factoid question answering, in which it is relatively easy to extract justifications since most questions are informative. In comparison, we focus on multi-choice MRC that requires deep understanding, and we pay particular attention to denoising strategies.

5 Conclusions

We focus on extracting evidence sentences for multiple-choice MRC tasks, which has not been studied before. We propose to apply distant supervision to noisy labels and apply a deep probabilistic logic framework that incorporates linguistic indicators for denoising noisy labels during training. To indirectly evaluate the quality of the extracted evidence sentences, we feed extracted evidence sentences as input to two existing neural readers. Experimental results show that we can achieve comparable or better performance on three multiple-choice MRC datasets, in comparison with the same readers taking as input the entire document. However, there still exist significant differences between the predicted sentences and ground truth sentences selected by humans, indicating the room for further improvements.

Abstract

Conversational AI systems are gaining a lot of attention recently in both industrial and scientific domains, providing a natural way of interaction between customers and adaptive intelligent systems. A key requirement in these systems is the ability to efficiently parse user queries, understand the intent behind each query, and provide adequate responses to users. Therefore, many applications such as conversation bots and smart IoT devices has a natural language understanding (LU) service integrated within. One of the greatest challenges of language understanding services is efficient utterance (sentence) representation in vector space, which is an essential step for most ML tasks. In this paper, we propose a novel approach for generating vector space representations of conversational utterances using pair-wise similarity metrics. The proposed approach uses only a few corpora to tune the weights of the similarity metric without relying on external general purpose ontologies. Our experiments confirm that the generated vectors can improve the performance of LU services in unsupervised, semi-supervised and supervised learning tasks over state-of-the-art prior works.

1 Introduction

Challenges of conversational AI systems: Conversational AI systems empower virtual assistants in many applications such as conversation bots (also known as Chatbots) and smart IoT devices. Their ability to understand user spoken commands and identify the user's intent(s) is one of their main benefits. However, this is a very challenging task due to the diversity of domains and languages they are required to support. For example, Microsoft LUIS[1] currently supports 12 languages, whereas IBM Watson [2] supports 10 languages in their language understanding services. Moreover, conversational text queries are often very short and sparse, which hinders conventional text representations such as Bag-of-words (BOW) from capturing adequate features of the utterance.

In LU services, a language understanding application is often represented as a group of intents and entities that serve a specific business application. For example, a restaurant application may define intents such as *Order Food*, *Show Menu* and *Cancel Order*. The task of the language understanding service then is to classify newly received queries (utterances) into one (or more) of the defined intents.

Although many prior works were focused on constructing word-level vector representation such as (Mikolov et al., 2013) and (Pennington et al., 2014), generating an utterance-level vector representation is still a challenging task. Existing language modeling (LM) based approaches such as Para2Vec (Le and Mikolov, 2014) rely on deep neural networks to generate vector representations for the paragraph-level. However, these approaches are normally trained with an abundance of utterances to achieve the required performance, which is usually not present in the conversational text domain (Boyanov et al., 2017). Moreover, pre-trained vectors (i.e., vectors generated from an external corpus) provide the same vector representation for all domains (i.e. static). The desirable characteristic on the other hand is that for the same utterance to have different vector representations, and correspondingly, different intents, in different domains. Additionally, the current approaches make the embeddings more prone to bias towards the domain of the training data (Bolukbasi et al., 2016).

We propose a vector representation method, SIMVECS that generates dynamic utterance-level vector representations for different LU applications. With SIMVECS, each utterance is represented as a vector of similarity scores to a set of automatically identified "representative utterances" within the same application. This way the same utterance can have different representations depending on the application. As an example: the utterance *"I want a large pizza"* can be of type *Order Food* for a restaurant application, while the same utterance can be of type *None* (i.e., outlier) for a bus-tracking application. Therefore, application-determined vector representations are essential for capturing the semantics of utterances in LU services and hence accurate mapping to user-defined intents.

The following list represents our key contributions:

1. A novel approach to combine multiple similarity sub-metrics into one metric, automatically adjusting the weight for each sub-metric to the overall similarity score.

2. A novel approach for the vector representation of each utterance in a conversational AI system.

3. A semi-supervised algorithm for refining the vector representations based on user's feedback.

The rest of the paper is organized as follows. Section 2 covers related work and separates our approach from existing solutions. Section 3 gives an overview of the main components in our proposed solution. Section 4 describes how we calculate the similarity scores between utterances and generate the vector representations. Sections 5, 6, and 7 evaluate the generated vectors in unsupervised, semi-supervised, and supervised learning tasks respectively and compares the performance of SIMVECS to several baselines.

2 Related Work

2.1 Similarity metrics

Measuring the similarity between natural language sentences is crucial in many tasks such as: Question-answering systems (Achananuparp et al., 2008b) and information retrieval (Li et al., 2006; Zahran et al., 2015). Authors in (Achananuparp et al., 2008a) provide an evaluation for 14 different similarity metrics. The authors reported the best metric found was a composite between word-order and ontology-based similarity. However, the weights for how much each of the two sub-metrics contributes to the overall similarity metric is selected based on human intuition. Such selection becomes harder when several sub-metrics are considered and multiple domains have to be satisfied. We consider these weights as hyper-parameters and hence use an automated technique that applies Genetic-Algorithms (GA) (Mitchell, 1996) to find the optimal weights as it has been used in multiple hyper-parameter tuning tasks such as in (Friedrichs and Igel, 2005), (Lam et al., 2001), and (Mahgoub et al., 2017).

2.2 Vector Representation

One of the most common vector representation for both documents and sentences is the Bag-of-Words (BOW) model (Harris, 1954). In BOW, the sentence is represented as a binary vector that donates the existence or absence of individual words (i.e. vocabulary) in that sentence. One of the major disadvantages of BOW representation is the loss of word order. Consequently, two sentences with totally different meaning can have very close representation just because they use similar vocabulary. A variation of the model is bag-of-ngrams (Mcnamee and Mayfield, 2004), which aims at preserving the word order. However, both representations are very sparse and generate vectors with very high dimensions. (Mikolov et al., 2013) proposed a technique that uses deep neural-networks to learn efficient representations for the word level. Although the trained vectors capture many semantic features, generating a sentence-level representation from individual words vectors is still a challenging task. One simple approach is to represent the sentence as weighted average of all the words in the document. However, this approach has the same weakness of not preserving the word order (Le and Mikolov, 2014). A recent approach proposed by (Le and Mikolov, 2014) generates both word-level and paragraph-level representations. However, the approach relies on training the network with a large corpus with billions of tokens, which is rarely available in the conversational text domain. Moreover, the generated vectors can still suffer from being biased by the train-

ing data domain and cannot generalize for different domains. (Dai and Le, 2015) proposed an approach to improve the vector representations with pre-trained recurrent neural networks. The proposed approach showed significant improvement over both BOW and Paragraph vectors. SIMVECS uses only a few corpora to tune the weights of the similarity metric without relying on external general purpose ontologies.

3 Overview of SIMVECS

SIMVECS relies on pair-wise similarity metrics. Each metric serves as a function that assigns similarity (or distance) scores to a pair of utterances. Many similarity metrics have been proposed in the literature. Although we use only six, our solution is generic and can incorporate any additional similarity sub-metrics.

3.1 Similarity sub-metrics definition

The six similarity sub-metrics which SIMVECS uses are:

(1)Unigrams: measures similarity based on the inverse-document-frequency (IDF) scores of common unigrams. The resulting score is then normalized by dividing over the sum of IDF scores of all unique words in the two utterances:

$$Sim_{uni}(U_i.U_j) = \frac{\sum_{w \in U_i \cap U_j} IDF[w]}{\sum_{w' \in U_i \cup U_j} IDF[w']} \quad (1)$$

(2)Character N-grams: measures similarity based on the overlapping character n-gram tokenization. We use an equation similar to the unigram except that words (and their corresponding IDF scores) are replaced by overlapping character N-grams. We use tokens of size n=4 as recommended by literature (Mcnamee and Mayfield, 2004).

(3)Bigrams: similar to unigram except that it uses tokens of two adjacent words. For each bigram, we set the IDF score to be the max between the two words in the token (presented as IDF_{bi}).

(4)Trigrams: similar to bigrams except that it uses tokens of three adjacent words.

(5)Utterance Length: this captures the similarity between a pair of utterances based on their number of tokens. Although this might be a dangerous feature to rely on individually, it becomes very useful in the domain of conversational text when combined with other features. For example, Table. 1 shows the average utterance lengths per intent in the WebApp corpus. We observe a large variance in utterance lengths of different intents. This is because one might need more tokens to specify a complex intent such as booking a flight (which requires lots of details) than simpler intents like asking for help or canceling a request. We use the following formula for utterance length similarity:

$$Sim_{len}(U_i.U_j) = \frac{min(Length(U_i), Length(U_j))}{max(Length(U_i), Length(U_j))} \quad (2)$$

(6)Word order: measures the normalized difference of word order between the two utterances.

$$Sim_{wo}(U_i.U_j) = 1 - \frac{||ri - rj||}{||ri + rj||} \quad (3)$$

where ri and rj are word order vectors (a vector which represents the order of each word in the utterance) of utterances U_i and U_j respectively.

3.2 IDF scores calculation

The first 4 metrics (i.e. unigram, bigram, trigrams, and character N-grams) rely on pre-calculated IDF scores. All these IDF scores are pre-calculated from a large corpus of conversational text generated from Cortana virtual assistant[3]. This corpus contains 18M utterances that resembles conversations between a user and Cortana in different domains. With the calculated IDF scores, these sub-metrics can be calculated and used to calculate a composite similarity metric as follows:

$$Sim_{comp}(U_i.U_j, \bar{W}) = \bar{W} \quad . \quad \bar{Sim}$$
$$= [W1..W6] \begin{bmatrix} Sim_{uni}(U_i.U_j) \\ Sim_{char}(U_i.U_j) \\ Sim_{bi}(U_i.U_j) \\ Sim_{tri}(U_i.U_j) \\ Sim_{len}(U_i.U_j) \\ Sim_{wo}(U_i.U_j) \end{bmatrix} \quad (4)$$

where W_i's are normalized weights which represent the collaboration of each sub-similarity metric to the overall metric. W_i's serve as hyper-parameters that control the quality of the composite similarity metric. The different sub-metrics have different relative importances in detecting similarities between utterances within the application. Therefore, the weights should be tuned automatically according to the LU application.

[3]https://www.microsoft.com/en-us/cortana

3.3 Application-based weights tuning

In this section, we describe our method in tuning the weight (W_i) for every sub-metric in Eq. 4. First, we use 15 real-world applications from a popular language understanding service to serve as our training and testing data set. These applications represent different domains (e.g. restaurants, flight booking services, smart homes, etc.) and they are created by system admins. Therefore, they contain a user-defined label for every utterance, which serves as our ground truth. For every pair of utterances with the same label, we assign a similarity score of 1 (max similarity). Similarly, for every pair of utterances with different labels, we assign a similarity score of 0 (min similarity). Now the task of tuning the weights for the sub-metrics can be viewed as an optimization problem, which is given by the following formula:

$$\bar{W}^* = \underset{\bar{W}}{\operatorname{argmin}} \sum_{\forall i,j} RMSE(Sim_{gt}(U_i.U_j), Sim_{comp}(U_i.U_j, \bar{W})) \quad (5)$$

Where Sim_{gt} is the ground truth similarity (either 0 or 1), $RMSE$ is the root mean square error between the estimated similarity score and the ground truth. Therefore, the target of equation 5 is to find the vector of weights that minimizes the differences between the estimated similarity scores and the ground truth similarly provided by application users. We use genetic algorithms (GA) to find the best values of $\bar{W}^*$. GA is a metaheuristic optimization algorithm that is inspired by biological evolution. It has the nice feature of balancing between exploration (a.k.a mutation) and exploitation (a.k.a crossover) of different solution candidates (a.k.a chromosome) in the search space (Črepinšek et al., 2013). GA is favorable in solving optimization problems which convexity is not known, since it does not rely on derivative information in finding good search directions (i.e. derivative-free). We used all pair-wise utterances from the 15 applications to train and validate our approach. Each candidate solution in GA simply represents a vector of weights in Eq. 4, and the fitness function is the resulting sum or RMSEs across all pairs of utterances (the lower the better). We perform 5-fold cross validation on the 15 applications and take the average of the best vectors of each fold. The resulting vector is then used for all subsequent experiments.

Table 1: Average number of tokens per utterance for the WebApp Corpora.

4 Similarity-based utterance representation

We estimate all pair-wise similarity scores using Eq. 4 and store them in a matrix of size NxN where N is the number of utterances. We then apply Principal Component Analysis (PCA) (Wold et al., 1987) to reduce the dimensionality of this matrix. This pair-wise similarity matrix, *SimMatrix* for short, is then used to generate the vector representation for each utterance. Consider the example shown in Fig. 1. On the left hand, we show 10 utterances (selected from (Coucke et al., 2018)) and their corresponding intents. On the right hand, we show the corresponding *SimMatrix* (before we apply PCA). The resulting matrix is a symmetric matrix with all its diagonal values = 1, representing maximum similarity. Then we use PCA to reduce the number of columns, loosely speaking, creating a set of representative utterances in a data-driven manner. At this point, we use each row as the vector representation of the corresponding utterance. Thus, each representative utterance serves as a dimension in the vector space, allowing utterances with similar neighbors to have similar vector representations.

This approach has a number of advantages over conventional vector representations (such as BOW) and LM based techniques (such as Para2Vec) in the domain of conversational text understanding. The data collected by (Braun et al., 2017) shows that conversational text tends to be very short with an average of 7.8 tokens per utterance. Moreover, 80% of the collected utterances are shorter than 9 tokens. This makes BOW representation very sparse. Also for LM-based techniques, it is hard to learn efficient vector representations because of the shortness of the context sequences used for training. Another advantage of SIMVECS is the easier detection of utterances that have no intent (i.e. the "None" intent utterances). As shown Fig. 1, the "None" intent utterances are expected to have similarity scores close to zero to

all other utterances, including other "None" utterances. This makes them located closer to the origin in SIMVECS's vector space and allows distance-based clustering techniques (such as K-means) to group "None" intent utterances in the same cluster. The second advantage is representative vector lengths: instead of using vectors of arbitrary lengths or length equal to the vocabulary size, we use vectors of length equal to the number of representative utterances in the given application. This can reduce the size of the generated vector representation significantly, especially when large vocabularies are used, while the LU application itself may have only a few tens or hundreds of utterances.

5 Unsupervised learning with conversational text

The problem of applying unsupervised learning techniques to text documents has been studied by many researchers in several domains such as (Beil et al., 2002),(Aggarwal and Zhai, 2012), and (Huang, 2008). The problem becomes more challenging with conversational text because of the shortness and the sparsity of the documents (Chen et al., 2011). We can categorize these techniques based on the input they need to perform clustering into two categories: 1) Techniques that require a vector representation for the data points, such as K-means and SVD. 2) Techniques that require a similarity (distance) function such as Affinity-Propagation (Frey and Dueck, 2007) and DBSCAN (Ester et al., 1996). However, the second category still requires an efficient vector representation to estimate the distances between pairs of utterances. We evaluate the efficacy of SIMVECS generated vectors in the unsupervised learning task against several baselines. We vary the vector representation while the clustering algorithm itself (K-means) remains the same. We show a comparison against the following techniques:

Spherical K-means (Buchta et al., 2012): This baseline uses BOW representation for the utterances and cosine-similarity as a distance function.

LDA (Blei et al., 2003): This baseline represents documents as probability distributions over latent topics. Documents with similar topic assignments are grouped together. Similar to K-means, it takes the number of latent topics (clusters) as an input. We set the number of topics to the number of intents in the corpus and then assign each utterance to the cluster with the maximum probability.

LDA + K-means: Here we use LDA's latent topic distribution as a vector representation to the utterance. Then we apply K-means for clustering the utterances.

Seq-Auto-encoder + K-means (Dai and Le, 2015): A Neural-network based technique using recurrent language models. The network is trained on a large corpus of conversational text generated from the same Cortana corpus used for generating the IDF scores. Afterwards, the network is used to encode each utterance of the test data in a vector of length 1024. K-means is then used to cluster the utterances.

Fast-text + K-means (Joulin et al., 2016): Also a Neural-network based technique that incorporates several features such as BOW and N-gram features. The model generates word-level vectors which are averaged together to form sentence-level representations. We used English pre-trained word vectors[4]. These vectors are pre-trained with 16 billion tokens collected from *Wikipedia 2017, UMBC webbase* corpus and *statmt.org* news.

SIMVECS+ K-means: K-means applied to our similarity-based vectors.

To make the comparison fair, K-means algorithm with the same number of clusters (K*) is used for the all techniques (Except LDA). Here K* is the number of intents in the corpora. For LDA, we set number of latent topics to be also K*.

Corpora	# Intents	# Utterances	# Tokens
AskUbuntu	5	162	1289
Chatbot	2	200	1539
WebApp	8	89	717
Combined	15	451	3545

Table 2: Conversational text corpora details.

5.1 Dataset description

We use the conversational text dataset presented in (Braun et al., 2017)[5]. The dataset represents a collection of three corpora, two corpora were extracted from StackExchange (Ask Ubuntu & WebApp), while the third one was extracted from a Telegram chatbot. *Combined* is a corpus that combines the intents of all three. Table 2 shows the number of intents, number of utterances, and number of tokens for each corpus in the dataset.

Figure 1: An example showing extracting the vector representation for each utterance. The table on the left shows 10 utterances (examples) for 5 different intents, whereas the table on the right shows the corresponding SimMatrix for the 10 utterances. Each row (or column) is then used as the vector representation for the corresponding utterance

5.2 Unsupervised learning results

In this section, we show the efficacy of SIMVECS's vector representation and compare to other baseline techniques. We collected both purity and normalized mutual information (NMI) scores for the generated clusters. We omit NMI scores for space reasons as it shows the same trend as purity. As shown in table 3, SIMVECS shows better performance (in terms of Purity) in comparison to other baseline except in one corpors, "Chatbot". Our solution (SIMVECS+ K-means) outperforms all baselines by at least 10% on average. Fast-text, Seq-Auto-Encoder, and BOW have very similar performance. We also notice that LDA+K-means outperforms LDA by 9%, suggesting that using topic distributions as vector representations is more efficient than mapping the utterance to the topic with the maximum corresponding probability. We also notice that Fast-text outperforms all other techniques (including SIMVECS) in one corpus (Chatbot). The reason is that Fast-text through training on billions of words, can find similarities between words that belong to the same domain. For example: the vector representation for the words "Pizza" and "Burger" have a cosine-similarity of 0.63 using Fast-text vectors as both words are very frequent in the "Restaurants" domain. Although this might be useful in some situations, it can be very misleading in others, causing non-similar utterances to have high silimarity scores. For instance, a particular restaurant might only serve burgers while any pizza orders are not supported and therefore should be considered outliers (i.e. "None" intent). This means the similarity between the two words will cause an overlap between these two intents ("Order" and "None"), driving the clustering algorithm to mistakenly combine the two intents into one cluster. This behavior is highlighted in the poor performance of Fast-text in all other corpora compared to SIMVECS.

6 Semi-Supervised learning with conversational text

In this section, we evaluate the efficacy of SIMVECS vector representations in semi-supervised learning tasks. One of the main requirements in language understanding services is to improve their performance during operation using active learning techniques. This is achieved by adapting to different user perspectives in different domains. Moreover, it is hard in many cases to perform clustering efficiently without taking the user perspective into consideration. For instance, Fig. 2 shows an example of two groups of utterances that can be clustered at different levels of granularity based on the user's needs. In many such cases, the same set of utterances can be clustered in different ways according to different

Corpora	Combined	AskUbuntu	Chatbot	WebApplications	Average
Spherical Kmeans	61%	63%	61%	64%	62%
LDA	46%	59%	61%	35%	50%
LDA+Kmeans	55%	67%	62%	54%	59%
Seq-Auto-encoder+Kmeans	65%	64%	62%	57%	62%
Fast-Text+Kmeans	53%	56%	**94%**	49%	63%
SIMVECS+Kmeans	**71%**	**83%**	61%	**76%**	**73%**

Table 3: Purity scores for SIMVECS vs several baselines

criteria. Moreover, it is not known which criteria is to be used by the clustering algorithm without user feedback. Therefore, semi-supervised learning is typically used in directing SIMVECS to the correct context-sensitive clustering. In this section, we evaluate the ability of SIMVECS in a semi-supervised learning mode, compared to several baselines.

In semi-supervised clustering, few data points are labeled and used as constraints to the clustering technique. These constraints are of the form **"Must-Link"** and **"Cannot-Link"** for pairs of data points. A "Must-Link" constraint arises when the user indicates that two utterances belong to the same intent, while a "Cannot-Link" constraint is when to the user indicates two utterances as belonging to different intents. We propose a simple algorithm to refine SIMVECS vectors based on the provided constraints: Whenever a "Must-Link" constraint is provided for a pair of points, we collapse their 2 vectors into one vector in the space. This is achieved by taking the max value of each entry of the corresponding indexes. Thus, the resulting vector is closer to neighbors of both points, shrinking the distances between neighbors of both utterances.Moreover, because each feature (dimension) in the space is a representative utterance, after the collapsing of two utterances, we perform PCA to come up with the new dimensions after the user is done with the labeling.

On the other hand, whenever a "Cannot-Link" constraint is provided, the similarity score between the two utterances is set to zero in the corresponding entry in SimMatrix. This increases the distance between the two points and transitively, between the neighbors of these two points.
To evaluate the effieciency of the resulting vectore, we vary the amount of user-labeled data points and estimate the corresponding clustering purity scores. As shown in Fig. 3, semi-supervised learning can significantly improve the performance of the clustering algorithm. We compare the performance of SIMVECS to BOW, Seq-Auto-encoder, and Fast-text. We use constrained K-means (COP-Kmeans) (Wagstaff et al., 2001) as the semi-supervised learner for SIMVECS as well as all baseline techniques. We see that SIMVECS achieves its maximum gain against other techniques when the proportion of labeled data is small. This is very useful in our problem as it reduces the labeling effort required from the user side to assist the clustering algorithm. The results show improvements over all three baselines, while the difference between the approaches shrinks with more labeled data points as expected. Also we notice that with few labeled data points (from 10% to 30%), Seq-Auto-encoder and Fast-text representations are performing better than BOW. However, with more labeled data ($\geq 50\%$) BOW starts to perform better. The reason is that with more labeled data points, the training examples (constraints) start to cover most of the expressions that can be used for a particular intent.

7 Supervised learning with conversational text

Supervised learning is critical to language understanding services in order to identify both intents and entities in new utterances coming in the stream. We compare the performance of intent classifiers when SIMVECS is used against BOW, Seq-auto-encoders, and Fast-text vector representations. For all corpora, a linear SVM classifier is trained per intent in one-vs-all fashion. For each intent, the utterances that belong to that intent represent the positive class, whereas all other utterances represent the negative class. We apply 5-fold cross validation and calculate the average F1-Score across all runs. Fig. 4 shows the improvement in F1-Score with both variants over baseline

Get Weather	
Is Warm	**Weather Update**
1 Will it get warmer, in Holy Cross Wilderness	4 What's the weather in Waretown, Lebanon
2 Will it be warmer, in five years, in Slemp, Kansas	5 What's the weather like in Saint Regis Falls, ND
3 Will it be warm, in Powersville, Guam, 23 hours from now	6 Tell me the weather forecast for Carmichaels, , Gambia, at one am

Figure 2: Example of clustering with different levels of granularity. Without user feedback, it is not clear whether the clustering algorithm should put all the utterances in the same cluster (Get Weather) or split them into two separate clusters (Is Worm & Weather Update).

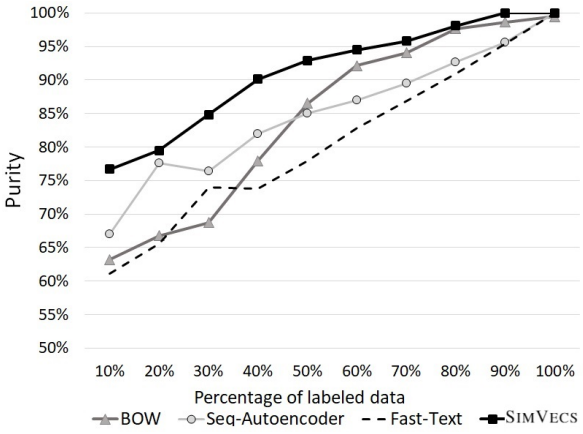

Figure 3: Improvement on clusters Purity using SIMVECS with COP-Kmeans vs several baselines

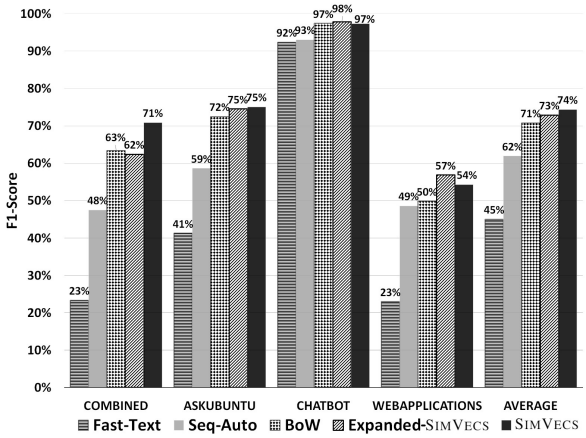

Figure 4: Improvement on classification accuracy using SIMVECS vs several baselines.

techniques. An improvement of 29% is observed over Fast-text representation, whereas an improvement of 13% over Seq-Auto-encoder representation is observed. SIMVECS is only slightly better than BOW (3% improvement on average). Additionally, we introduce a variant of SIMVECS that doesn't use the automatically tuned weights shown in Eq. 4. Instead, we concatenate all 6 similarity sub-metrics with all other utterances into one vector and use the resulting vector as the utterance representation (called Expanded-SIMVECS). Notice that this approach generates vector representations of size 6X compared to SIMVECS. We notice that using SIMVECS with our pre-trained weights is achieving better results than Expanded-SIMVECS across all corpora. The reason is that as Expanded-SIMVECS increases the number of dimensions, it also increases the sparsity of the space and hence requires more training data, which is known as "the curse of dimensionality" (Poggio et al., 2017). We also notice that the performance gain is proportional to the number of intents in the corpus. The peak gains of 8%, 25%, and 48% over BOW, Seq-Auto-encoder, and Fast-text respectively are observed with "Combined" corpora (which combines the 15 intents in all three corpora).

8 Background

In this section, we give the formulas used to estimate our evaluation metrics: Purity (Manning et al.) and F1-Score (Sasaki et al., 2007).

8.1 Purity:

is evaluated by the given formula:

$$Purity = \frac{1}{N}\sum_{i=1}^{k} Max_j |C_i \cap t_j| \quad (6)$$

Where N is the number of data points, k is the number of clusters, C_i is a generated cluster, and t_j is the intent which represents the majority in C_i.

8.2 F1-Score:

is evaluated by the given formula:

$$F_1 = 2.\frac{P * R}{P + R} \quad (7)$$

Where P is the precision, and R is the recall.

9 Discussion

One of the practical challenges in implementing SIMVECS can be the size of the SimMatrix, particularly when the number of utterances grows very large. Currently, this is not be a critical issue for current LU services as they tend to limit the number of utterances per application to a few thousands. But the maximium number of supported utterances is expected to grow in the future. For example, IBM Watson currently limits the number of utterances to 25,000 per workspace (application) whereas Microsoft LUIS limits the number of utterances to 15,000 per application. One approach to improve the scalability of SIMVECS is by constraining further the number of dimensions of the vector space thus reducing the memory requirements for storing SimMatrix. For reducing the computational time, multi-threading can be used to calculate similarity scores between different pairs of utterances concurrently and hence speedup the matrix construction process.

10 Conclusion

This paper introduces SIMVECS, a similarity-based vector representation technique designed to overcome prior work limitations in the field of conversational AI. We discussed the main challenges in vector representation for conversational AI applications and how SIMVECS overcomes these challenges. Through evaluation on different corpora and for different learning tasks, we showed the efficacy of vector representations generated by SIMVECS over several baselines.

Abstract

Conventional chatbots focus on two-party response generation, which simplifies the real dialogue scene. In this paper, we strive toward a novel task of Response Generation on Multi-Party Chatbot (RGMPC), where the generated responses heavily rely on the interlocutors' roles (e.g., speaker and addressee) and their utterances. Unfortunately, complex interactions among the interlocutors' roles make it challenging to precisely capture conversational contexts and interlocutors' information. Facing this challenge, we present a response generation model which incorporates Interlocutor-aware Contexts into Recurrent Encoder-Decoder frameworks (ICRED) for RGMPC. Specifically, we employ interactive representations to capture dialogue contexts for different interlocutors. Moreover, we leverage an addressee memory to enhance contextual interlocutor information for the target addressee. Finally, we construct a corpus for RGMPC based on an existing open-access dataset. Automatic and manual evaluations demonstrate that the ICRED remarkably outperforms strong baselines.

1 Introduction

Human computer conversation has been an important and challenging task in NLP and AI since the Turing Test was proposed in 1950 (Turing, 1950). Recently, with the rapid growth of social conversation data available on the Internet, data-driven chatbots are able to learn to generate responses directly and have attracted much more attention than before (Li et al., 2016a; Tian et al., 2017).

Researches in this area mostly focus on the dialog with two interlocutors (Maíra Gatti de Bayser et al., 2017). However, the real-life interaction involves a substantial part of Multi-Party Chatbots (MPC, such as internet forum and chat group), which is a form of conversation with multiple interlocutors (Ouchi and Tsuboi, 2016). For example, there are more than three interlocutors $(a_1, a_2, a_3 ... a_m)$ involved in the conversation in Figure 1, and their roles (e.g., speaker and addressee) may change across different dialog turns.

	t	Speaker	Addressee	Utterance

		Responding Speaker	Target Addressee	(Generated) Response

Figure 1: An example of Multi-Party Chatbots (MPC). At each turn, a speaker said one utterance to an addressee. There are many interlocutors (e.g., Alan, Bert and so on) in a conversation, where a_i represents interlocutor's ID.

As shown in Figure 1, at each turn, the core issue of MPC is to capture *who* (speaker) talks to *whom* (addressee) about *what* (utterance). In order to obtain responses in MPC, in our best knowledge, previous approaches usually employ a response selection paradigm, which simply selects one response from a set of existing utterances as the final response according to the contexts. Obviously, this paradigm, which could not generate new responses, is not so flexible. In this study, to build a more broadly applicable system, we concentrate on producing new responses word by word, named as Response Generation on Multi-Party Chatbots (RGMPC).

RGMPC is a very challenging task. The primary challenge is that the generated response has strong relevance to the interlocutor's roles, such as the speaker and the addressee. For example, in the same context of Figure 1, what a_1 says to a_2 is different from what a_1 says to a_3 because different addressees (a_2 and a_3) have different information demands. Similarly, as for the same addressee, ut-

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 718–727
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

terances from different speakers may be different because each speaker has personal background knowledge and style of speaking. Moreover, the roles of the same interlocutor may vary across different dialog turns. For instance, in Figure 1, a_3 plays different roles in different dialog turns: speaker in the turn 2 and n-1, addressee in the turn n and n+1.

Therefore, it is very important for RGMPC to capture interlocutor information. Currently, most response generation methods consider only the contextual utterance information (Serban et al., 2016, 2017) but neglect the interlocutor information. Although some researches have exploited the interlocutor information for response generation, they are still suffering from certain critical limitations. Li et al. (2016b) learn a fixed vector for each person from all conversational texts in the training corpus. However, as a global representation, the fixed person vector needs to be trained from large-scale dialogue turns for each interlocutor, and it may have a **sparsity issue** since some interlocutors have very few dialogue turns.

To address the aforementioned problems of RGMPC, this paper incorporates Interlocutor-aware Contexts into a Recurrent Encoder-Decoder model (ICRED) for RGMPC, which is also an end-to-end framework. Specifically, in order to capture interlocutor information, we exploit interactive interlocutor representations learned from current dialog context rather than the fixed person vectors (Li et al., 2016b) obtained from all dialogs in the training corpus. We expect that the learned contextual interlocutor representation could be a good alternative to the fixed person vectors (Li et al., 2016b) due to its ability of alleviating the sparsity issue. Furthermore, from the view of conversation analysis, responses are usually used for answering the addressee's question or expanding the addressee's utterances. Therefore, we originally introduce an addressee memory mechanism to enhance contextual information for the target addressee especially. Finally, both of the interactive interlocutor representation and addressee memory are utilized for decoding response utterances. In particular, the addressee memory is leveraged to capture the addressee information for each generated word dynamically.

In order to prove the effectiveness of the proposed model, we construct a dataset for RGMPC based on an open dataset[1]. Experimental results show that the proposed model is fairly competitive on both automatic and manual evaluations compared with state-of-the-arts.

In brief, the main contributions of the paper are as follows:

(1) We propose an end-to-end response generation model called ICRED which incorporates Interlocutor-aware Contexts into Recurrent Encoder-Decoder framework for RGMPC.

(2) We leverage an addressee memory mechanism to enhance contextual interlocutor information for the addressee.

(3) We construct an open-access dataset for RGMPC. Both automatic and manual evaluations demonstrate that our model is remarkably better than strong baselines in this dataset.

2 Task Formulation

	Data	Notation
Input	Context	$\mathcal{C} = [(a^t_{spk}, a^t_{adr}, \mathbf{u}^t)]^n_{t=1}$
	Responding Speaker	a^{n+1}_{spk} (or a_{res})
	Target Addressee	a^{n+1}_{adr} (or a_{tgt})
Output	Response	$\mathbf{u}^{n+1}$ (or $\{r_j\}^{L_r}_{j=1}$)

Table 1: Notations for RGMPC.

On multi-party chatbots, lots of interlocutors talk about one or more topics. At each dialogue turn (or time step) t, there is a speaker (a^t_{spk}), who may talk something ($\mathbf{u}^t$) to a specific addressee (a^t_{adr}), while the others are observers. As shown in Table 1, given the context $\mathcal{C}$ of previous n dialog turns, the responding speaker a_{res} and the target addressee a_{tgt} at time step n+1, the task of RGMPC aims to automatically generate the next utterance $\mathbf{u}^{n+1}$ as the final response. Here, $\mathcal{C}$ is a list ordered by the time step t: $\mathcal{C} = [\mathcal{C}^t]^n_{t=1} = [(a^t_{spk}, a^t_{adr}, \mathbf{u}^t)]^n_{t=1}$, where $\mathcal{C}^t$ means a^t_{spk} says $\mathbf{u}^t$ to a^t_{adr} at time step t, n is the maximum number of previous dialog turns in a context. $\mathbf{u}^t = (w^t_1, w^t_2 ... w^t_{L_u})$ is the input utterance (word sequence) at time step t, where L_u is the number of maximum words in utterances.

3 Methodology

The overview of the proposed ICRED for RGMPC is shown in Figure 2 along with its caption. The details are as follows.

[1]The dataset is available at https://www.dropbox.com/s/4chh64yaxajh0j7/RGMPC.zip?dl=0

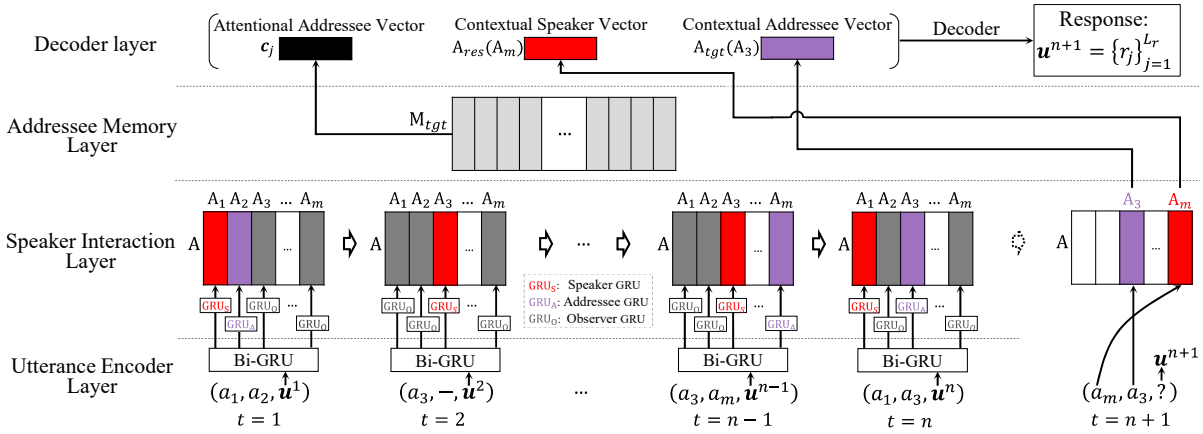

Figure 2: Overall structure of the proposed ICRED for RGMPC. At each time step t, $(a_i, a_j, \mathbf{u}^t)$ means that a speaker a_i said an utterance $\mathbf{u}^t$ to an addressee a_j, where the time step t is denoted on the bottom, and the superscript t may be omitted for brevity. Our ICRED includes: ① Utterance Encoder Layer: encoding each utterance ($\mathbf{u}^t$) into distributed vectors; ② Speaker Interaction Layer: capturing interactive interlocutor information from contexts, and it updates all interlocutors' representation by different GRUs according to their roles at each time step, where the embedding for an interlocutor a_i is obtained by extracting the i-th column (A_i) from the interlocutor embedding matrix A; ③ Addressee Memory Layer: enhancing contextual information for the target addressee (a_3); ④ Decoder Layer: generating responses.

3.1 Utterance Encoder Layer

The utterance encoder layer transforms input utterance into distributional representations. We leverage the bi-directional Gated Recurrent Units (GRU) (Cho et al., 2014) to capture the long-term dependency. For an utterance $\mathbf{u}^t = (w_1^t, w_2^t ... w_{L_u}^t)$ at time step t, the concatenated representation for hidden states in bi-directions is denoted as $\mathbf{h}_i^t = [\overrightarrow{\mathbf{h}}_i^t, \overleftarrow{\mathbf{h}}_{L_u-i+1}^t]$, where $\mathbf{h}_i^t$ is considered as the contextual word representation of the input word w_i^t. The state ($\mathbf{h}_{L_u}^t$) of the last word is treated as the representation of the utterance at time step t, which is denoted as $\mathbf{h}^t$, and it could be sent to the speaker interaction layer for updating contextual representation.

3.2 Speaker Interaction Layer

The speaker interaction layer is leveraged to obtain the interlocutor information in the context. Similar to the Speaker Interaction RNNs (Zhang et al., 2018), we utilize the interactive speaker encoder for RGMPC.

As shown in Figure 2, an interlocutor embedding matrix A is used to record all interlocutors' representation, and A is initiated with a zero matrix. Each column of A corresponds to an interlocutor's embedding: $A_i = A[*, a_i]$, where A_i is the embedding for the interlocutor a_i. The speaker interaction layer updates the entire interlocutors' embeddings at each time step based on their roles (speaker, addressee or observer). Embeddings for the speaker, addressee and observer are updated by following role-differentiated GRUs: GRU_S, GRU_A and GRU_O, respectively.

$$A_{spk}^t = \mathrm{GRU}_S(A_{spk}^{t-1}, \mathbf{h}^t) \quad (1)$$

$$A_{adr}^t = \mathrm{GRU}_A(A_{adr}^{t-1}, \mathbf{h}^t) \quad (2)$$

$$A_{obv}^t = \mathrm{GRU}_O(A_{obv}^{t-1}, \mathbf{h}^t) \quad (3)$$

where A_{spk}^t (A_{adr}^t / A_{obv}^t) is the embedding for the speaker (addressee / observer) at time step t, and $\mathbf{h}^t$ is the utterance representation obtained from the utterance encoder layer. Take the first time step "$(a_1, a_2, \mathbf{u}^1)$" in Figure 2 as an example, when a_1 says $\mathbf{u}^1$ to a_2, the speaker's (a_1's) embedding A_1 is updated by the speaker GRU—GRU_S, and the addressee's (a_2's) embedding A_2 is updated by the addressee GRU—GRU_A, while other interlocutors' embeddings are updated by the observer GRU—GRU_O. Note that the addressee may be missing (such as "$(a_3, -, \mathbf{u}^2)$" at time step 2 in Figure 2), where embeddings for all interlocutors except for the speaker are updated by the observer GRU. The interlocutor embedding matrix (A) is updated up to the maximum time step n. The final interlocutor embedding matrix is used in decoding.

3.3 Addressee Memory Layer

The interlocutor embedding matrix is updated by utterance representations and interlocutor's roles,

so it captures interlocutor's context on the utterance level. In fact, contextual word representation is important for response generation, too. A context contains consecutive utterances, and each utterance is a word sequence. Therefore, memorizing all contextual word representations in the entire context is complex, and it is difficult to work on large-scale utterances in one context.

Intuitively, from the view of conversational analysis, responses are usually used for answering the addressee's question or expanding the addressee's utterances. Therefore, we design an addressee memory layer, which only memorizes the contextual word representations (noted as M_{tgt}) in the last utterance said by the target addressee, and the contextual representation for each word is obtained from the utterance encoder layer. Take "$(a_m, a_3, ?)$" at time step n+1 in Figure 2 as an example, $\mathbf{u}^{n-1}$ is the last utterance said by the target addressee a_3 because of "$(a_3, a_m, \mathbf{u}^{n-1})$" at time step n-1, so the addressee memory layer merely memorizes contextual word representation $M_{tgt} = [\mathbf{h}_1^{n-1}, \mathbf{h}_2^{n-1}, ..., \mathbf{h}_{L_u}^{n-1}]$ from the utterance $\mathbf{u}^{n-1}$, where $\mathbf{h}_i^{n-1}$ is obtained from Section 3.1.

3.4 Decoder Layer

The decoder is responsible for generating target sequences. Different from a single contextual representation in previous work (Serban et al., 2017), the speaker interaction layer is able to capture different interlocutor information from contexts (e.g., personal background knowledge and style of speaking for the responding speaker, special information demands for the target addressee). Moreover, the addressee memory layer records contextual word representation for the target addressee. Therefore, we extract **contextual speaker vector** A_{res} for the responding speaker a_{res} from the final interlocutor embedding matrix A (e.g., the responding speaker's embedding obtained by $A_m = A[*, a_m]$ for the responding speaker a_m in Figure 2). Similarly, **contextual addressee vector** A_{tgt} for the target addressee is also extracted from A. However, A_{res} and A_{tgt} keep same for each generated word. In order to capture dynamic information for different generated words, we leverage an attention mechanism to selectively reads different contextual word representations from the addressee memory. For each target word, the decoder attentively reads the contextual word representation as follows:

$$\mathbf{c}_j = \sum_{k=1}^{L_u} \alpha_{jk} M_{tgt}[*, k]; \tag{4}$$

$$\alpha_{jk} = \frac{e^{\rho(\mathbf{s}_{j-1}, M_{tgt}[*,k])}}{\sum_{k'} e^{\rho(\mathbf{s}_{j-1}, M_{tgt}[*,k'])}} \tag{5}$$

where $\mathbf{c}_j$ is the **attentional addressee vector**, $M_{tgt}[*, k]$ is the contextual word representation for the k-th word in the addressee memory, and $\mathbf{s}_j$ represents the hidden state in decoding GRU. A function ρ is leveraged to compute the attentive strength, which is calculated by a projected matrix to connect $\mathbf{s}_{j-1}^T$ and $M_{tgt}[*, k]$. Finally, the attentional addressee vector $\mathbf{c}_j$, contextual speaker vector A_{res} and contextual addressee vector A_{tgt} are concatenated to estimate the probability for predicted words:

$$p(r_j | r_{<j}, a_{spk}, a_{tgt}, \mathcal{C}) = p(r_j | r_{j-1}, \mathbf{c}_j, A_{res}, A_{tgt}, \mathbf{s}_j) \tag{6}$$

$$\mathbf{s}_j = \mathrm{GRU}_{dec}(\mathbf{s}_{j-1}, [\mathbf{c}_j, A_{res}, A_{tgt}, \mathbf{x}_{j-1}]) \tag{7}$$

where $\mathbf{s}_j$ is the hidden state of the decoding GRU—$\mathrm{GRU}_{\mathrm{dec}}$. $\mathbf{x}_j$ is the word vector of the predicted target word r_j, and r_j is typically performed by a $softmax$ classifier over a settled vocabulary based on word embedding similarity.

3.5 Learning

The proposed ICRED for RGMPC is totally differentiable, and it can be optimized in an end-to-end manner using back-propagation. Given the context $\mathcal{C}$, responding speaker a_{res}, target addressee a_{tgt} and target word sequence $\{r_j\}_{j=1}^{L_r}$, the objective function is to minimize the loss function:

$$\mathcal{L} = \frac{-1}{L_r} \sum_{j=1}^{L_r} log[p(r_j | r_{<j}, \mathcal{C}, a_{res}, a_{tgt}] + \lambda \mathcal{L}_2 \tag{8}$$

It contains a negative log-likelihood for generated responses and L2 regularization ($\mathcal{L}_2$), where λ is a hyperparameter for $\mathcal{L}_2$.

4 Experiment

4.1 Dataset

Our dataset is constructed based on the Ubuntu multi-party chatbot corpus[2], which has been widely used as the evaluation dataset for the response selection task (Ouchi and Tsuboi, 2016; Zhang

[2]https://github.com/hiroki13/response-ranking

	Total	Train	Dev	Test
# Contexts	423.5K	338.9K	42.3K	42.3K
# Speaker	35.3K	33.5K	15.6K	15.6K
# Addressee	23.4K	22.4K	10.8K	10.8K
# Vocab	276.1K	254.8K	82.2K	82.0K
# Tokens	26.3M	21.0M	2.62M	2.62M
Avg. Tok/Ctx	51.4	51.5	51.4	51.3
Avg. Tok/Res	10.6	10.6	10.7	10.6

Table 2: Data statistics. "#" means number, and "Avg. Tok/Ctx (or Res)" is the number of tokens per context (or response).

et al., 2018). The original data comes from the Ubuntu IRC chat log, where each line consists of (Time, Speaker, Utterance). If the addressee is explicitly mentioned in the utterance, it is extracted as the addressee. Otherwise, all interlocutors except the speaker are observers. Considering that generating new responses in this paper is more complicated than retrieving responses, the generative task requires higher-quality data. We suppose that the responding speaker and target addressee have appeared in the context, where the contextual window is set to 5. Moreover, the words are tokenized by NLTK, and some general responses are removed by human rules[3]. Finally, we randomly split the dataset into Train/Dev/Test (8:1:1), and it is publicly available[1]. The detailed statistics of the dataset are shown in Table 2.

4.2 Implement Details

In order to keep our model comparable to other typical existing methods, we keep the same parameters and experimental environments for ICRED and the comparative models. We take a maximum of 20 words for the utterance. The word vector dimension is 300 and it is initialized with the public released fasttext[4] pre-trained on Wikipedia. The utterance and interlocutor are encoded by 512-dimensional and 1024-dimensional vectors, respectively. The joint loss function with 0.0001 L2 weight is minimized by an Adam optimizer. We implemented all the models with Tensorflow on an NVIDIA TITAN X GPU.

4.3 Automatic Evaluation Metrics

Automatic evaluations (AEs) for Natural Language Generation (NLG) is a challenging and under-researched problem (Novikova et al., 2017). Following (Liu et al., 2018), we leverage two referenced measurements (BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004)[5]) for automatic evaluations. Considering that current data-driven approaches tend to generate short and generic (meaningless) responses, two unreferenced ("intrinsic") metrics are also leveraged to the evaluation. The first one is the average length of responses, which is an objective and surfaced metric reflected the substance of responses (Mou et al., 2016; He et al., 2017a). The other one is the number of nouns[6] per response (Liu et al., 2018), which shows the richness of responses since nouns are usually content words. Note that the unreferenced metrics could enrich the evaluations, though they are weak metrics. The detailed results and analyses are shown as follows.

4.4 The Effectiveness of ICRED for RGMPC

Model	Referenced		Unreferenced	
	BLEU	ROUGE	Length	#Noun
Seq2Seq	8.86	7.62	9.48	1.24
Persona Model	9.12	7.38	11.04	1.29
VHRED	9.38	7.65	10.25	1.55
ICRED (ours)	**10.63**	**8.73**	**11.34**	**1.68**

Table 3: Overall comparisons of ICRED.

Comparison Methods. We compared ICRED with the following methods:

(1) Seq2Seq (Sutskever et al., 2014): Seq2Seq is one of the mainstream methods for text generation. In order to capture as much information as possible, the input sequence is all utterances concatenated in order in a context.

(2) Persona Model (Li et al., 2016b): The persona-based model modified a Seq2Seq to encode a global vector for each interlocutor that appears in the training data, and it could alleviate the issue of speaker consistency for response generation.

(3) VHRED (Serban et al., 2017): VHRED is essentially a conditional variational auto-encoder with hierarchical encoders, and it extends HRED (Serban et al., 2016) by adding a high-dimensional latent variable for utterances.

Comparative Results. Table 3 demonstrates overall comparisons of ICRED. We can clearly obtain the following observations:

[3]We list some general responses, such as containing "*i don't know*", "*you are welcome*".

[4]https://github.com/facebookresearch/fastText

[5]Implemented by https://github.com/Maluuba-/nlg-eval. BLEU and ROUGE are transformed into percentages (%).

[6]NLTK is utilized for part-of-speech tagging.

Interlocutor's Dialogue Turns	Persona Model		ICRED (ours)	
	BLEU	ROUGE	BLEU	ROUGE
[0, 100]	8.47	6.72	10.63	8.60
(100, 1000]	8.87	7.14	10.50	8.61
(1000, 5000]	9.48	7.74	**10.77**	**8.90**
(5000, +∞)	**9.51**	**7.80**	10.60	8.79

Table 4: Performances on sparse and plentiful learning data with different numbers of interlocutor's dialogue turns, where the test data is divided into different intervals according to the number of dialogue turns in training dataset said by target addressee (named as interlocutor's dialogue turns).

(1) ICRED obtains the highest performance on all metrics (marked as **bold**), and it indicates that incorporating interlocutor-aware context into RGMPC contributes to generating better responses.

(2) Although the persona-based model utilizes interlocutor information, it performs poorly. The average dialogue turn for the interlocutor is more than 5000 in (Li et al., 2016a), while there is less than 100 dialogue turns per interlocutor in our dataset. Therefore, it is hard to learn a global vector for each interlocutor from the sparse corpus. In contrast, our ICRED performs well on such a sparse corpus (details in Section 4.5).

(3) VHRED brings slight improvements over the Seq2Seq and persona-base model. Even that VHRED enhances the contextual information by a high-dimensional latent variable, VHRED is still remarkably worse than ICRED because VHRED neglects the interlocutor information.

4.5 The Effect of Sparse Data on ICRED

Comparison Settings. Persona model (Li et al., 2016b) may have a sparsity issue since some interlocutors have very few dialogue turns. To investigate whether ICRED has the sparsity issue or not, we divide the test data into four intervals according to the number of training dialogue turns said by the target addressee (called interlocutor dialogue turns), where small turns represent sparse learning data (e.g., "[0, 100]") and large turns mean plentiful learning data (e.g., "(5000, +∞)").

Comparative Results. Table 4 reports the performances of persona model and ICRED on different interlocutor's dialogue turns for learning. We can clearly see that the persona model has a sparsity issue: it performs very poorly on sparse learning data (e.g., BLEU score = 8.47 on "[0, 100]") while it achieves good performances on plentiful learning data (e.g., BLEU score = 9.51 on "(5000, +∞)"), which demonstrates that the fixed person vectors in the persona model need to be learned from large-scale training data for each interlocutor. In contrast, ICRED exploits interactive interlocutor representation learned from current dialog context rather than the fixed person vectors obtained from all training dialog utterances. Therefore, ICRED has no sparsity issues and it performs closely on sparse and plentiful learning data.

4.6 Ablation Study for Model Components

Model	Referenced		Unreferenced	
	BLEU	ROUGE	Length	#Noun
ICRED	**10.63**	**8.73**	**11.34**	**1.68**
w/o Adr_Mem	10.25	8.23	10.73	1.27
w/o Ctx_Spk_Vec	10.13	8.22	10.86	1.59
w/o Ctx_Adr_Vec	9.95	8.18	10.93	1.26

Table 5: Ablation Experiments by removing the main components.

Comparison Settings. In order to validate the effectiveness of model components, we have tried to remove some main components in decoding as follows. (1) w/o Adr_Mem: without the addressee memory, such as removing $\mathbf{c}_j$ in Equation 6-7; (2) w/o Ctx_Spk_Vec: without the contextual speaker vector, such as removing A_{res} in Equation 6-7; (3) w/o Ctx_Adr_Vec: without the contextual addressee vector, such as removing A_{tgt} in Equation 6-7.

Comparative Results. Results of the ablation study are shown in Table 5. We can see that removing any component causes obvious performance degradation. In particular, "w/o Ctx_Adr_Vec" performs the worst on almost all of the metrics, which demonstrates the importance of contextual information for the target addressee.

4.7 The Effectiveness of Addressee Memory

Memory Type	Referenced		Unreferenced	
	BLEU	ROUGE	Length	#Noun
addressee memory	**10.63**	8.73	11.34	**1.68**
all utterance memory	10.39	**8.78**	**11.38**	1.37
latest memory	10.43	8.40	10.16	1.28
speaker memory	10.03	8.28	10.72	1.66
w/o memory	10.25	8.23	10.73	1.27

Table 6: Performances over different memory types.

Comparison Settings. In order to demonstrate the effectiveness of the addressee memory, we

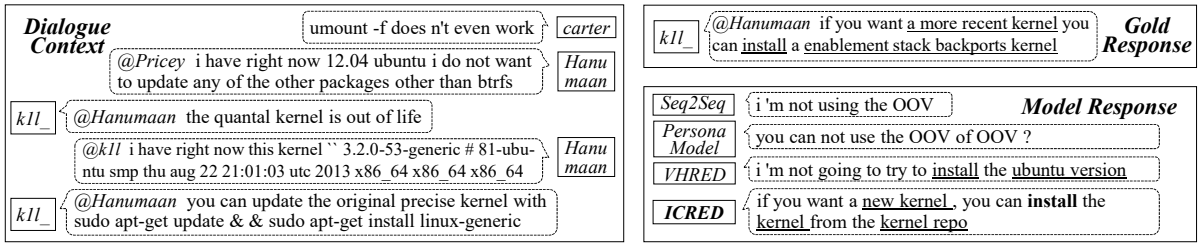

Figure 3: An example of different model responses for the same dialogue context. The input dialogue context is on the left. The gold (referenced) response and model responses are on the top right and bottom right, respectively. The rounded rectangle is the message box, where the *italic* behind "@" is the addressee, and the solid-line box near to the message box represents the speaker or model.

change the memory type, and then the attention model in Equation 5 is based on the new memory. The comparison settings are shown as follows. (1) addressee memory: memorizing contextual word representations in the last utterance said by the *target addressee* (e.g., $\mathbf{u}^{n-1}$ in Figure 2); (2) all utterance memory: memorizing contextual word representations in *all* utterances of the context (e.g., $\mathbf{u}^1$ to $\mathbf{u}^n$ in Figure 2); (3) latest memory: memorizing contextual word representations of the *latest* utterance in the context (e.g., the latest utterance $\mathbf{u}^n$ in Figure 2); (4) speaker memory: memorizing contextual word representations in the last utterance said by the *responding speaker*; (5) w/o memory: without any memory.

Comparative Results. We report the results of different memory types as shown in Table 6. It can see that our method, the addressee memory, achieves the best or near-best performances on all metrics. Although memorizing all utterances is competitive, the complexity of all utterance memory is n times compared with the one in the addressee memory, where n is the number of utterances in a context. The speaker memory performs closely to without memory, which indicates that not all memories can improve the performance.

4.8 Manual Evaluations

Besides automatic evaluations, we employ manual evaluations (MEs), which is important for response generation. Similar to (He et al., 2017b; Zhou et al., 2018), and we select three metrics for MEs, which measure the following aspects. (1) Fluency: measuring whether responses are grammatically correct or wrong. (2) Consistency: measuring whether responses are coherent to the context or not. (3) Informativeness: measuring how much informational (knowledgeable) content obtained from the responses.

Model	Flu.	Con.	Inf.
ICRED vs. Seq2Seq	77.25	83.69	84.35
ICRED vs. Persona.	78.44	80.41	82.35
ICRED vs. VHRED	73.20	81.29	79.47

Table 7: Manual evaluations (%) with fluency (Flu.), consistency (Con.) and informativeness (Inf.). The Score is the percentage that ICRED wins baselines after removing the "tie" pairs.

We conduct a pair-wise comparison between the response generated by ICRED and the one for the same input by three typical baselines. We sample 100 responses from each compared methods. Two curators judge (win, tie and lose) between these two methods. The Cohen Kappa of inter-annotator statistics is 0.750, 0.658 and 0.580 for the fluency, consistency and informativeness, respectively. As shown in Table 7, the score is the percentage that ICRED wins baselines after removing the "tie" pairs, and we can obtain that ICRED is significantly (sign test, p-value < 0.005) superior to all baselines on any metric. It demonstrates our model is able to deliver more fluent, consistent and informative responses.

4.9 Case Study

Figure 3 shows an example of responses on different models for the same dialogue context. It is clearly observed that our model (**ICRED**) generates more fluent, consistent and knowledgeable (marked as underline) responses compared to baselines. In particular, the response given by ICRED "*if you want a new kernel , you can install the kernel from the kernel repo*", not only explains the *reason for kernel installation* but also suggests a *source of the installation*. It fully captures the context and then produces a fluent, consistent and knowledgeable response, which is semantically similar to the gold one.

4.10 Discussion

Interlocutor Prediction and RGMPC. The above methods assume that the responding speaker and target addressee are given for RGMPC. Though the speaker and the addressee could be obtained in some situations (e.g., extracted from chat logs), it is still a researchable task to interlocutor prediction. There have been some researches to predict either the responding speaker or the target addressee based on the given textual contexts or multimodal information (Akhtiamov et al., 2017a; Meng et al., 2017; Akhtiamov et al., 2017b). Nevertheless, in order to obtain the interaction between interlocutor prediction and RGMPC, we further design a joint model for RGMPC and interlocutor prediction. Note that both the speaker and the addressee are predicted based on textual contexts, simultaneously. Firstly, the responding speaker is predicted from contexts:

$$p(a_{res}|\mathcal{C}) = \sigma([\mathbf{h}_{\mathcal{C}}; \mathbf{h}^n_{L_u}] \cdot \mathbf{W} \cdot A_{res}) \quad (9)$$

where $\mathbf{h}_{\mathcal{C}}$ is a summary contextual vector, which is max-pooled by the final interlocutor embedding matrix (A), and $\mathbf{h}^n_{L_u}$ is the hidden state of the last utterance. $\mathbf{W}$ is a projected matrix. a_{res} and A_{res} are the ID and the embedding of the responding speaker, respectively. The responding speaker is predicted by a *softmax* classifier based on the embedding similarity, and the target addressee is obtained in the same way. Secondly, the predicted interlocutors replace the gold ones for the addressee memory and extracting interlocutor's embeddings from A. Finally, the interlocutor prediction loss is added to the response generation loss for training. Table 8 shows the response generation performance on the situation that responding interlocutors are given and predicted. We can observe that:

(1) The overall performance on predicted interlocutors ("* / *" in Table 8) is slightly worse than the one with gold interlocutors (the first line in Table 8). Nevertheless, "* / *" still outperforms the strongest baseline (VHRED in Table 3).

(2) The correctness of interlocutor prediction has a significant impact on response generation performance. It performs the best when the responding speaker and the target addressee are predicted correctly. "False / False" (both are mispredicted) obtains the worst performance on the referenced metrics. These results demonstrate that both responding speaker and target addressee contribute to generating better responses.

Person	Speaker / Addressee	Referenced		Unreferenced	
		BLEU	ROUGE	Length	#Noun
Gold	True / True	10.63	8.73	11.34	1.68
Predict	$*$ / $*$	9.62	7.88	11.99	1.44
	True / True	**10.05**	**8.36**	12.04	1.43
	True / $*$	9.91	8.18	11.95	1.43
	$*$ / True	9.89	8.21	11.97	1.43
	False / False	9.20	7.41	**12.18**	**1.47**

Table 8: Performance on learning interlocutor prediction and RGMPC. "True" and "False" means right and wrong interlocutor, respectively. "*" represents both "True" and "False". The correctness of the responding speaker and target addressee is segmented by "/". For example, "True / *" means that the responding speaker is right, and the target addressee is right or wrong.

(3) Surprisingly, the unreferenced metrics perform well on "False / False". One possible reason is that the wrong interlocutors also capture rich contexts, and it generates long and meaningful responses but with a weak correlation to the gold interlocutors. Therefore, it achieves very poor performance on the referenced metrics.

5 Related Work

Our work is inspired by a large number of applications utilizing recurrent encoder-decoder frameworks (Cho et al., 2014) on NLP tasks such as machine translation (Bahdanau et al., 2015) and text summarization (Chopra et al., 2016). Recently, many researches extend the encoder-decoder framework on response generation. HRED (Serban et al., 2016) utilizes hierarchical encoder to capture the context. VHRED (Serban et al., 2017) extends HRED by adding a high-dimensional latent variable for utterances. These researches demonstrate the importance of contexts on response generation.

Our work is also inspired by researches on multi-party chatbots. Dielmann and Renals (2008) automatically recognize dialogue acts in multi-party speech conversations. Recently, some studies focus on the three elements (speaker, addressee, response) on multi-party chatbots. Meng et al. (2017) introduce speaker classification as a surrogate task. Addressee selection is researched by (Akhtiamov et al., 2017b). Some researches strive to the response selection (Ouchi and Tsuboi, 2016; Zhang et al., 2018). However, the response selection heavily relies on the candidates, and it can not generate new responses in new dialogue contexts. Response generation could solve

this problem. Li et al. (2016b) learn fixed person vector for response generation. Unfortunately, it needs to be obtained from large-scale dialogue turns, which has a sparsity issue: some interlocutors have very little dialog data. Differently, our model has no such restrictions.

6 Conclusion

In this study, we formalize a novel task of Response Generation for Multi-Party Chatbots (RGMPC) and propose an end-to-end model which incorporates Interlocutor-aware Contexts into Recurrent Encoder-Decoder frameworks (ICRED) for RGMPC. Specifically, we employ interactive speaker models to capture contextual interlocutor information. Moreover, we leverage an addressee memory mechanism to enrich contextual information. Furthermore, we propose to predict both the speaker and the addressee when generating responses. Finally, we construct a corpus for RGMPC. Experimental results demonstrate the ICRED remarkably outperforms strong baselines on automatic and manual evaluation metrics.

Memory Graph Networks for Explainable Memory-grounded Question Answering

Abstract

We introduce Episodic Memory QA, the task of answering personal user questions grounded on memory graph (MG), where episodic memories and related entity nodes are connected via relational edges. We create a new benchmark dataset first by generating synthetic memory graphs with simulated attributes, and by composing 100K QA pairs for the generated MG with bootstrapped scripts. To address the unique challenges for the proposed task, we propose Memory Graph Networks (MGN), a novel extension of memory networks to enable dynamic expansion of memory slots through graph traversals, thus able to answer queries in which contexts from multiple linked episodes and external knowledge are required. We then propose the Episodic Memory QA Net with multiple module networks to effectively handle various question types. Empirical results show improvement over the QA baselines in top-k answer prediction accuracy in the proposed task. The proposed model also generates a graph walk path and attention vectors for each predicted answer, providing a natural way to explain its QA reasoning.

1 Introduction

The task of question and answering (QA) has been extensively studied, where many of the existing applications and datasets have been focused on the fact retrieval task from a large-scale knowledge graph (KG) (Bordes et al., 2015), or machine reading comprehension (MRC) approaches given unstructured text (Rajpurkar et al., 2018). In this work, we introduce the new task and dataset for **Episodic Memory QA**, in which the model answers personal and retrospective questions based on **memory graphs** (MG), where each episodic memory and its related entities (*e.g.* knowledge graph (KG) entities, participants, ...) are represented as the nodes connected via corresponding edges (Figure 1). Examples of such queries include "*Where did we go **after** we had brunch with Jon?*", "*How many times did I go to **jazz** concerts last year?*", etc. For Episodic Memory QA, a machine has to understand the contexts of a question and navigate multiple MG episode nodes as well as KG nodes to gather comprehensive information to match the query requirement.

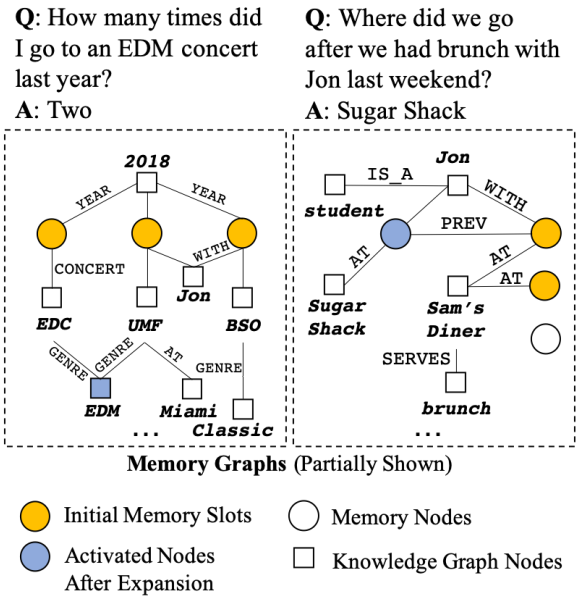

Figure 1: Illustration of **Episodic Memory QA** with user queries and memory graphs (MG) with knowledge graph (KG) entities. Relevant memory nodes are provided as initial memory slots via graph search lookup. The Memory Graph Network walks from the initial nodes to attend to relevant contexts and expands the memory slots when necessary. The main QA model takes these graph traversal paths and expanded memory slots as input, and predicts correct answers via multiple module networks (*e.g.* `COUNT`, `CHOOSE`, etc.)

While the ability of querying a personal database could lead to many potential applications, previous work in this domain (Jiang et al., 2018) is limited due to the lack of a large-scale

Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

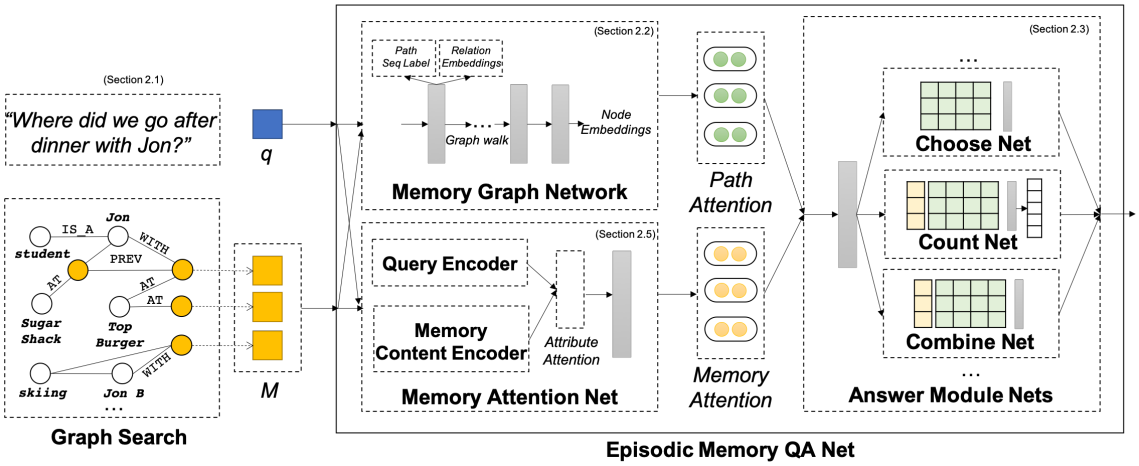

Figure 2: **Overall architecture** of the Episodic Memory QA Network. For an input query $\mathbf{q}$, candidate memory nodes $\mathbf{m} = \{\mathbf{m}^{(k)}\}$ are provided as input memory slots for the Memory QA Network. The Memory Graph Network then traverses the memory graph to expand the initial memory slots and activate other relevant entity and memory nodes based on the input queries. The Answer Module Networks execute the predicted neural programs to decode answers given the memory graph network outputs.

dataset and a unique set of challenges unseen in other tasks: For example, we observe that 1) Memory QA queries often include ambiguous and incomplete descriptions of reference memory (as opposed to many conventional Fact QAs with unambiguous mentions, *e.g.* "*Who painted the Mona Lisa?*"), hence requiring extensive candidate memory generation. Another challenge we observe is the case where 2) target memory is only indirectly linked to reference memory or entities (*e.g.* "*Where did we go after brunch?*"), which makes the conventional information retrieval (IR) approaches for generating answer candidates ineffective. In addition, 3) queries are not confined to retrieval tasks, but include various types of questions such as counting, set comparing, etc., many of which remain unsolved or not considered in many QA tasks.

To this end, we propose a new model called the Memory Graph Network (MGN) to address the specific challenges stated above that come with Memory QA. While Memory Networks have successfully been used in QA applications, typical limitations are that memory slots are limited to the fixed number of slots, often in sentence or bag-of-symbols forms. MGN extends the popular memory networks by storing graph nodes as memory slots and by allowing the network to dynamically expand memory slots through graph traversals. We then implement the main Episodic Memory QA Network with multiple module networks such as `CHOOSE`, `COUNT`, etc., to effectively handle various question types not easily handled via graph networks.

To bootstrap a large-scale dataset collection for Episodic Memory QA, we first build a synthetic memory graph generator, which creates multiple episodic memory graph nodes connected with real entities (*e.g.* locations, events, public entities) appearing on common-fact KGs. By creating a realistic memory graph that is synthetically generated, we avoid the need for inferring memory graphs from other structured data (*e.g.* photo albums) which are often limited in size. We then generate 100K QA pairs for each memory node with templates composed by human annotators, combined with 1K manual paraphrasing steps. More details for dataset collection are provided in Section 3.

2 Method

Figure 2 illustrates the overall architecture and the model components that make up the Episodic Memory QA Net. We examine each module in detail and provide our rationale about its formulation in the following sections.

Input Module (Section 2.1): For a given query $\mathbf{q}$, its relevant memory nodes $\mathbf{m} = \{\mathbf{m}^{(k)}\}_{k=1}^{K}$ for slot size K are given as initial memory slots. At test time, relevant memory nodes can be retrieved from a graph search engine that measures textual similarity (*e.g.* n-gram TF-IDF) between its connected node contexts and query. The Query Encoder then encodes the input query with a language model, and the Memory Encoder encodes each memory slot for both structural and semantic properties of each memory.

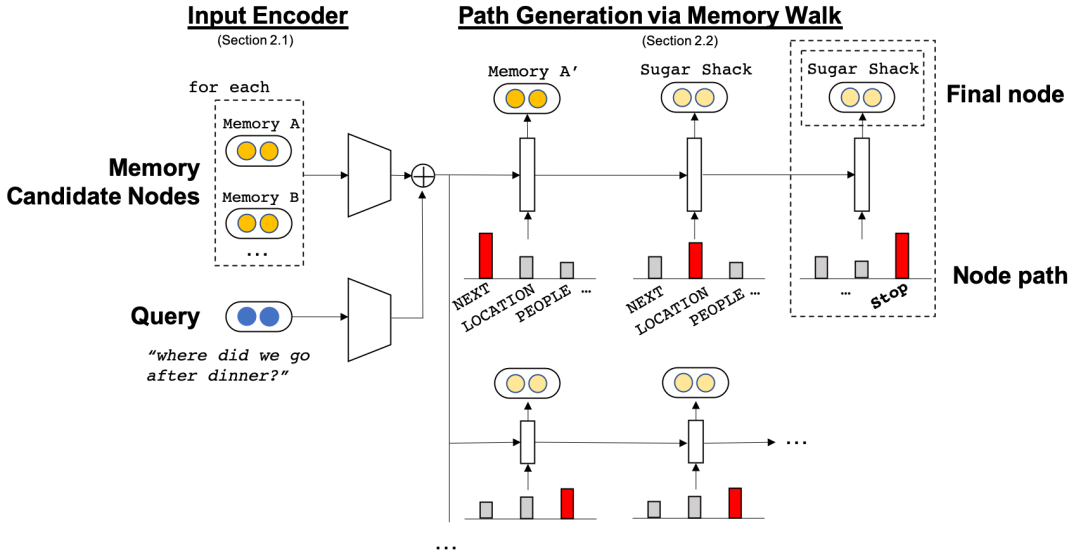

Figure 3: **Memory Graph Network (MGN) Walker**. Input query $\mathbf{q}$ and candidate memory nodes $\mathbf{m} = \{\mathbf{m}^{(k)}\}$ are encoded with the query encoder and the memory encoder, respectively (left). The decoder (right) predicts both the optimal paths and the final nodes $\mathbf{p} = \{\mathbf{p}_t\}_{t=1}^{T}$ based on their relevance scores as well as soft-attention based walk paths, which expands the initial memory slots.

Memory Graph Networks (MGN) (Section 2.2): Many previous work in QA or MRC systems use memory networks to evaluate multiple answer candidates with transitive reasoning, and typically store all potentially relevant raw sentences or bag-of-symbols as memory slots. However, naive increase of memory slot size or retention-based sequential update of memory slots often increase search space for answer candidates, leading to poor precision especially for the Episodic Memory QA task. To overcome this issue, with MGN we store memory graph nodes as initial memory slots, where additional contexts and answer candidates can be succinctly expanded and reached via graph traversals. For each $(\mathbf{q}, \mathbf{m}^{(k)})$ pair, MGN predicts optimal memory slot expansion steps: $\mathbf{p^{(k)}} = \{[\mathbf{p}_{e,t}^{(k)}; \mathbf{p}_{n,t}^{(k)}]\}_{t=1}^{T}$ for edge paths $\mathbf{p}_e$ and corresponding node paths $\mathbf{p}_n$ (Figure 3).

QA Modules (Section 2.3, 2.4): An estimated answer $\hat{\mathbf{a}} = \text{QA}(\mathbf{m}, \mathbf{q})$ is predicted given a query and MGN graph path output from initial memory slots. Specifically, the model outputs a module program $\{\mathbf{u}^{(k)}\}$ for several module networks (*e.g.* `CHOOSE`, `COUNT`, ...) via module selector, each of which produces an answer vector . The aggregated result of module network outputs determines the top-k answers.

2.1 Input Encoding

Query encoder: We represent each textual query with an attention-based Bi-LSTM language model (Conneau et al., 2017) with GloVe (Pennington et al., 2014) distributed word embeddings trained on the Wikipedia and the Gigaword corpus with a total of 6B tokens.

Memory encoder: We represent each memory node based on both its structural features (graph embeddings) and contextual multi-modal features from its neighboring nodes (*e.g.* attribute values).

Structural contexts of each memory node ($\mathbf{m}_s$) are encoded via graph embeddings projection approaches (Bordes et al., 2013), in which nodes with similar relation connectivity are mapped closer in the embeddings space. The model for obtaining embeddings from a MG (composed of subject-relation-object (s, r, o) triples) can be formulated as follows:

$$P(\mathbb{I}_r(s,o)=1|\theta) = \text{score}\big(\mathbf{e}(s), \mathbf{e}_r(r), \mathbf{e}(o)\big) \quad (1)$$

where $\mathbb{I}_r$ is an indicator function of a known relation r for two entities (s,o) (1: valid relation, 0: unknown relation), $\mathbf{e}$ is a function that extracts embeddings for entities, $\mathbf{e}_r$ extracts embeddings for relations, and score$(\cdot)$ is a function (*e.g.* multi-layer perceptrons) that produces a likelihood of a valid triple.

For contextual representation of memories ($\mathbf{m}_c$), we compute attention-weighted sum of textual representation of neighboring nodes and attributes (connected via $\mathbf{r}_j \in \mathbf{R}$), using the same

language model as the query encoder:

$$\mathbf{m}_c = \sum \gamma_j \mathbf{m}_{c,j}$$
$$\gamma = \sigma(\mathbf{W}_{q\gamma}\mathbf{q})$$

Note that the query attention vector γ attenuates or amplifies each attribute of memory based on a query vector to better account for query-memory compatibility accordingly. We then concatenate the structural features with semantic contextual features to obtain the final memory representation ($\mathbf{m} = [\mathbf{m}_s; \mathbf{m}_c]$).

2.2 Memory Graph Network

Inspired by the recently introduced graph traversal networks (Moon et al., 2019) which output discrete graph operations given input contexts, we formulate our MGN as follows. Given a set of initial memory slots ($\mathbf{m}$) and a query ($\mathbf{q}$), the MGN model outputs a sequence path of walk steps ($\mathbf{p}$) within MG to attend to relevant nodes or expand initial memory slots (Figure 3):

$$\{\mathbf{p}^{(k)}\} = \text{MGN}(\mathbf{q}, \{\mathbf{m}^{(k)}\}) \tag{2}$$

Specifically, we define the attention-based graph decoder model which prunes unattended paths, which effectively reduce the search space for memory expansion. We formulate the decoding steps for MGN as follows (bias terms for gates are omitted for simplicity of notation):

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}_{hi}\mathbf{h}_{t-1} + \mathbf{W}_{ci}\mathbf{c}_{t-1}) \\
\mathbf{c}_t &= (1 - \mathbf{i}_t) \odot \mathbf{c}_{t-1} \\
&\quad + \mathbf{i}_t \odot \tanh(\mathbf{W}_{zc}\mathbf{z}_t + \mathbf{W}_{hc}\mathbf{h}_{t-1}) \\
\mathbf{o}_t &= \sigma(\mathbf{W}_{zo}\mathbf{z}_t + \mathbf{W}_{ho}\mathbf{h}_{t-1} + \mathbf{W}_{co}\mathbf{c}_t) \\
\mathbf{h}_t &= \text{WALK}(\overline{\mathbf{x}}, \mathbf{z}_t) = \mathbf{o}_t \odot \tanh(\mathbf{c}_t)
\end{aligned} \tag{3}$$

where $\mathbf{z}_t$ is a context vector at decoding step t, produced from the attention over graph relations which is defined as follows:

$$\begin{aligned}
\overline{\mathbf{x}} &= \mathbf{W}_{qmx}[\mathbf{q}; \mathbf{m}^{(k)}] \\
\alpha_t &= \sigma(\mathbf{W}_{h\alpha}\mathbf{h}_{t-1} + \mathbf{W}_{x\alpha}\overline{\mathbf{x}}) \\
\mathbf{z}_t &= \mathbf{h}_{t-1} + \sum_{\mathbf{r}_j \in \mathbf{R}} \alpha_{t,j}\mathbf{r}_j
\end{aligned} \tag{4}$$

where $\alpha_t \in \mathbb{R}^{|\mathbf{R}|}$ is an attention vector over the relations space, $\mathbf{r}_k$ is relation embeddings, and $\mathbf{z}_t$ is a resulting node context vector after walking from its previous node on an attended path.

The graph decoder is trained with the ground-truth walk paths by computing the combined loss of $\mathcal{L}_{\text{walk}}(\mathbf{m}, \mathbf{q}, \mathbf{p}) = \sum_{i,t} \mathcal{L}_e + \mathcal{L}_n$ between predicted paths and each of $\{\mathbf{p}_e, \mathbf{p}_n\}$, respectively ($\mathcal{L}_e$: loss for edge paths, and $\mathcal{L}_n$ for node paths):

$$\begin{aligned}
&\sum_{\tilde{\mathbf{p}_e} \neq \mathbf{p}_{e,t}^{(i)}} \max[0, \tilde{\mathbf{p}_e} \cdot \mathbf{p}_{e,t}{}^{(i)} - \alpha_t \mathbf{r} \cdot (\mathbf{p}_{e,t}^{(i)} - \tilde{\mathbf{y}_e})^\top] \\
+ &\sum_{\tilde{\mathbf{p}_n} \neq \mathbf{p}_{n,t}^{(i)}} \max[0, \tilde{\mathbf{p}_n} \cdot \mathbf{p}_{n,t}{}^{(i)} - \mathbf{h}_t{}^{(i)} \cdot (\mathbf{p}_{n,t}^{(i)} - \tilde{\mathbf{p}_n})^\top]
\end{aligned}$$

At test time, we expand the memory slots by activating the nodes along the optimal paths based on the sum of their relevance scores (left) and soft-attention-based output path scores (right) at each decoding step:

$$\mathbf{p}_{n,t}^{(k)} = \underset{\mathbf{p}_n^{(k)} \in \mathbf{V}_{R,1}(\mathbf{p}_{n,t-1}^{(k)})}{\text{argmax}} \mathbf{h}_t \cdot \mathbf{p}_n^{(i)\top} + \sum \alpha_{t,j}\mathbf{r}_j \cdot \mathbf{p}_e^{(k)\top} \tag{5}$$

2.3 Module Networks

MGN outputs are then passed to module networks for the final stage of answer prediction. We extend the previous work in module networks (Kottur et al., 2018), often used in VQA tasks, to accommodate for graph nodes output via MGN. We first formulate the module selector which outputs the module label probability $\{\mathbf{u}^{(k)}\}$ given input contexts for each memory node, trained with cross-entropy loss $\mathcal{L}_{\text{module}}$:

$$\{\mathbf{u}^{(k)}\} = \text{Softmax}(\text{MLP}(\mathbf{q}, \{\mathbf{m}^{(k)}\})) \tag{6}$$

We then define the memory attention to attenuate or amplify all activated memory nodes based on their compatibility with query, formulated as follows:

$$\beta = \text{MLP}(\mathbf{q}, \{\mathbf{m}^{(k)}\}, \{\mathbf{p}^{(k)}\}) \tag{7}$$
$$\alpha = \text{Softmax}(\mathbf{W}_\beta^\top \beta) \in \mathbb{R}^K \tag{8}$$

For this work, we propose the following four modules: `CHOOSE`, `COUNT`, `CONFIRM`, `SET_OR`, and `SET_AND`, hence $\mathbf{u}^{(k)} \in \mathbb{R}^5$. Note that the formulation can be extended to the auto-regressive decoder in case sequential execution of modules is required.

`CHOOSE` module outputs answer space vector by assigning weighted sum scores to nodes along the MGN soft-attention walk paths. End nodes with the most probable walk paths thus get the

highest scores, and their node attribute values are considered as answer candidates. `COUNT` module counts the query-compatible among the activated nodes, $\mathbf{a} = \mathbf{W}_K^\top([\alpha; \max\{\alpha\}; \min\{\alpha\}])$. `CONFIRM` uses a similar approach to `COUNT`, except it outputs a binary label indicating whether the memory nodes match the query condition: $\mathbf{a} = \mathbf{W}_b^\top([\alpha; \max\{\alpha\}; \min\{\alpha\}])$. `SET` modules either combine or find intersection among answer candidates by updating the answer vectors with $\mathbf{a} = \max\{\mathbf{W}_s^\top\{\mathbf{a}^{(k)}\}\}$ or $\mathbf{a} = \min\{\mathbf{W}_s^\top\{\mathbf{a}^{(k)}\}\}$.

2.4 Answer Decoding

Answers from each module network (Section 2.3 are then aggregated as weighted sum of answer vectors with module probability (Eq.6), guided by memory attention (Eq.7). Predicted answers are evaluated with cross-entropy loss $\mathcal{L}_{\text{ans}}$

We observe that the model performs better when the MGN component of the model is pre-trained with ground-truth paths. We thus first train the MGN network with the same training split (without answer labels), and then train the entire model with module networks, fully end-to-end supervised with $\mathcal{L} = \mathcal{L}_{\text{walk}} + \mathcal{L}_{\text{module}} + \mathcal{L}_{\text{ans}}$.

3 Dataset

To empirically evaluate the proposed approach for the Episodic Memory QA task, we create a new dataset, *MemQA*, of 100K question and answer pairs composed based on synthetic memory graphs that are artificially generated. We specifically use the synthetically generated MG to avoid the need for inferring memory graphs from other structured data (such as publicly available photo albums such as Flicker, etc.) which are often limited in size and domains. We bootstrap our large-scale realistic memory graph dataset with the following procedures: first, we construct a synthetic social graph with a set number of artificial users, each with randomly generated interest embeddings. We then create a realistic memory graph by randomly choosing participants within the synthetic social graph as well as activities and associated entities from the curated list (of locations, events, public entities, etc.), which is a subset of common-fact Freebase knowledge base (Bast et al., 2014). Each generated memory node thus has connections to entities appearing in KGs, comprising the memory graph together. Finally, given a set of reference memory nodes and neighboring attributes, we pragmatically generate target ground-truth answer samples (*e.g.* single-hop / multi-hop node value, count, set comparison, yes/no, etc.) We then collect QA pairs for each sample with templates composed with human annotators, which are combined with 1K manual paraphrasing steps for added variety and confirmation. We randomly split the QA corpus into into train (70%), validation (15%), and test sets (15%).

Answer Type	%	**Examples**
Location	18	Mt. Rainier, AMC Theater
KG entities & events	17	Iron Man, Coachella
Common nouns, etc.	16	skiing, movie
Person / Group	16	Mark, Jon
Count	15	zero, three
Date / Time	10	01-02-2018, 7 PM
Yes/No	6	-
Miscellaneous	2	-

Table 1: Types of Answers in $MemQA$

4 Empirical Evaluation

Task: Given a query and a set of initial memory graph nodes via graph search, we evaluate the model on the open-ended question answering prediction task.

4.1 Baselines

We choose as baselines the following QA systems (see Section 5 for details), and modify them accordingly to make comparisons with our task:

- MemN2N (Sukhbaatar et al., 2016): uses the end-to-end memory networks with the static set of initial memory slots. Each memory slot is represented with a bag-of-symbols for surrounding attributes and nodes. We use a single Softmax layer for answer classification. Memory slot size is tuned as a hyper-parameter.

- MemexNet (Jiang et al., 2018): uses the textual representation for multi-modal attributes, and frames the problem into a classification problem via text kernel match approaches to predict approximate answers. Since the dataset does not contain images, we omit the CNN representations.

We also consider several configurations of our proposed approach to examine contributions of

Components	Model	Precision@k			
		k=1	3	5	10
A	`MemN2N` (Sukhbaatar et al., 2016)	29.7	43.8	51.0	50.5
A	`Memex` (Jiang et al., 2018)	32.6	50.3	58.2	59.1
G	`MemQANet` (ablation)	36.7	56.8	63.5	67.9
G + N	`MemQANet` (ablation)	41.1	65.8	75.5	80.0
G + N + E	`MemQANet` (**proposed**)	**45.8**	**68.1**	**75.7**	**80.9**

Table 2: QA performance on the *MemQA* dataset (metric: precision@k). Our proposed model is compared against the selected baseline models as well as several ablation variations of the proposed model (model components (G): Memory Graph Network, (N): Module Networks, (E): graph embeddings).

each component (model components (G): Memory Graph Network, (N): Module Networks, (E): structural graph embeddings).

- (**Proposed**; G+N+E): is the proposed approach as described in Figure 2.
- (G+N): does not structural graph embeddings for MGN, and relies on semantic representation of surrounding nodes.
- (G): does not use any of the module networks (*e.g.* `COUNT`, ...), and predicts MGN graph output as answers instead.

4.2 Results

Parameters: We tune the parameters of each model with the following search space (bold indicate the choice for our final model): graph embeddings size: {64, **128**, 256, 512}, Bi-LSTM hidden states for the language model: {64, **128**, 256, 512}, MGN hidden states: {64, **128**, 256, 512}, word embeddings size: {100, 200, **300**}, and max memory slots: {1, 5, **10**, 20, 40, 80}. We optimize the parameters with Adagrad (Duchi et al., 2011) with batch size 10, learning rate 0.01, epsilon 10^{-8}, and decay 0.1.

Main Results: Table 2 shows the results of the top-k predictions of the proposed model and the baselines. It can be seen that the proposed Memory QA model outperforms other QA baselines for precision at all ks.

Specifically, with the MGN walker model, the MemQA model learns to condition its walk path on query contexts and attend and expand memory nodes, thus outperforming the baseline models that simply rely on their initial memory slots, typically large in size to maintain reasonable recall. The node expansion via MGN allows the model to keep the initial memory slots small (10) and expand only when necessary (*e.g.* for queries that require references to related memories, *"... where did I go after ..."*), thus improving the precision performance. Note that memory slot sizes for baselines are tuned for their performance on the validation set.

In addition, it can be seen that the neural module components (G+N and G+N+E) greatly outperform the ablation model (G) and the baselines by aggregating answers with the modules specifically designed for various types of questions. These neural modules allow the model to answer questions that are typically hard to answer (*e.g.* count, set comparison, etc.) by explicitly reducing the answer space accordingly.

Note also that the graph embeddings (G+N+E) improve the performance over the ablation model that does not use structural contexts (G+N), indicating that the model learns to better leverage knowledge graph contexts to answer questions.

Error Analysis: Table 3 shows some of the example output from the proposed model, given the input question and memory graph nodes. It can be seen that the model is able to predict answers by combining answer contexts from multiple components (walk path, node attention, neural modules, etc.) In general, the MGN walker successfully explores the respective single-hop or multi-hop relations within the memory graph, while keeping the initial memory slots small enough. The activated nodes via graph traversals are then used as input for each neural module, the aggregated results of which are the final top-k answer predictions. There are some cases where the final answer prediction is incorrect, whereas its walk path is correctly predicted. This is due to inaccurate prediction of memory attention vector given a query and initial memory slots, which requires compre-

Question and Answer	Model Preidction		
	Walk Path	Neural Module	Top-k Answers

hensive understanding of surrounding knowledge nodes in the context of the query.

5 Related Work

Memory Networks: Weston et al. (2014); Sukhbaatar et al. (2016) propose Memory Networks with explicit memory slots to contain auxiliary multi-input, now widely used in many QA and MRC tasks for its transitive reasoning capability. Traditional limitations are that memory slots for storing answer candidates are fixed in size, and naively increasing the slot size typically decreases the precision. Several work extend this line of research, for example by allowing for dynamic update of memory slots given streams of input (Kumar et al., 2016; Tran et al., 2016; Xu et al., 2019), reinforcement learning based retention control (Jung et al., 2018), etc. By allowing for storing graph nodes as memory slots and for slot expansion via graph traversals, our proposed Memory Graph Networks (MGN) effectively bypass the issues.

Structured QA systems: often answer questions based on large-scale common fact knowledge graphs (Bordes et al., 2015; tau Yih et al., 2015; Xu et al., 2016; Jain, 2016; Yin et al., 2016; Dubey et al., 2018), typically via an entity linking system and a QA model for predicting graph operations through template matching approaches, etc. Our approach is inspired by this line of work, and we utilize the proposed module networks and the MGN walker model to address unique challenges to Episodic Memory QA.

Machine Reading Comprehension (MRC) systems: aim at predicting answers given evidence documents, typically in length of a few paragraphs (Seo et al., 2017; Rajpurkar et al., 2016, 2018; Cao et al., 2019; tau Yih et al., 2015). Several recent work address multi-hop reasoning within multiple documents (Yang et al., 2018; Welbl et al., 2018; Bauer et al., 2018; Clark et al., 2018) or conversational settings (Choi et al., 2018; Reddy et al., 2018), which require often complex reasoning tools. Unlike in MRC systems that typically rely on language understanding, we effectively utilize structural properties of memory graph to traverse and highlight specific attributes or nodes that are required to answer questions.

Visual QA systems: aim to answer questions based on contexts from images (Antol et al., 2015; Wang et al., 2018; Wu et al., 2018). Recently, neural modules (Kottur et al., 2018) are proposed to address specific challenges to VQA such as visual co-reference resolutions, etc. Our work extends the idea of neural modules for Episodic Memory QA by implementing modules that can take graph paths as input for answer decoding. Jiang et al. (2018) proposes visual memex QA which tackles similar problem domains given a dataset collected around photo albums. Instead of relying on meta information and multi-modal content of a photo album, our work explicitly utilizes semantic and structural contexts from memory and knowledge graphs. Another recent line of work for VQA includes graph based visual learning (Hudson and Manning, 2019), which aims to represent each image with a sub-graph of visual contexts. While graph-based VQA operates on a graph constructed from a single scene, Episodic Memory QA operates on a large-scale memory graph with knowledge nodes. We therefore propose memory graph networks to handle ambiguous candidate nodes, a main contribution of the proposed work.

6 Conclusions

We introduce Episodic Memory QA, the task of answering personal user questions grounded on memory graph (MG). The dataset is generated with synthetic memory graphs with simulated attributes, and accompanied with 100K QA pairs composed via bootstrapped scripts and manual annotations. Several novel model components are proposed for unique challenges for the Episodic Memory QA: 1) Memory Graph Networks (MGN) extends the conventional memory networks by enabling dynamic expansion of memory slots through graph traversals, which also naturally allows for explainable predictions. 2) Several neural module networks are proposed for the proposed task, each of which takes queries and memory graphs as input to infer answers. 3) The main Episodic Memory QA Net aggregates answer prediction from each neural module to generate final answer candidates. The empirical results demonstrate the efficacy of the proposed model in the Memory QA reasoning.

Abstract

We consider the importance of different utterances in the context for selecting the response usually depends on the current query.[1] In this paper, we propose the model TripleNet to fully model the task with the triple $\langle context, query, response \rangle$ instead of $\langle context, response \rangle$ in previous works. The heart of TripeNet is a novel attention mechanism named triple attention to model the relationships within the triple at four levels. The new mechanism updates the representation for each element based on the attention with the other two concurrently and symmetrically. We match the triple $\langle C, Q, R \rangle$ centered on the response from char to context level for prediction. Experimental results on two large-scale multi-turn response selection datasets show that the proposed model can significantly outperform the state-of-the-art methods. [2]

1 Introduction

To establish a human-machine dialogue system is one of the most challenging tasks in Artificial Intelligence (AI). Existing works on building dialogue systems are mainly divided into two categories: retrieval-based method (Yan et al., 2016; Zhou et al., 2016), and generation-based method (Vinyals and Le, 2015). The retrieval-based method retrieves multiple candidate responses from the massive repository and selects the best one as the system's response, while the generation-based method uses the encoder-decoder framework to generate the response, which is similar to machine translation.

A: i downloaded angry ip scanner and now it doesn't work and i can't **uninstall** it
B: you **installed** it via package or via some binary installer
A: i **installed** from ubuntu soft center
B: hm i do n't know what package it is but it should let you remove it the same way
A: ah makes sense then ... hm was it a deb **file**

True Response: i think it was another **format** mayge sth starting with r
False Response: thanks i appreciate it try sudo apt-get **install** libxine-extracodecs

Figure 1: A real example in the Ubuntu Corpus. The upper part is the conversation between speaker A and B. The speaker A want to uninstall the ip scanner and the current query is about the format of the package, so the true response is about the format, but the existing conversation model can be easily misled by the high frequency term 'install' as they deal with the query and other utterances in the same way.

In this paper, we are focusing on the retrieval-based method because it is more practical in applications. Selecting a response from a set of candidates is an important and challenging task for the retrieval-based method. Many of the previous approaches are based on Deep Neural Network (DNN) to select the response for single-turn conversation (Lu and Li, 2013). We study multi-turn response selection in this paper, which is rather difficult because it not only requires identification of the important information such as keywords, phrases, and sentences, but also the latent dependencies between the context, query, and candidate response.

Previous works (Zhou et al., 2018; Wu et al., 2017) show that representing the context at different granularities is vital for multi-turn response selection. However, it is not enough for multi-turn response selection. Figure 1 illustrates the problem with a real example in Ubuntu Corpus. As demonstrated, the following two points should be

[1] In this paper, we define the last message which is waiting for a response as the 'query,' the conversation history including the query as 'context,' and each message in the context as an 'utterance.'

[2] TripleNet source code is available at https://github.com/wtma/TripleNet.

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 737–746
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

modeled to solve the problem: (1) the importance of current query should be highlighted, because it has great impact on the importance of different utterances in the context. For example, the query in the case is about the format of the file ('deb file'), which leads the last two utterances (including the query) are more important than the previous ones. If we only match the response with the context, the model may be misled by the high frequency word 'install' and choose the false candidate. (2) the information of different granularities is important, which includes not only the word, utterance, and context level, but also the char level. For example, the different tenses ('install,' 'installed') and the misspelling word ('angry') appear constantly in the conversation. Similar to the role of question for the task of machine reading comprehension (Seo et al., 2016; Cui et al., 2017; Chen et al., 2019), the query in this task is also the key to selecting the response. In this paper, we propose a model named TripleNet to excavate the role of query. The main contributions of our work are listed as follows.

- we use a novel triple attention mechanism to model the relationships within $\langle C, Q, R\rangle$ instead of $\langle C, R\rangle$;
- we propose a hierarchical representation module to fully model the conversation from char to context level;
- The experimental results on Ubuntu and Douban corpus show that TripleNet significantly outperform the state-of-the-art result.

2 Related Works

Earlier works on building the conversation systems are generally based on rules or templates (Walker et al., 2001), which are designed for the specific domain and need much human effort to collect the rules and domain knowledge. As the portability and coverage of such systems are far from satisfaction, people pay more attention to the data-driven approaches for the open-domain conversation system (Ritter et al., 2011; Higashinaka et al., 2014). The main challenge for open-domain conversation is to produce a corresponding response based on the current context. As mentioned previously, the retrieval-based and generation-based methods are the mainstream approaches for conversational response generation. In this paper, we focus on the task response selection which belongs to retrieval-based approach.

The early studies of response selection generally focus on the single-turn conversation, which use only the current query to select the response (Lu and Li, 2013; Ji et al., 2014; Wang et al., 2015). Since it is hard to get the topic and intention of the conversation by single-turn, researchers turn their attention to multi-turn conversation and model the context instead of the current query to predict the response. First, Lowe et al. (2015) released the Ubuntu Dialogue dataset and proposed a neural model which matches the context and response with corresponding representations via RNNs and LSTMs. Kadlec et al. (2015) evaluate the performances of various models on the dataset, such as LSTMs, Bi-LSTMs, and CNNs. Later, Yan et al. (2016) concatenated utterances with the reformulated query and various features in a deep neural network. Baudiš et al. (2016) regarded the task as sentence pair scoring and implemented an RNN-CNN neural network model with attention. Zhou et al. (2016) proposed a multi-view model with CNN and RNN, modeling the context in both word and utterance view. Further, Xu et al. (2017) proposed a deep neural network to incorporate background knowledge for conversation by LSTM with a specially designed recall gate. Wu et al. (2017) proposed matching the context and response by their word and phrase representations, which had significant improvement from previous work. Zhang et al. (2018) introduced a self-matching attention to route the vital information in each utterance, and used RNN to fuse the matching result. Zhou et al. (2018) used self-attention and cross-attention to construct the representations at different granularities, achieving a state-of-the-art result.

Our model is different from the previous methods: first we model the task with the triple $\langle C, Q, R\rangle$ instead of $\langle C, R\rangle$ in the early works, and use a novel triple attention matching mechanism to model the relationships within the triple. Then we represent the context from low (character) to high (context) level, which constructs the representations for the context more comprehensively.

3 Model

In this section, we will give a detailed introduction of the proposed model TripleNet. We first formal-

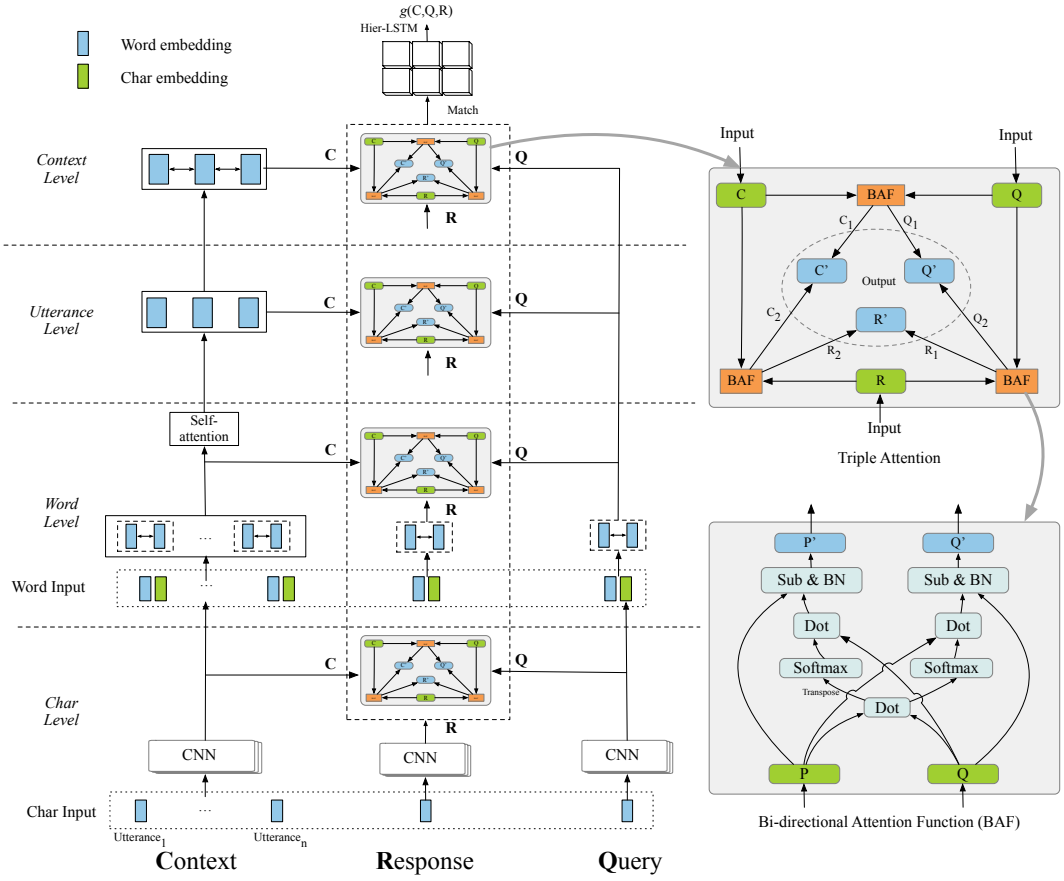

Figure 2: The neural architecture of the model TripleNet. *(best viewed in color)*

ize the problem of the response selection for multi-turn conversation. Then we briefly introduce the overall architecture of the proposed model. Finally, the details of each part of our model will be illustrated.

3.1 Task Definition

For the response selection, we define the task as given the context C, current query Q and candidate response R, which is different from almost all the previous works (Zhou et al., 2018; Wu et al., 2017). We aim to build a model function $g(C, Q, R)$ to predict the possibility of the candidate response to be the correct response.

$$score = g(C, Q, R) \tag{1}$$

The information in context is composed of four levels: context, utterances, words and characters, which can be formulated as $C = (u_1, u_2, ..., u_i, ..., u_n)$, where u_i represents the ith utterance, and n is the maximum utterance number. The last utterance in the context is query $Q = U_n$; we still use query as the end of context to maintain the integrity of the information in context. Each utterance can be formulated as $u_i = (w_1, ..., w_j, .., w_m)$, where w_j is the jth word in the utterance and m is the maximum word number in the utterance. Each word can be represented by multiply characters $w_j = (ch_1, ..., ch_k, .., ch_l)$, where ch_k is the kth char and l is the length of the word in char-level. The latter two levels are similar in the query and response.

3.2 Model Overview

The overall architecture of the model TripleNet is displayed in Figure 2. The model has a bottom-up architecture that organizes the calculation from char to context level. In each level, we first uses the hierarchical representation module to construct the representations of context, response and query. Then the triple attention mechanism is applied to update the representations. At last, the model matches them while focused on the response and fuses the result for prediction.

In the hierarchical representation module, we represent the conversation in four perspectives including char, word, utterance, and context. In the char-level, a convolutional neural network (CNN)

is applied to the embedding matrix of each word and produces the embedding of the word by convolution and maxpooling operations as the char-level representation. In word-level, we use a shared LSTM layer to obtain the word-level embedding for each word. After that, we use self-attention to encode the representation of each utterance into a vector which is the utterance-level representation. At last, the utterance-level representation of each utterance is fed into another LSTM layer to further model the information among different utterances, forming the context-level representation.

The structure of the triple attention mechanism can be seen in the right part of Figure 2. We first design a bi-directional attention function (BAF) to calculate the attention between two sequences and output their new representations. To model the relationship of the triple $\langle C, Q, R\rangle$, we apply BAF to each pair within the triple and get two new representations for each one element, and then we add them together as its final attention-based representation. In the triple attention mechanism, we can update the representation of each one based on the attention result with the other two simultaneously, and each element participates in the whole calculation in the same way.

3.3 Hierarchical Representation

Char-level Representation. At first, we embed the characters in each word into fixed size vectors and use a CNN followed by max-pooling to get character-derived embeddings for each word, which can be formulated by

$$ch_{j,t} = tanh(W_1^j * x_{t:t+s_j-1} + b_1^j) \quad (2)$$

$$ch_j = MaxPooling_{t=0}^{L}[ch_{j,t}] \quad (3)$$

where W_1^j, b_1^j are parameters, $x_{t:t+s_j-1}$ refers to the concatenation of the embedding of (x_t,...,x_{t+s_j-1}), s_j is the window size of jth filter, and the ch is the representation of the word in char-level.

Word-level Representation. Furthermore, we embed word x by pre-trained word vectors, and we also introduce a word matching (MF) feature to the embedding to make the model more sensitive to concurrent words. If the word appears in the response and context or query simultaneously, we set the feature to 1, otherwise to 0.

$$e(x) = [W_e \cdot x; ch(x); MF] \quad (4)$$

where $e(x)$ to denotes the embedding representation, W_e is the pre-trained word embedding, and $ch(x)$ is the character embedding function. We use a shared bi-directional LSTM to get contextual word representations in each utterance, query, and the response. The representation of each word is formed by concatenating the forward and backward LSTM hidden output.

$$\overleftarrow{h(x)} = \overleftarrow{\text{LSTM}}(e(x)) \quad (5)$$

$$\overrightarrow{h(x)} = \overrightarrow{\text{LSTM}}(e(x)) \quad (6)$$

$$h(x) = [\overleftarrow{h(x)}; \overrightarrow{h(x)}] \quad (7)$$

where $h(x)$ is the representation of the word. We denote the word-level representation of the context as $h_u \in \mathbb{R}^{m*d_w}$ and the response as $h_r \in \mathbb{R}^{m*d_w}$, where d_w is the dimension of Bi-LSTMs. Until now, we have constructed the representations of context, query, and response in char and word level, and we only represent the latter two in these two levels because they don't have such rich contextual information as the context.

Utterance-level Representation. Given the k_{th} utterance $u_k = [h_{u_k}^i]_{i=1}^m$, we construct the utterance-level representation by self-attention (Lin et al., 2017):

$$\alpha_i^k = softmax(W_3 tanh(W_2 h_{u_k}(i)^T)) \quad (8)$$

$$u_k = \sum_{i=1}^{m} h_{u_k}^i \alpha_i^k \quad (9)$$

where $W_2 \in \mathbb{R}^{d*d_w}$, $W_3 \in \mathbb{R}^d$ are trainable weights, d is a hyperparameter, u_k is the utterance-level representation, and α_i^k is the attention weight for the ith word in the kth utterance, which signifies the importance of the word in the utterance.

Context-level Representation. To further model the continuity and contextual information among the utterances, we fed the utterance-level representations into another bi-directional LSTM layer to obtain the representation for each utterance in context perspective.

$$c_k = \text{Bi-LSTM}([u_k]_{k=1}^n) \quad (10)$$

where $c_k \in \mathbb{R}^{d_c}$ is the context-level representation for the kth utterance in the context and d_c is the output size of the Bi-LSTM.

3.4 Triple Attention

In this part, we update the representations of context, query, and response in each level

by triple attention, the motivation of which is to model the latent relationships within $\langle context, query, response \rangle$.

Given the triple $\langle C, Q, R \rangle$, we fed each of its pairs into bi-directional attention function (BAF).

$$C_1, Q_1 = BAF(C, Q) \quad (11)$$
$$C_2, R_1 = BAF(C, Q) \quad (12)$$
$$Q_2, R_2 = BAF(C, R) \quad (13)$$
$$C' = BN(C_1 + C_2) \quad (14)$$
$$Q' = BN(Q_1 + Q_2) \quad (15)$$
$$R' = BN(R_1 + R_2) \quad (16)$$

where BN denotes the batch normalization layer (Ioffe and Szegedy, 2015) which is conducive to preventing vanishing or exploding of gradients. BAF produces the new representations for two sequences (P, Q) by the attention from two directions, which is inspired by Seo et al. (2016). We can formulate it by

$$M_{pq} = P^T tanh(W_3 Q) \quad (17)$$
$$Att_{pq} = softmax(M_{pq}) \quad (18)$$
$$Att_{qp} = softmax(M_{pq}^T) \quad (19)$$
$$P' = P - \tilde{Q}; \;\; \tilde{Q} = Q Att_{pq}; \quad (20)$$
$$Q' = Q - \tilde{P}; \;\; \tilde{P} = P Att_{qp}; \quad (21)$$

where Att_{pq}, Att_{qp} are the attention between P and Q in two directions, P', Q' are the new representations the two sequences (P, Q), and we apply a batch normalization layer upon them too.

We find that the triple attention has some interesting features: (1) triple, the representation for each element in the triple $\langle C, Q, R \rangle$ is updated based on the attention to the other two concurrently; (2) symmetrical, which means each element in the triple plays the same role in the structure because their contents are similar in the whole conversation; (3) unchanged dimension, all the outputs of triple attention has the same dimensions as the inputs, so we can stack multiple layers as needed.

3.5 Triple Matching and Prediction

Triple Matching. We match the triple $\langle C, Q, R \rangle$ in each level with the cosine distance using new representations produced by triple attention. This process focuses on the response because it is our target. For example, in the char-level, we match the triple by

$$\tilde{M}^1_{rc}(i, k, j) = cosine(ch'_r(i), ch'_{u_k}(j)) \quad (22)$$
$$M^1_{rc}(i, k) = \max_{0<j<m} \tilde{M}_1(i, j, k) \quad (23)$$
$$M^1_{rq}(i, j) = cosine(ch'_r(i), ch'_q(j)) \quad (24)$$
$$M_1 = [M^1_{rc}(i, k); M^1_{rq}(i, j)] \quad (25)$$

where ch' is the representation updated by triple attention, $M_1 \in \mathbb{R}^{m*(n+m)}$ is the char-level matching result, the word-level matches the triple in the same way, and the utterance and the context level match the triple without the maxpooling operation. We use M_2, M_3, M_4 as the matching results in the word, utterance and context levels.

Fusion. After obtaining the four-level matching matrix, we use hierarchical RNN to get highly abstract features. Firstly, we concatenate the four matrices to form a 3D cube $M \in \mathbb{R}^{m*(n+m)*4}$ and we use m as one of the matrix in M, which denotes the matching result for one word in response in four levels.

$$M = [M_1; M_2; M_3; M_4] \quad (26)$$
$$\tilde{m} = MaxPooling_{i=0}^{n+m}[\text{Bi-LSTM}(m_i)] \quad (27)$$
$$v = MaxPooling_{j=0}^{m}[\text{Bi-LSTM}(\tilde{m}_j)] \quad (28)$$

Where m_i and $\tilde{m}_j$ are the ith, jth row in the matrix m and $\tilde{m}$. We merge the results from different time steps in the outputs of LSTM by max-pooling operation. Until now, we encode the matching result into a single feature vector v.

Final Prediction. For the final prediction, we fed the vector V into a full-connected layer with sigmoid output activation.

$$g(C, Q, R) = sigmoid(W_4 \cdot v + b_4) \quad (29)$$

where W_4, b_4 are trainable weights. Our purpose is to predict the matching score between the context, query and candidate response, which can be seen as a binary classification task. To train our model, we minimize the cross entropy loss between the prediction and ground truth.

4 Experiments

4.1 Dataset

We first evaluate our model on Ubuntu Dialogue Corpus (Lowe et al., 2015) because it is the largest public multi-turn dialogue corpus which consists of about one million conversations in the specific domain. To reduce the number of unknown words,

Table 1: Experimental results on two public dialogue datasets. The table is segmented into three sections: Non-Attention models, Attention-based models and our models. The italics denotes the previous best results, and the scores in bold express the new state-of-the-art result of single model without any pre-training layer.

we use the shared copy of the Ubuntu corpus by Xu et al. (2017) which replaces the numbers, paths, and URLs by specific symbols.[3] Furthermore, to verify the generalization of our model, we also carry out experiments on Douban Conversation Corpus (Wu et al., 2017), which shares similar format with the Ubuntu corpus but is open-domain and in the Chinese language.

For the Ubuntu corpus, we use the recall at position k in n candidate responses ($R_n@k$) as evaluation metrics, and we use MAP (Mean Average Precision), MRR (Mean Reciprocal Rank), and Precision-at-one as the additional metrics for Douban corpus, following the previous work (Wu et al., 2017).

4.2 Experiment Setup

We implement our model by Keras (Chollet et al., 2015) with TensorFlow backend. In the Embedding Layer, the word embeddings are pre-trained using the training set via GloVe (Pennington et al., 2014), the weights of which are trainable. For char embedding, we set the kernel shape as 3 and filter number as 200 in the CNN layer. For all the Bi-directional LSTM layers, we set their hidden size to 200. We use Adamax (Kingma and Ba, 2014) for weight updating with an initial learning rate of 0.002. For ensemble models, we generate 6 models for each corpus using different random seeds and merge the result by voting.

For better comparison with the baseline models, the main super parameters in TripleNet, such as the embedding size, max length of each turn, and the vocabularies, are the same as those of the baseline models. The maximum number of conversation turns, which changes with the models, is 12 in our model, 9 in DAM (Wu et al., 2017), and 10 in SMN (Wu et al., 2017).

4.3 Baseline Models

We basically divided baseline models into two categories for comparisons.

Non-Attention Models. The majority of the previous works on this task are designed without attention mechanisms, including the Sequential Matching Network (SMN) (Wu et al., 2017), Multi-View model (Zhou et al., 2016), Deep Learning to Respond (DL2R) (Yan et al., 2016), Match-LSTM (Wang and Jiang, 2016), MV-LSTM (Wan et al., 2016), and DualEncoder (Lowe et al., 2015).

Attention-based Models. The attention-based models typically match the context and the candidate response based on the attention among them, including DAM (Zhou et al., 2018), DUA (Zhang et al., 2018), and RNN-CNN (Baudiš et al., 2016).

4.4 Overall Results

The overall results on two datasets are depicted in Table 1. Our results are obviously better on the two datasets compared with recently attention-based model DAM, which exceeds 2.3% in $R_{10}@1$ of Ubuntu and 2.6% in $P@1$ of Douban. Furthermore, our score is significantly exceeding in almost all metrics except the $R_{10}@5$ in Douban when compared with DUA, which may be be-

[3] https://www.dropbox.com/s/2fdn26rj6h9bpvl/ubuntudata.zip

cause the metric is not very stable as the test set in Douban is very small (1000).

To further improve the performance, we utilize pre-trained ELMo (Peters et al., 2018) and fine-tune it on the training set in the Ubuntu condition while we train ELMo from scratch using the Douban training set. As the baseline of Douban corpus is relatively lower, we observe much bigger improvements in the corpus using ELMo. The model ensemble has further improvements based on the single model with ELMo; the score of $R_{10}@1$ in Ubuntu is close to the average performance of human experts at 83.8 (Lowe et al., 2016).

Compared to non-attention models such as the SMN and Multi-view, which match the context and response at two levels, TripleNet shows substantial improvements. On $R_{10}@1$ for Ubuntu corpus, there is a 6.3% absolute improvement from SMN and 12.8% from Multi-view, showing the effectiveness of triple attention.

4.5 Model Ablation

To better demonstrate the effectiveness of TripleNet, we conduct the ablations on the model under the Ubuntu corpus for its larger data size.

We first remove the triple attention and matching parts (-TAM); the result shows a marked decline (2.4% in $R_{10}@1$), which is in the second part of Table 2. The performance of the model is similar to the baseline model DAM. This indicates that our four-level hierarchical representation may play a similar role to the five stacks Transformer in DAM. We then remove the triple attention part, which means we match the pairs $\langle C, R\rangle$ and $\langle Q, R\rangle$ with their original representation in each level; the score of $R_{10}@1$ drops 1.4%, which shows the effect of triple attention. We also have tried to remove all the parts related to the query (-Query). That means the attention and matching parts are only calculated within the pair $\langle C, R\rangle$. It is worth mentioning that the information of the query is still contained at the end of the context. The performance also has a marked drop (1.6% in $R_{10}@1$), which shows that it is necessary to model the query separately. To find out which subsection in those parts is more important, we remove each one of them.

Triple attention matching ablation. As we can see in the third part of Table 2, when attention between context and response is removed (-A_{CR}), the largest decrease (0.6% in $R_{10}@1$) appears, which indicates that the relationship between context and response is most important in the triple. The attentions in the other two pairs $\langle C, Q\rangle$ and $\langle Q, R\rangle$ all lead to a slight performance drop (0.3 and 0.5 in $R_{10}@1$), which may be because they overlap with each other for updating the representation of the triple.

When we remove the matching between context and response, we find that the performance of the model has a marked drop (2.1 in $R_{10}@1$), which shows that the relationship within $\langle C, R\rangle$ is the base for selecting the response. The query and response matching part also leads to a significant decline. This shows that we should pay more attention to query within the whole context.

Hierarchical representation ablation. To find out the calculation of which level is most important, we also tried to remove each level calculation from the hierarchical representation module, which can be seen in the fourth part of Table 2. To our surprise, when we remove char (-char) and context level calculation (-context), we observe that the reduction (0.5 in $R_{10}@1$) is more significant than the other two, indicating that we should pay more attention to the lowest and highest level information. Also by removing the other two levels, there is also a significant reduction from TripleNet, which means each level of the three is indispensable for our TripleNet .

From the experiments in this part, we find that each subsection of the hierarchical representation module only leads to a slight performance drop. Maybe it's because the representation from each

	$R_2@1$	$R_{10}@1$	$R_{10}@2$	$R_{10}@5$
TripleNet	94.3	79.0	88.5	97.0
-TAM	93.5	76.6	86.8	96.6
-A_{tri}	93.8	77.6	87.6	96.9
-Query	93.8	77.4	87.3	96.6
-A_{CR}	94.1	78.4	87.9	97.0
-A_{QR}	94.1	78.5	88.1	97.0

level represent the conversation from a unique and indispensable perspective, and the information conveyed by different representations may have some overlap.

5 Analysis and Discussion

5.1 Visualization

By decoding our model for the case in Figure 1, we find that our model TripleNet can choose the true response. To analyze in detail how triple attention works, we get the attention in word-level as the example and visualize it in Figure 3. As there are so many words in the context, we only use the second utterance in the upper part of Figure 1 for its relatively rich semantics.

In the query-context attention, the query mainly pays attention to the keyword 'package.' This is helpful to get the topic of the conversation. While the attention of context focuses on the word 'a' which is near the key phrase 'deb file,' which may be because the representation of the word catches some information from the words nearby by Bi-LSTM. In the query-response attention, the result shows that the attention of the query mainly focuses on the word 'format,' which is the most important word in the response. But we can also find that the response does not catch the important words in the query. In the response-context attention, the response pays more attention to the word 'binary,' which is another important word in the context.

From the three maps, we find that each attention can catch some important information but miss some useful information too. If we join the information in query-context and response-context attention, we can catch the most import information in the context. Furthermore, the query-response attention can help us catch the most important word in the response. So it is natural for TripleNet to select the right response because the model can integrate the three attentions together.

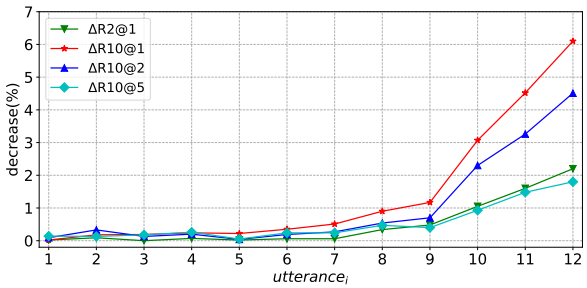

Figure 4: The decrease of the performance when the $utterance_i$ is removed in Ubuntu Corpus.

5.2 Discussion

In this section, we will discuss the importance of different utterances in the context. To find out the importance of different utterances in the context, we conduct an experiment by removing each one of them with the model (-Query) in the ablation experiment part because the model deals all the utterances include the query in the same way. For each experiment in this part, we remove the ith ($0 < i < 13$ and $Q = U_{12}$) utterance in the context both in training and evaluation processes and report the decrease of performance in Figure 4. We find that the removing of the query leads the most significant decline (more than 6% in $R_{10}@1$), that indicates the query is much more important than any other utterances. Furthermore, the decrease is stable before the 9th utterances and raises rapidly in the last 3 utterances. We can deduce that the last three utterances are more important than the other ones.

From the whole result, we can conclude that it's better to model the query separately than deal all of the utterances in the same way for their significantly different importance; we also find that we should pay more attention to the utterances near

the query because they are more important.

6 Conclusion

In this paper, we propose a model TripleNet for multi-turn response selection. We model the context from low (character) to high (context) level, update the representation by triple attention within $\langle C, Q, R \rangle$, match the triple focused on response, and fuse the matching results with hierarchical LSTM for prediction. Experimental results show that the proposed model achieves state-of-the-art results on both Ubuntu and Douban corpus, which ranges from a specific domain to open domain, and English to Chinese language, demonstrating the effectiveness and generalization of our model. In the future, we will apply the proposed triple attention mechanism to other NLP tasks to further testify its extensibility.

Abstract

Machine reading comprehension (MRC) has attracted significant amounts of research attention recently, due to an increase of challenging reading comprehension datasets. In this paper, we aim to improve a MRC model's ability to determine whether a question has an answer in a given context (e.g. the recently proposed SQuAD 2.0 task). Our solution is a relation module that is adaptable to any MRC model. The relation module consists of both semantic extraction and relational information. We first extract high level semantics as objects from both question and context with multi-head self-attentive pooling. These semantic objects are then passed to a relation network, which generates relationship scores for each object pair in a sentence. These scores are used to determine whether a question is non-answerable. We test the relation module on the SQuAD 2.0 dataset using both the BiDAF and BERT models as baseline readers. We obtain 1.8% gain of F1 accuracy on top of the BiDAF reader, and 1.0% on top of the BERT base model. These results show the effectiveness of our relation module on MRC.

1 Introduction

Ever since the release of many challenging large scale datasets for machine reading comprehension (MRC) (Rajpurkar et al., 2016; Joshi et al., 2017; Trischler et al., 2016; Yang et al., 2018; Reddy et al., 2018; Jia and Liang, 2017), there have been correspondingly many models for these datasets (Yu et al., 2018; Seo et al., 2017; Liu et al., 2018b; Hu et al., 2017; Xiong et al., 2017; Wang et al., 2018; Liu et al., 2018c; Tay et al., 2018). Knowing what you don't know (Rajpurkar et al., 2018) is important in real applications of reading comprehension. Unanswerable questions are commonplace in the real world, and SQuAD 2.0 was released specifically to target this problem (see Figure 1 for an example of non-answerable questions).

Example 1
Context: Each year, the southern California area has about 10,000 earthquakes. Nearly all of them are so small that they are not felt. Only several hundred are greater than magnitude 3.0, and only about 1520 are greater than magnitude 4.0. The magnitude 6.7 1994 **Northridge earthquake** was particularly destructive, causing a substantial number of deaths, injuries, and structural collapses. It caused the most property damage of any earthquake in U.S. history, estimated at over $20 billion.
Question: What earthquake caused $20 million in damage?
Answer: None.

Figure 1: An example of non-answerable question in SQuAD 2.0. Highlighted words are the output from the BERT base model. The true answer is "None".

One problem that most of the early MRC readers have in common is the inability to predict non-answerable questions. Readers on the popular SQuAD dataset have to be modified in order to accommodate a non-answerable possibility. Current methods on SQuAD 2.0 generally attempt to learn a single fully connected layer (Clark and Gardner, 2018; Liu et al., 2018a; Devlin et al., 2018) in order to determine whether a question/context pair is answerable. This leaves out relational information that may be useful for determining answerability. We believe that relationships between different high-level semantics in the context are helpful to make better answerable or unanswerable decision. For example, "Northridge earthquake" is mistakenly taken as the answer to the question about what earthquake caused $20 million in damage. Because "$20 billon" is positioned far away from "Northridge earthquake", it is hard for a model to link these two concepts together and recognize the mismatch of "$20 million" in the question and "$20 billion" in the context.

Motivated by exploiting high level semantic relationships in the context, our first step is to extract meaningful high-level semantics from question/context. Multi-head self-attentive pooling

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 747–756
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

(Lin et al., 2017) has shown to be able to extract different views of a sentence with multiple heads. Each head from the multi-head self attentive pooling has different weights on the context with learned parameters. This allows each head to act as a filter in order to emphasize part of the context. By summing up the weighted context, we obtain a vector representing an instance of a high-level semantic, which we can call it an "object". With multiple heads, we generate different semantic objects, which are then fed in to a relation network.

Relation networks (Santoro et al., 2017) are specifically designed to model relationships between pairs of objects. In the case of reading comprehension, an object would ideally be phrase level semantics within a sentence. Relation networks are able to accomplish modeling these relationships by constraining the network to learn a score for each pair of these objects. After learning all of the pairwise scores, the relation network then summarizes all of the relations to a single vector. By taking a weighted sum of all of the relation scores that the sentence has, we generate a non-answerable score that is trained jointly with answer span scores from any MRC model to determine non-answerability.

In addition, we add in plausible answers from unanswerable examples to help train the relation module. These plausible answers help the base model learn a better span prediction and are also used to help guide our object extractor to extract relevant semantics. We train a separate layer for start-end probabilities based on the plausible answers. We then augment the context vector with hidden states from this layer. This allows the multi-head self-attentive pooling to focus on objects related to the proposed answer span, and differentiate from other objects that are not as relevant in the context.

In summary we propose a new relation module dedicated to learning relationships between high-level semantics and deciding whether a question is answerable. Our contributions are four-fold:

1. Introduce the concept of using multi-head self-attentive pooling outputs as high level semantic objects.

2. Exploit relation networks to model the relationships between different objects in a context. We then summarize these relationships to get a final decision.

3. Introduce a separate feed-forward layer trained on plausible answers so that we can augment the context vector passed into the object extractor. This results in the object extractor extracting phrases more relevant to the proposed answer span.

4. Combining all of the above into a flexible relation module that can be added to the end of a question answering model to boost non-answerable prediction.

To our knowledge, this is the first case of utilizing an object extractor to extract high level semantics, and a relation networks to encode relationships between these semantics in reading comprehension. Our results show improvement on top of the baseline BiDAF model and the state-of-the-art reader based on BERT, on the SQuAD 2.0 task.

2 Related Work

Relation Networks (RN) were first proposed by (Santoro et al., 2017) in order to help neural models to reason over the relationships between two objects. Relation networks learn relationships between objects by learning a pairwise score for each object pair. Relation networks have been applied to CLEVR (Johnson et al., 2017) as well as bAbI (Weston et al., 2015). In the CLEVR dataset, the object inputs to the relation network are visual objects in an image, extracted by a CNN, and in bAbI the object inputs are sentence encodings. In both tasks, the relation network is then used to compute a relationship score over these objects. Relation Networks were further applied to general reasoning by training the model on images (You et al., 2018).

MAC (Memory, Attention and Composition) networks (Hudson and Manning, 2018) are different models that have also been shown to learn relations from the CLEVR dataset. MAC networks operate with read and write cells. Each cell would compute a relation score between a knowledge base and question and write it into memory. Multiple read and write cells are strung together sequentially in order to model long chains of multi-hop reasoning. Although MAC networks do not explicitly reason between pairwise objects as relation networks do, MAC networks are an interesting way of generating multi-hop reasoning between objects within a context.

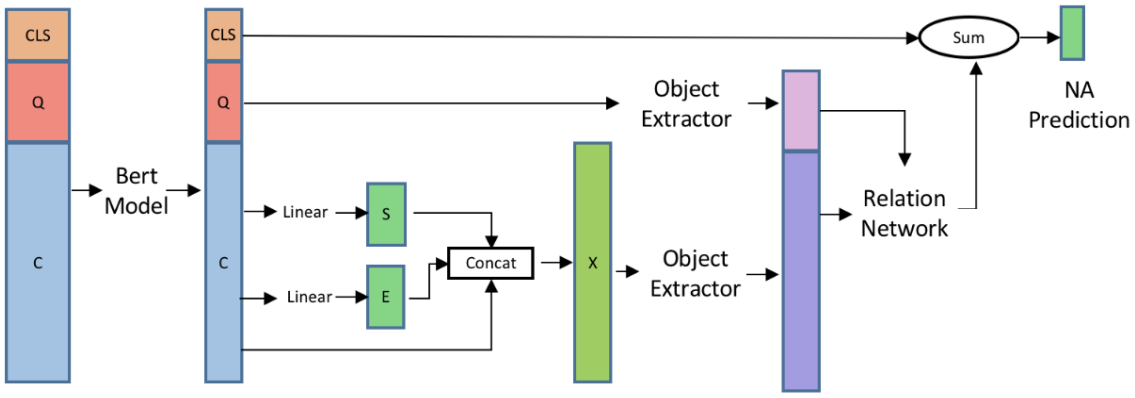

Figure 2: Relation Module on BERT. S and E are hidden states trained by plausible answers. We then concatenate S and E with the contextual representation to feed into the object extractor. After we obtain the extracted objects, we then feed into a Relation Network and pass it down for NA predictions.

Another similar line of work investigated pre-training relationship embeddings across word pairs on large unlabelled corpus (Jameel et al., 2018; Joshi et al., 2018). These pre-trained pairwise relational embeddings were added to the attention layers of BiDAF, where higher level abstract reasoning occurs. The paper showed an impressive gain of 2.7% on the SQuAD 2.0 development set on top of their version of BiDAF.

Many MRC models have been adapted to work on SQuAD 2.0 recently (Hu et al., 2019; Liu et al., 2018a; Sun et al., 2018; Devlin et al., 2018). (Hu et al., 2019) added a separately trained answer verifier for no-answer detection with their Mnemonic Reader. The answer sentence that is proposed by the reader and the question are passed to three combinations of differently configured verifiers for fine-grained local entailment recognition. (Liu et al., 2018a) just added one layer as the unanswerable binary classifier to their SAN reader. (Sun et al., 2018) proposed the U-net with a universal node that encodes the fused information from both the question and passage. The summary U-node, question vector and two context vectors are passed to predict whether the question is answerable. Plausible answers were used for no-answer pointer prediction, while in our approach, plausible answers were used to augment context vector for object extraction that later help the no-answer prediction.

Pretraining embeddings on large unlabelled corpus has been shown to improve many downstream tasks (Peters et al., 2018; Howard and Ruder, 2018; Alec et al., 2018). The recently released BERT (Devlin et al., 2018) greatly increased the F1 scores on the SQuAD 2.0 leaderboard. BERT consists of stacked Transformers (Vaswani et al., 2017), that are pre-trained on vast amounts of unlabeled data with a masked language model. The masked language model helps finetuning on downstream tasks, such as SQuAD 2.0. BERT models contains a special CLS token which is helpful for the SQuAD 2.0 task. This CLS token is trained to predict if a pair of sentences follow each other during the pre-training, which helps encode entailment information between the sentence pair. Due to a strong masked language model to help predict answers and a strong CLS token to encode entailment, BERT models are the current state-of-the art for SQuAD 2.0.

3 Relation Module

Our relation module is flexible, and can be placed on top of any MRC model. We now describe the relation module in detail.

3.1 Augmenting Inputs

Figure 2 shows our relation module on top of the base reader BERT. In addition to the original start-end prediction layers trained from true answers in the base reader, we include a separate start-end prediction layer, with separate parameters, trained specifically on plausible and true answers available in SQuAD 2.0. The context output C from BERT is projected into two hidden state layers S and E, where C, S and $E \in \mathbf{R}^{L \times h}$, L is the context length and h is the hidden size. The S and E layers are then projected down to a hidden

dimension of 1, and trained with Cross-Entropy Loss against the plausible and true answer starts and ends. The hidden states S and E of this layer are concatenated with the last context layer output C and projected back to the original dimension to obtain the augmented context vector X, which is fused with start-end span information.

$$S = tanh(CW_1 + b_1) \quad (1)$$
$$E = tanh(CW_2 + b_2) \quad (2)$$
$$X = [C; S; E]W \quad (3)$$

where [;;] is concatenation of multiple tensors and $X \in \mathbf{R}^{L \times h}$. This process is shown in Figure 2, where S and E are hidden states trained on plausible and true answer spans. This tensor X and the last question layer output Q are passed to the object extractor layer.

3.2 Object Extractor

The augmented context tensor X (and separately, question tensor Q) is passed through the object extractor to generate object representations from the tensor. We pass the inputs through a multi-head self-attentive pooling layer. This object extractor can be thought of as a set filters extracting out areas of interest within a sentence. We multiply the input tensor X with a multi-head self attention matrix A which is defined as

$$A = Softmax(W_4\sigma(W_3X^T)) \quad (4)$$
$$O = AX \quad (5)$$

where $W_3 \in R^{h \times h}$, and $W_4 \in R^{n \times h}$; σ is an activation function, such as $tanh$; n is the number of heads, and h is the hidden dimension. The output $O \in R^{n \times h}$ contains the n objects with hidden dimension h that are passed to the next layer.

3.2.1 Object Extraction Regularization

In order to help encourage the multiple heads to extract different meaningful semantics in the text, a regularization loss (Xia et al., 2018) is introduced to encourage each head to attend to slightly different sections of the context. Overlapping objects centered on the answer span are expected, due to information fused from S and E, but we do not want the entire weight distribution of the head to be solely focused on the answer span. As we show in later figures, many heads heavily weight the answer span, but also weight information relevant to the answer span needed to make a better non-answerable prediction. Our regularization term also helps prevent the multi-headed attentive pooling from learning a noisy distribution over all of the context. This regularization loss is defined as

$$L_{aux} = \alpha||AA^T - I||_2 \quad (6)$$

where A is the weight matrix for the attention heads and I is the identity matrix. α is set to be 0.0005 in our experiments.

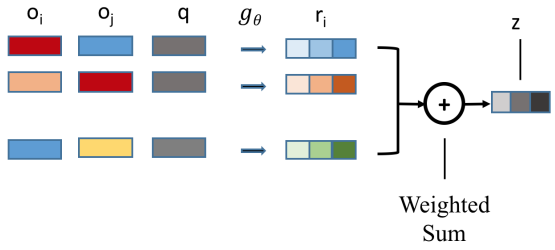

Figure 3: Illustration of a Relation Network. The g_θ is a MLP to score relationships between pairs

3.3 Relation Networks

Extracted objects are subsequently passed to a relation network. We use two layer MLP g_θ (in Figure 3) as a scoring function to compute the similarity between objects. In the question-answering task, the context contains the contextual information necessary to determine whether a question is answerable. Phrases and ideas from various parts of the context need to come together in order to fully understand whether or not a question is answerable. Therefore our relation module takes all pairs of context objects to score, and use the question objects to guide the scoring function. We use 2 question heads q_0, q_1, so our scoring function is:

$$r_i = \sum_{j=0}^{n} \omega_{i,j} * g_\theta(o_i, o_j, q_0, q_1) \quad (7)$$
$$z = \sum_{i=0}^{n} \gamma_i * f_\phi(r_i) \quad (8)$$

where the outputs r_i is the weighted sum of the relation values for object o_i from O, and z is a summarized relation vector. The weights $\Omega_i = [\omega_{i,0}, ..., \omega_{i,n}]$ and $\Gamma = [\gamma_0, ..., \gamma_n]$ are computed by projecting down the relations scores into a hidden size of 1, and applying softmax.

$$\Omega_i = Softmax(g_\theta(o_i, :, q_0, q_1)w_g) \quad (9)$$
$$\Gamma = Softmax(f_\phi(:)w_f) \quad (10)$$

g_θ and f_ϕ are two layer MLP with activation function $tanh$ to compute and aggregate relational scores. Figure 3 shows the process of a single relation network, where two context objects and question objects are passed in to g_θ to obtain the output z.

We project the weighted sum of f_ϕ with a linear layer to a single value as a representation of the non-answerable score. This score is combined with the start/end logits from the base reader, and trained jointly with the reader's cross-entropy loss. By training jointly, the model is able to make a better prediction based on the confidence of the span prediction, as well as the confidence based on the non-answerable score from the relation module.

4 Question Answering Baselines

We test the relation module on top of our own PyTorch implementation of the BiDAF model (Seo et al., 2017), as well as the recent released BERT base model (Devlin et al., 2018) for the SQuAD 2.0 task. For both of these models, we obtain improvement from adding the relation module. Note that, we do not test our relation module on top of the current leaderboard, as the details are not yet out. We also do not test on top of BERT + Synthetic Self Training (Devlin, 2019) due to lack of computational resources available. We are showing the effectiveness of our method and not trying to compete with the top of the leaderboard.

4.1 BiDAF

We implement the baseline BiDAF model for SQuAD 2.0 task (Clark and Gardner, 2018) with some modifications: adding features that are commonly used in question answering tasks such as TF-IDF, POS/NER tagging, etc, and the auxiliary training losses from (Hu et al., 2019). These modifications to the original BiDAF bring about 3.8% gain of F1 on the SQuAD 2.0 development set (see Table 1).

The input to the relation module is the context vector that is generated from the bi-directional attention flow layer. This context layer is augmented with the hidden states of linear layers trained against plausible answers, which also takes the context layer from the attention flow layer as input. This configuration is shown in Figure 4.

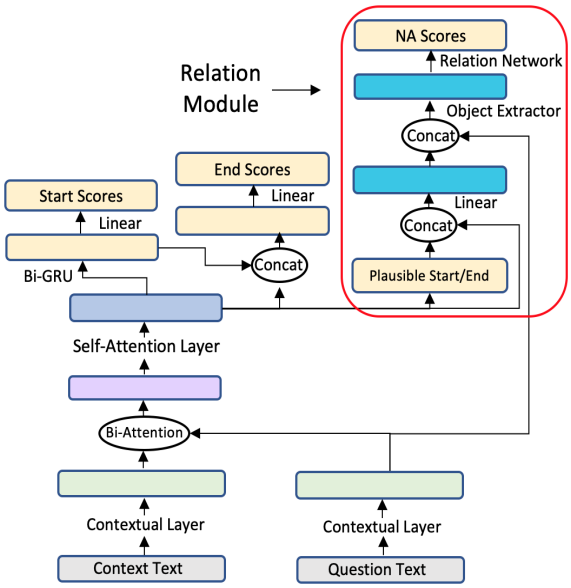

Figure 4: Relation Module applied on BiDAF.

4.2 BERT

BERT is a masked language model pre-trained on large amounts of data that is the core component of all of the current state-of-the-art models on the SQuAD 2.0 task. The input to BERT is the concatenation of a question and context pair in the form of ["CLS"; question; "SEP"; context; "SEP"]. BERT comes with its own special "CLS" token, which is pre-trained on a next sentence pair objective in order to encode entailment information between the two sentences during the pre-training scheme.

We leverage this "CLS" node with the relation module by concatenating it with the output of our Relation Module, and projecting the values down to a single dimension. This combines the information stored in the "CLS" token that has been learned from the pre-training, as well as the information that we learn through our relation module. We allow gradients to be passed through all layers of BERT, and finetune the initialized weights with the SQuAD 2.0 dataset.

5 Experiments

We experiment on the SQuAD 2.0 dataset (Rajpurkar et al., 2018) which contains question and context examples that are crowd-sourced from Wikipedia. Each example contains an answer span in the passage, or an empty string, indicating that an answer doesn't exist. The results are reported on the SQuAD 2.0 development set.

Model	EM(%)	F1(%)
(Clark and Gardner, 2018)	61.9	64.8
Our Implementation of BiDAF	65.7	68.6
BiDAF + Relation Module	**67.7**	**70.4**
BERT-base	73.6	76.6
BERT-base + Relation Module	**74.2**	**77.6**
BERT-large	78.9	82.1
BERT-large + Relation Module	**79.2**	**82.6**

Table 1: Model performance on SQuAD 2.0 development set averaged over three random seeds.

Model	EM(%)	F1(%)
BERT-base	70.7	74.4
BERT-base +Answer Verifier	71.7	75.5
BERT-base + Relation Module	**73.2**	**76.8**

Table 2: SQuAD 2.0 leaderboard numbers on the BERT-base Models. Our model shows improvement over the public BERT-base models on the official evaluation.

We use the following parameters in our BiDAF experiment: 16 context heads, 2 question heads. We set our regularization loss weight for the object extractor to be 0.0005. We use Adam optimizer (Kingma and Ba, 2014), with a start learning rate of 0.0008 and decay the learning rate by 0.5 with a patience of 3 epochs. We add auxiliary losses for plausible answers, and re-rank the non-answerable loss as in (Hu et al., 2019).

BERT comes in two different sizes, a BERT-base model (comprising of roughly 110 million parameters), and a BERT-large model (comprising of roughly 340 million parameters). We use the BERT-base model to run our experiments due to the limited computing resources that training the BERT-large model would take. We only use the BERT-large model to show that we still get improvements with the relation module. The relation module on top of the BERT-base model only contains roughly 10 million parameters.

We use the BERT-base model to run our experiments with the same hyper-parameters given on the official BERT GitHub repository. We use 16 context objects, 2 question heads, and a regularization loss of 0.0005. We also show that on top of the BERT-large model, on the development set, our relation module still obtains performance gain[1]. We use the same number of objects, and the same regularization losses for the BiDAF model experiments.

[1]We do not have enough time to get official SQuAD 2.0 evaluation results for the large BERT models.

	Answerable	Non-Answerable
BERT-base	81.5	78.3
+ Relation Module	**82.1**	**82.1**

Table 3: Prediction accuracies on answerable and non-answerable questions on development set.

Table 1 presents the results of the baseline readers with and without the relation module on the SQuAD development set. Our proposed relation module improves the overall F1 and EM accuracy: 2.0% gain on EM and 1.8% gain on F1 on the BiDAF, as well as 0.8% gain on EM and 1.0% gain on F1 on the BERT-base model. Our relation module is able to take relational information between object-pairs and form a better no-answer prediction than a model without it. The module obtains less gain (0.5% gain of F1) on BERT large model due to the better performance of BERT large model. This module is reader independent and works for any reading comprehension model related to non-answerable tasks.

Table 2 presents performance of three BERT-base models with minimum additions taken from the official SQuAD 2.0 leaderboard. We see that our relation module gives more gain than an Answer Verifier on top of the BERT-base model. Our module gains 1.3% F1 over the Answer Verifier.

Since our relation module is designed to help a MRC model's ability to judge non-answerable questions, we examine the accuracy when a question is answerable and when a question is non-answerable. Table 3 compares these accuracy numbers for these questions with and without the relation module on top of the BERT-base model. The relation module improves prediction accuracy for both types of questions, and with more accuracy gain on the non-answerable questions: close to 4% gain on the non-answerable questions, which is more than 200 non-answerable questions are correctly predicted.

6 Ablation Study

We conduct an ablation study to show how different components of the relation module affects the overall performance for the BERT-base model. First we test only adding plausible answers on top of the BERT-base model, in order to quantify the gain in span prediction that adding these extra answers in would give. We show that with just adding plausible answers, the average of the

Model	EM(%)	F1(%)
BERT-base	73.6	76.6
BERT-base+Plausible Answers	73.5	76.9
BERT-base+RM-Plausible Answers	73.6	76.9
BERT-base+RM (4 heads)	74.1	77.4
BERT-base+RM (16 heads)	**74.2**	**77.6**
BERT-base+RM (64 heads)	74.0	77.2

Table 4: Ablation study on our Relation Module. We experiment with just having plausible answers, just having relation network, and different number of heads for the objects extracted by the relation network. Each of these values are averaged over three random seeds.

three seeds gain only about a 0.3 F1. This gain in F1 is due to the BERT layers being fine-tuned on more answer span data that we provide. Next we study the effects of removing augmenting the context vector with plausible answers. We feed the output of our BERT-base model directly into the object extractor and subsequently to the relation network. This quantifies the effect of forcing the self-attentive heads to focus on a plausible answer span. We notice that this performs comparably to just adding plausible answers, also with only around a 0.3 F1 gain.

Finally, we conduct a study to see the effects of different number of heads on our relation module. We experiment with 4, 16, and 64 heads, with 16 heads performing the best out of these three configurations. Having too few heads hinders the performance due to not enough information being propagated for the relation network to operate on. Having too many heads will introduce redundant information, as well as incorporating extraneous noise for our model to sift through to generate meaningful relations.

7 Analysis

In order to gain better understanding on how the relation module helps on the unanswerable prediction, we examine the objects extracted from the multi-head self-attentive pooling. This is to check whether the relevant semantics are extracted for the relation network. Examples are selected from the development set for data analysis.

In Example 1, the BERT-base model incorrectly outputs "Northridge earthquake" (in red) as the answer. However, after adding our relation module, the model rejects this possible answer and outputs a non-answerable prediction.

The two objects from the question highly attend to token "million" (see the bottom subplot in Figure 5). The top row purple object covers token "1994" , "##ridge earthquake" in the possible answer span window, and "billion" near the end of the context window. We hypothesize that the relation network rejects the possible answer "Northridge earthquake" due to the mismatch of "million" in the question objects and "billion" in the purple context object, and relation scores from all other object pairs.

Example 2 shows another example of non-answerable question and context pair. The BERT-base model incorrectly outputs "input encoding" (in red) as its prediction, while adding our relation module on the BERT-base model predicts correctly that the question is not answerable. Fig-

Example 1
Context: Each year, the southern California area has about 10,000 earthquakes. Nearly all of them are so small that they are not felt. Only several hundred are greater than magnitude 3.0, and only about 1520 are greater than magnitude 4.0. The magnitude 6.7 1994 **Northridge earthquake** was particularly destructive, causing a substantial number of deaths, injuries, and structural collapses. It caused the most property damage of any earthquake in U.S. history, estimated at over $20 billion.
Question: What earthquake caused $20 million in damage?
Answer: None.

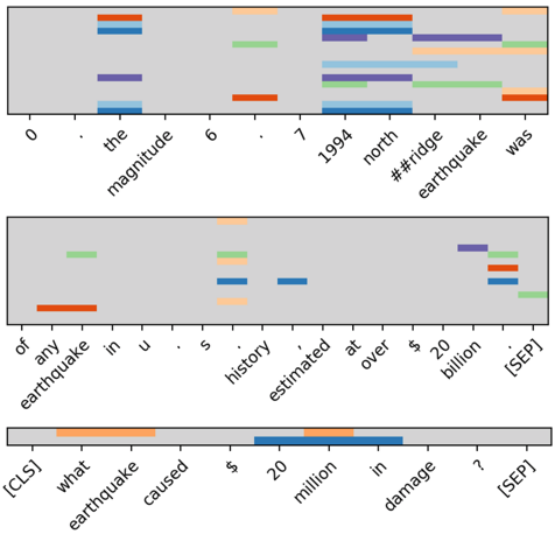

Figure 5: In each subplot, each row represents one object from our object extractor; for each object we highlight the top 5 tokens with highest weights in the entire context and question. We show the two windows where the majority of these top 5 weights occur. For example, the top purple object in the context looks at key phrases such as "##ridge earthquake" in the top subplot and "billion" in the middle subplot; the blue object in the question looks at "20 million in" in the bottom subplot.

Example 2
Context: Even though some proofs of complexity-theoretic theorems regularly assume some concrete choice of **input encoding**, one tries to keep the discussion abstract enough to be independent of the choice of encoding. This can be achieved by ensuring that different representations can be transformed into each other efficiently.
Question: What is the abstract choice typically assumed by most complexity-theoretic theorems?
Answer: None.

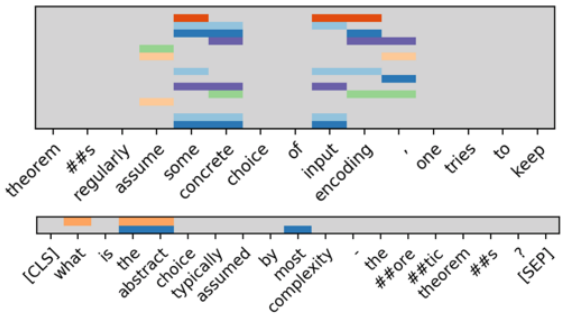

Figure 6: In each subplot, each row represents one object from our object extractor; for each object we highlight the top 5 tokens with highest weights in the entire context and question. We show a window where the majority of the top 5 weights occur. For example, there are numerous objects in the context window that look at the key phrase "some concrete" in the top subplot; the two objects in the question look at the key phrase "the abstract" in the bottom subplot.

ure 6 gives a visual illustration of objects extracted from context and question. In Figure 6, the upper plot illustrates the 16 semantic objects shown in this context window and the lower plot illustrates the two semantic objects from the question. We see that from the upper plot, "some concrete" and "input encoding" are highlighted, while in the lower plot, "what", "the abstract", "most" are highlighted. The mismatch of "the abstract" from the question objects and "some concrete" from the context objects helps indicate that the question is unanswerable.

8 Conclusion

In this work we propose a new relation module that can be applied on any MRC reader and help increase the prediction accuracy on non-answerable questions. We extract high level semantics from multi-head self-attentive pooling. The semantic object pairs are fed into the relation network which makes a guided decision as to whether a question is answerable. In addition we augment the context vector with plausible answers, allowing us to extract objects focused on the proposed answer span, and differentiate from other objects that are not as relevant in the context. Our results on the SQuAD 2.0 dataset using the relation module on both BiDAF and BERT models show improvements from the relation module. These results prove the effectiveness of our relation module.

For future work, we plan to generalize the relation module to other aspects of question answering, including span prediction or multi-hop reasoning.

Abstract

Task oriented language understanding (LU) in human-to-machine (H2M) conversations has been extensively studied for personal digital assistants. In this work, we extend the task oriented LU problem to human-to-human (H2H) conversations, focusing on the slot tagging task. Recent advances on LU in H2M conversations have shown accuracy improvements by adding encoded knowledge from different sources. Inspired by this, we explore several variants of a bidirectional LSTM architecture that relies on different knowledge sources, such as Web data, search engine click logs, expert feedback from H2M models, as well as previous utterances in the conversation. We also propose ensemble techniques that aggregate these different knowledge sources into a single model. Experimental evaluation on a four-turn Twitter dataset in the restaurant and music domains shows improvements in the slot tagging F1-score of up to 6.09% compared to existing approaches.

1 Introduction

Spoken Language Understanding (SLU) is the first component in digital assistants geared towards task completion, such as Amazon Alexa or Microsoft Cortana. The input to an SLU component is a natural language utterance from the user and its output is a structured representation that can be used by the downstream dialog components to select the next action. The structured representation used by most standard dialog agents is a semantic frame consisting of domains, intents and slots (Tur and De Mori, 2011). For example, the structured representation of "Find me a cheap Italian restaurant" is the domain **Restaurant**, the intent *find_place*, and slots $[cheap]_{price_range}$, $[Italian]_{cuisine}$, $[restaurant]_{place_type}$. Different sub-tasks within SLU have been extensively studied for human-to-machine (H2M) task completion scenarios (Sarikaya et al., 2016).

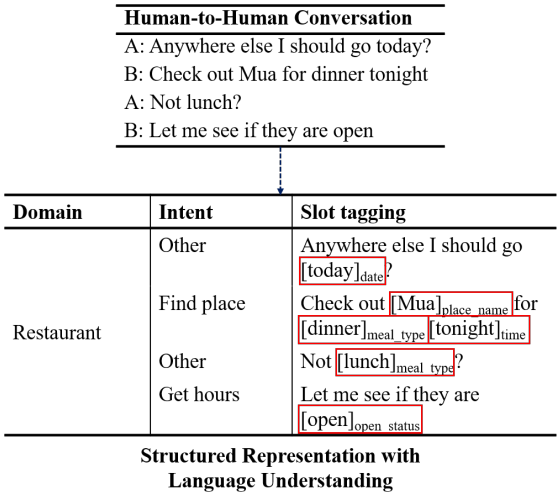

Figure 1: Example of language understanding for task completion on a H2H conversation. In this work, our goal is to identify useful slots (marked with red rectangles).

We extend the task oriented SLU problem to human-to-human (H2H) conversations. A digital assistant can listen to the conversation between two or more humans and provide relevant information or suggest actions based on the structured representation captured with SLU. Figure 1 shows an example of capturing intents and slots expressed implicitly during a conversation between two humans. The digital assistant can show general information about the restaurant Mua, and provide the opening hours based on the captured structured representation. These types of H2H task completion scenarios may allow digital assistants to suggest useful information to users in advance without them needing to explicitly ask questions.

In this paper, we investigate SLU oriented to-

*Work done while the author was at Microsoft Corporation

Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

wards task completion for H2H scenarios with a specific focus on solving the **slot tagging** task. Some early conceptual ideas on this problem were presented in DARPA projects on developing cognitive assistants, such as CALO[1] and RADAR[2]. This work can be seen as an effort to formalize the problem and propose a practical framework.

SLU for task completion in H2H conversations is a challenging problem. Firstly, since the problem has not been studied before, there are no existing datasets to use. Therefore, we built a multi-turn dataset for two H2H domains that we found to be prevalent in Twitter conversations: **Music** and **Restaurants**. The dataset is described in more detail in Section 4. Secondly, the task is harder than H2M conversations in several aspects. It is hard to identify the semantics of noisy H2H conversation text with slang and abbreviations, and such conversations have no explicit commands toward the digital assistants requiring the assistant to indirectly infer users intent.

In this work, we introduce a modular architecture with a core bi-directional LSTM network, and additional network components that utilize knowledge from multiple sources including: sentence embeddings to encode semantics and intents of noisy texts with web-data and click logs, H2M based expert feedback, and contextual models relying on previous turns in the conversation. The idea of adding components is inspired from some recent advances in H2M SLU that use additional encoded information (Chen et al., 2016; Su et al., 2018; Kim et al., 2017; Jha et al., 2018). However, these work only considered adding a component from a single knowledge resource. Furthermore, since these additional components bring in information from different perspectives, we also experimented with deep learning based ensemble methods. Our best ensemble method outperforms existing methods by 6.09% for the *Music* domain and 2.62% for the *Restaurant* domain.

In summary, this paper makes the following contributions:

- A practical framework on slot tagging for task oriented SLU on H2H conversations using bidirectional LSTM architecture.
- Extension of the LSTM architecture utilizing knowledge from external sources (e.g. Web data, click logs, H2M expert feedback, and pervious sentences) with deep learning based ensemble methods
- Newly developed dataset for evaluating task oriented LU on H2H conversations

We begin by describing our methods for H2H slot tagging in Section 3. We then describe the data used in our experiments in Section 4 and discuss results in Section 5. This is followed by a review of the related work and conclusion.

2 Related Work

LU involves domain classification, intent classification, and slot tagging (Tur and De Mori, 2011; Sarikaya et al., 2016). Recently various deep neural network (DNN) models have been studied to solve each of these task, such as deep belief network (Sarikaya et al., 2011), deep convex network (Deng et al., 2012), RNN and LSTM (Ravuri and Stolcke, 2015; Mesnil et al., 2015).

Recent advances in LU use additional encoded information to improve DNN based models. There have been some attempts to use data or models from existing domains. One direction is to do transfer learning. Kim et al. (2017) and Jha et al. (2018) utilized previously trained models relevant to the target domain as expert models. They use the output of expert models as additional input to add relevant knowledge while training for the target domain. Goyal et al. (2018) reused low-level features from previously trained models and only retrained high level layers to adapt to a new domain.

There have also been some attempts to use contextual information. Xu and Sarikaya (2014) used past predictions of domains and intents in the previous turn for predicting current utterance. Chen et al. (2016) expanded upon this work by using a set of past utterances utilizing a memory network (Sukhbaatar et al., 2015) with an attention model. Subsequent works attempted to use the order and time information. Bapna et al. (2017) additionally used the chronological order of previous sentences, and Su et al. (2018) used time decaying functions to add temporal information.

Our work trains a sentence embedding that encodes the semantics and intents. DSSM and its variants (Huang et al., 2013; Shen et al., 2014; Palangi et al., 2016) are used for training sentence embedding, which were originally used for finding

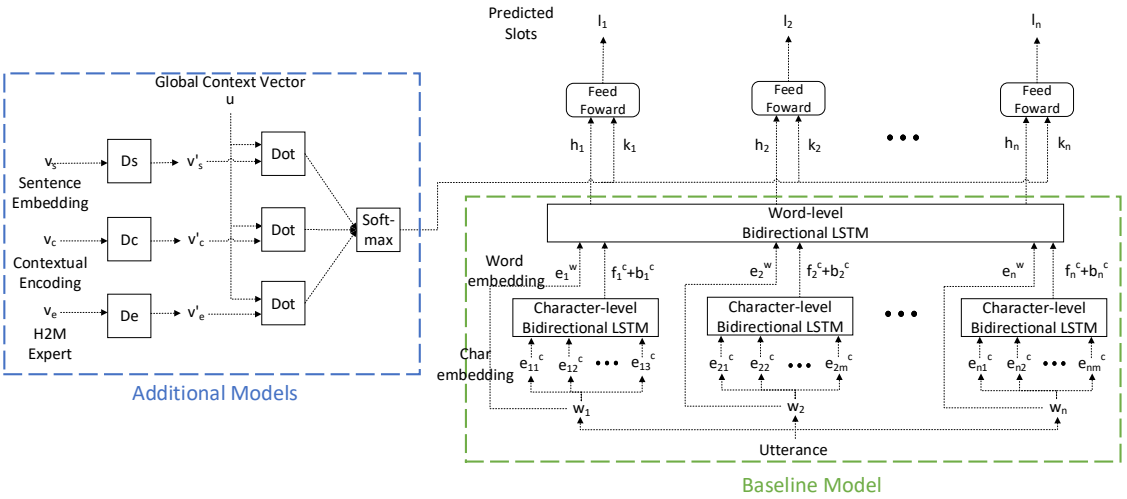

Figure 2: Overview of our slot tagging architecture. Our architecture consists with the core network (Section 3.1) and additional network components utilizing knowledge from multiple sources (Each discussed in Section 3.2.1, 3.2.2, 3.2.3). A network ensembling approach is applied on additional components (Section 3.3), figure shows with the attention mechanism.

relevance between the query and retrieved documents in a search engine. Also there have been attempts to use sentence embeddings similar to our data (Twitter). Dhingra et al. (2016) trained an embedding for predicting hash tags of a tweet using RNNs, Vosoughi et al. (2016) used an encoder-decoder model for sentiment classification.

All of the previous methods have studied LU components for task completion in H2M conversations. On the other hand, prior work on LU on H2H conversations has focused on dialog state detection and tracking for spoken dialog systems. Shi et al. (2017) used CNN model, and later extended multiple channel model for a cross-language scenario (Shi et al., 2016). Jang et al. (2018) used attention mechanism to focus on words with meaningful context, and Su et al. (2018) used a time decay model to incorporate temporal information.

3 Methods

Figure 2 shows the overview of our slot tagging architecture. Our modular architecture is a core LSTM-based network and additional network components that encode knowledge from multiple sources. Slot prediction is done with the final feed forward layer, whose input is the composition of the output of the core network and the additional components. We first describe our core network and then the additional network components, followed by our network ensembling approach.

3.1 Core Network

Our core network is a bidirectional model similar to Lample et al. (2016). The first character-level bidirectional LSTM layer extracts the encoding from a sequence of characters from each word. Each character c is represented with a character embedding $e^c \in \mathbb{R}^{25}$, and the sequence of the embedding is used as the input. The layer outputs

$$f^c = LSTM_{forward}(e^c) \quad (1)$$
$$b^c = LSTM_{backward}(e^c) \quad (2)$$

for each character, where $f^c, b^c \in \mathbb{R}^{25}$.

The second word-level bidirectional LSTM layer extracts the encoding from a sequence of words for each sentence. For each word w_i, the input of the layer is $g_i = f_i^c \oplus b_i^c \oplus e_i^w$ where f_i^c and b_i^c is the output of previous layer, $e_i^w \in \mathbb{R}^{100}$ is the word embedding vector, and $\oplus$ is a concatenation operator of vectors. We use pre-trained GloVe with 2B tweets [3] (Pennington et al., 2014) for the word embedding. The forward and backward word-level LSTM's produce

$$f_i^w = LSTM_{forward}(g_i) \quad (3)$$
$$b_i^w = LSTM_{backward}(g_i) \quad (4)$$

where $f_i^w, b_i^w \in \mathbb{R}^{100}$. Finally, slot l_i is predicted with the last feed forward layer with the input $h_i = f_i^w \oplus b_i^w$.

[3] Downloaded from https://nlp.stanford.edu/projects/glove/

Our model is trained using stochastic gradient descent with Adam optimizer (Kingma and Ba, 2015), with the mini batch size 64 and the learning rate 0.7×10^{-3}. We also apply dropout (Srivastava et al., 2014) on embeddings and other layers to avoid overfitting. The learning rate and dropout ratio were optimized using random search (Bergstra and Bengio, 2012). The core network can be used alone for slot tagging, however we discuss our additional network components in the following sections for improving our architecture.

3.2 Additional Network Components

In this section, we discuss additional network components that encode knowledge from different sources. Encoded vectors are used as additional input to the feed forward layer as shown in Figure 2.

3.2.1 Sentence Embedding for H2H Conversations

Texts from H2H conversations are noisy and contain slang and abbreviations, which can make identifying their semantics challengins. In addition, it can be challenging to infer their intents since there are no explicit commands toward the digital assistants. The upper part of Figure 3 shows part of a conversation from Twitter. The sentence lacks the semantics needed to fully understand "club and country". However, if we follow the URL in the original text, we can get additional information to assist with the understanding. For instance, the figure shows texts found from two sources, **1) web page title of the URL in the tweet** and **2) web search engine queries that lead to the URL in the tweet**. We use web search queries and click logs from a major commercial Web search engines to find queries that lead to clicks on the URL. Using this information, we can infer from the Web page title that the "club and country" referred to in the tweet are Atletico Madrid and Nigeria. Furthermore, the search queries from the search engine logs indicates possible user intents.

In our approach, we encode knowledge found from these two sources based on the URL. In our dataset, we were able to gather 2.35M pairs of tweet text with URL and web search engine queries that lead to the same URL, and 420K pairs of tweet text and web page titles of the URL. We then use this information to train a sentence embedding model that can be used to encode the semantics and implicit intents of each H2H conversation sentence. Our approach is to train a model that projects texts from H2H conversation and texts from each knowledge sources into a same embedding space, keeping the corresponding text pairs close to each other with other non-relevant texts being apart, as shown in Figure 3. The learned embedding model F then can be used to represent any texts from H2H sentences with a vector with semantically similar texts (or similar intents) being projected close to each other in the embedding space. Embeddings are used as additional component of our modular architecture, so that the semantic and intent information can be utilized in our slot tagging model.

We use the deep structured semantic model (DSSM) architecture (Huang et al., 2013) to train the sentence embedding encoder. DSSM uses letter-trigram word hashing, so it is capable of partially matching noisy spoken words so that we can get more robust sentence embeddings for H2H conversations. Let S be the set of sentences from the H2H conversations that have the URL. For each sentence $s \in S$, we find corresponding texts (**web page title of the URL, web search engine queries to the URL**) T_s^+ and randomly choose non-related texts T_s^- from corresponding texts of other sentences (in other words, from different URLs). Like the original DSSM model, each sentence s, $t_s^+ \in T_s^+$, and $t_s^- \in T_s^-$ are initially encoded with letter-trigram word hashing vector x, and used as the input of two consecutive dense layers,

$$x' = W_1 x + b_1 \tag{5}$$

$$y = W_2 x' + b_2 \tag{6}$$

where $x' \in \mathbb{R}^{1000}$ and $y \in \mathbb{R}^{300}$. We train the model to favor choosing $t_s^+ \in T_s^+$ over $t_s^- \in T_s^-$ for each s. So the loss function is defined as minimizing the likelihood,

$$\text{loss} = -\log \prod_{s, T_s^+} P(T_s^+|s) \tag{7}$$

$$P(T_s^+|s) = \prod_{s, t_s^+ \in T_s^+} \frac{\exp(\gamma \text{sim}(s, t_s^+))}{\sum_{t \in T} \exp(\gamma \text{sim}(s, t))} \tag{8}$$

$$\text{sim}(s, t_s^+) = \cos(y_s, y_{t_s^+}) \tag{9}$$

where cos is cosine similarity of two encoded vectors. Please refer to the original paper (Huang et al., 2013) for further details. The dropout ratio,

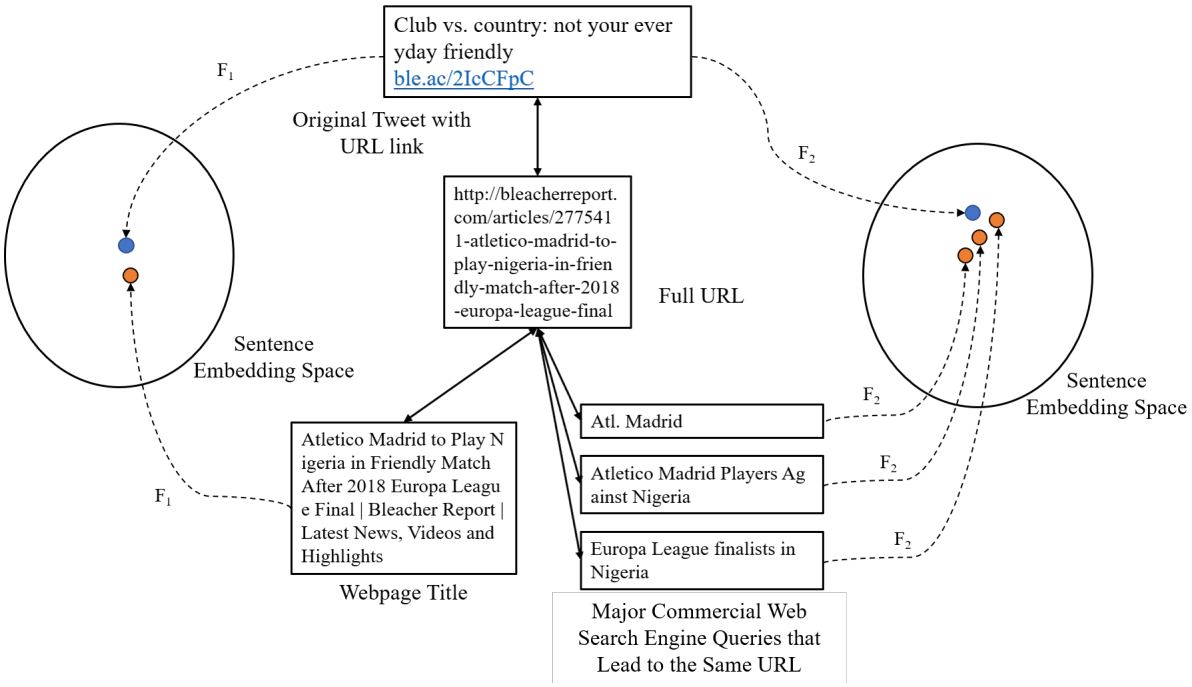

Figure 3: Example of H2H conversation text with URL link and corresponding texts found by following the URL. We use those two sources of corresponding texts to train sentence embedding models. Each model projects the original text and its corresponding texts to a close position in the sentence embedding space, while non-relevant texts are being apart.

learning rate, and γ are selected based on a random search (Bergstra and Bengio, 2012), which are 0.0275, 0.4035×10^{-2}, and 15 respectively. The output of the second dense layer y of trained model is used as the sentence embedding: for each sentence we extract the sentence embedding $v_s \in \mathbb{R}^{300}$.

3.2.2 Contextual Information

Contextual information extracted from previous sentences is known to be useful to improve understanding of human spoken language on other scenarios (Xu and Sarikaya, 2014; Chen et al., 2016; Su et al., 2018). To obtain knowledge from a previous sentence in the conversation, we extract a contextual encoded vector using the memory network (Chen et al., 2016), which uses the weighted sum of the output of word-level bidirectional LSTM h in the core network (Section 3.1) from previous sentences. We did not consider a time decaying model (Su et al., 2018) since our data has a small number of turns.

We tested the model with some variations on 1) number of previous sentences to use and 2) weighting scheme (uniform or with attention). using the implementation from the original paper[4]. From our experiments, the best result was achieved using the previous two sentences with a uniform weight. We use this model to extract the contextual encoded vector $v_c \in \mathbb{R}^{100}$.

3.2.3 Human-to-Machine Expert Feedback

Kim et al. (2017) and Jha et al. (2018) introduced a transfer learning method, which reuses the knowledge from existing trained models on relevant domains (i.e. expert models) to take advantage of previous knowledge to train on a new domain. They extract the output of the expert model and use it as an additional input of feed forward layer for the model on a new domain.

We adopt this idea to take advantage of massive amount of labeled data for H2M conversations. Instead of transferring knowledge from domain to domain, we transfer the knowledge of different tasks within a similar domain. For example, we use **Places (H2M)** domain for the **Restaurant (H2H)** domain, and **Entertainment (H2M)** domain for the **Music (H2H)** domain. We use previously trained slot tagging models on H2M conversations on similar domains as our expert model, which has the same architecture as our core net-

[4] https://github.com/yvchen/ContextualSLU

work (Section 3.1). These H2M models were originally used for the SLU component of a commercial digital assistant. The output of word-level bidirectional LSTM h is then extracted as the encoded vector from H2M expert model $v_e \in \mathbb{R}^{200}$.

3.3 Network Ensemble Approaches

Since additional network components (sentence embedding v_s, contextual information from previous turns of the conversation v_c, and H2M based expert feedback v_e) bring information from different perspectives, we discuss how to compose them into a single vector k with various ensemble approaches.

- **Concatenation**: Here, we simply concatenate all encodings into a single vector,

$$k = v_s \oplus v_c \oplus v_e \tag{10}$$

- **Mean:** We first apply a separate dense layer to each encoded vector to match dimensions and transform into the same latent space, and then take the arithmetic mean of transformed vectors.

$$v'_{\{s,c,e\}} = W_{\{s,c,e\}} + b_{\{s,c,e\}} \tag{11}$$
$$k = \text{mean}(v'_s, v'_c, v'_e) \tag{12}$$

  In the Figure 2, we denote the dense layer applied to each encoded vector $v_{\{s,c,e\}}$ as $D_{\{s,c,e\}}$ for simplicity of representation. Each transformed vector $v'_{\{s,c,e\}} \in \mathbb{R}^{100}$, so $k \in \mathbb{R}^{100}$.

- **Attention:** We apply an attention mechanism to apply different weights on the encoded vectors for each sentence. For our problem, it is not straightforward to define a context vector for each sentence to calculate the importance of each encoded vector; therefore, we adopted the idea of using a global context vector (Yang et al., 2016). The global context vector $u \in \mathbb{R}^{100}$ can be thought as a fixed query of "*finding the informative encoded vector for slot tagging*" used for each sentence. The weight of each encoded vector is calculated with the standard equation of calculating the attention weight, which is the softmax of the dot product of encoding and context vector,

$$w_{\{s,c,e\}} = \frac{\exp(\tanh(v'_{\{s,c,e\}})^\intercal u)}{\sum_{v' \in \{v'_s, v'_c, v'_e\}} \exp(\tanh(v')^\intercal u))} \tag{13}$$

$$k = w_s v'_s + w_c v'_c + w_e v'_e \tag{14}$$

  where $v'_{\{s,c,e\}}$ are same as Equation 11.

The combined single vector k is then aggregated with the output of core network h, $k \oplus h$ is used as the input of the final feed forward layer as shown in Figure 2. The same hyperparameters (mini batch size, learning rate, dropout ratio) and optimizer is used as stated in the baseline model (Section 3.1).

4 Data

Although some datasets with H2H conversations are available (Forsythand and Martell, 2007; Danescu-Niculescu-Mizil and Lee, 2011; Nio et al., 2014; Sordoni et al., 2015; Lowe et al., 2015; Li et al., 2017), they were not feasible to use for experimenting on our task. All datasets excluding the Ubuntu Dialogue (Lowe et al., 2015) were collected without any restrictions on the domain and, as a result, there were insufficient training samples to train a slot tagging model for a specific domain. In addition, the Ubuntu Dialogue dataset (Lowe et al., 2015) focuses on questions related to Ubuntu OS, which is not an attractive domain an intelligent focus that focuses on task completion rather than question answering.

Since there were no existing datasets that were sufficient for our task in H2H conversation, we built our own dataset for the experiments. It was difficult to acquire actual H2H conversations from instant messages due to privacy concerns. Therefore, we chose to use public conversations on Twitter and extracted sequences in which two users engage in a multi-turn conversation. Using this approach, we were able to collect 3.8 million sequences of four-turn conversations using Twitter Firehose.

We focused on two domains for our experiments: **Restaurants** and **Music**. To acquire the dataset for each domain, we first defined a set of key phrases and found the candidate conversations with at least one of those key phrases. Key phrases consisted of the top 100 most frequently used unigrams and bigrams on each relevant domain from the H2M conversation dataset. We used

Restaurant
A: *[lunch]*$_{meal_type}$?
B: *[lunch]*$_{meal_type}$ sounds good. Our routine usually involves sitting at *[Nano's]*$_{place_name}$ with our packed/purchased *[lunches]*$_{meal_type}$ care to join?
A: great. I'll get something from *[physiol]*$_{place_name}$ and meet you there at...?
B: I'll be there in *[5-10 mins]*$_{time}$
Music
A: *[quavo]*$_{media_person}$ got another one
B: I was bout to listen earlier but it said *[feat]*$_{media_role}$ *[Lil Uzi Vert]*$_{media_person}$ lol
A: he *[rap]*$_{media_genre}$ for about two minutes you don't even gotta listen to *[lil uzi]*$_{media_person}$
B: *[quavo]*$_{media_person}$ already a legend man

Table 1: Example conversation in each domain of our dataset

the H2M **Places** domain to find the top n-grams for the **Restaurant** domain and the H2M **Entertainment** domain to find top n-grams for the **Music** domain. **Places** includes other type of places besides restaurants (e.g. tour sights), and also **Entertainment** includes other genre (e.g. movies). So we manually replaced unigrams and bigrams that were not music or entertainment related, and also some terms that are too general (e.g. time, call, find). We were able to gather 16K and 22K candidate conversations for the **Restaurant** and **Music** domains, respectively, using the keyphrases.

We randomly sampled 10K conversations for each domain for annotating slots and domain. Annotation was done by managed judges, who had been trained over time for annotating SLU components such as intents, slots and domains. A guideline document was provided with the precise definition and annotated examples of each of the slots and intents. Agreement between judges and manual inspection of samples for quality assurance was done by a linguist trained for managing annotation tasks. We also ensured that judges did not attempt to guess at the underlying intents and slots, and annotate objectively within the context from the text. We only keep the conversations that are labeled relevant to each domain by annotators. Table 1 shows an example conversation from the dataset in each domain, and Table 2 shows the dataset statistics.

Domain	#Conv.	#Words/Conv.	#Slots
Restaurant	6,514	37.64	15[5]
Music	5,582	44.72	20[6]

Table 2: Statistics of our dataset. Each column shows the number of items in the dataset. "Conv." stands for conversations.

5 Experiments

5.1 Experimental Setup

All experiments were done with 10-fold cross validation for the slot tagging task, and we generated training, development, test datasets using 80%, 10%, and 10% of the data. The development dataset is used for hyperparameter tuning with random search (Bergstra and Bengio, 2012) and early stopping. The baseline is set with core network only (Section 3.1). We evaluated the performance of each of the models with precision, recall, and F1. We checked for statistical significance over the baseline at the p-value < 0.05 using the Wilcoxon signed-rank test.

5.2 Evaluation on Adding Sentence Embeddings for H2H Conversations

In this section, we evaluate adding the sentence embeddings into our slot tagging architecture introduced in Section 3.2.1. Table 3 shows the results of adding sentence embeddings, compared with the baseline and existing sentence embedding methods. We extracted two months of recent tweets that had non-twitter domain URLs in the text for our method. Below is the brief description of each method:

- DSSM (Deep Structured Semantic Model) (Huang et al., 2013): Pre-trained DSSM model from the authors , trained with pairs of *(Major commercial web search engine queries, clicked page titles)*.
- Tweet2Vec (Dhingra et al., 2016): The model was originally used to predict hashtags of a

[5]Slots in **Restaurant** domain include absolute_location, amenities, atmosphere, cuisine, date, distance, meal_type, open_status, place_name, place_type, price_range, product, rating, service_provided, time.

[6]Slots in **Music** domain include app_name, media_award, media_category, media_content_rating, media_genre, media_keyword, media_language, media_lyrics, media_nationality, media_person, media_price, media_release_date, media_role, media_source, media_technical_type, media_title, media_type, media_user_rating, radio_call_sign, radio_frequency

Model	Restaurant			Music		
	P	R	F1	P	R	F1
Core Network (Baseline)	71.23	62.68	66.63	**64.33**	44.14	51.61
+ DSSM (Huang et al., 2013)	70.82	61.60	65.88*	62.83	43.76	51.57
+ Tweet2Vec (Dhingra et al., 2016)	70.58	59.99	64.75*	62.67	41.38	49.79*
+ Ours *(Tweets, Web Search Engine Queries)*	**71.73**	62.38	66.70	63.13	44.09	51.86
+ Ours *(Tweets, Web Paage Titles)*	71.19	**63.51**	**67.11***	63.70	**44.44**	**52.32**

Table 3: Comparison of adding sentence embedding component to our architecture. P, R, F1 stands for precision, recall, F1-score (%) respectively. * denotes the F1-score is statistically significant compared to the baseline.

tweet. We use the pre-trained model from the authors, which used 2M tweets for training.

- Ours *(Tweets, Web Search Engine Queries)*: Trained our model with 2.35M pairs of *(Tweet text with shared URL, Web serach engine queries that lead to the shared URL)*. We extracted most frequent queries (up to eight) found from the major commercial web search engine query logs.
- Ours *(Tweets, Web Page Titles)*: Trained our model with 420K pairs of *(Tweet text with shared URL, web page title of URL)*.

The result shows that adding our proposed sentence embedding network improves the slot tagging result compared to the baseline, while other previous methods have a negative effect. This implies that 1) a sentence embedding specifically trained for H2H conversation texts are needed (compared with original DSSM), 2) our idea of embedding semantics and intentions from web data and search engine query logs can help to improve the slot tagging task (compared to the Tweet2Vec). Since our sentence embedding network trained with web page titles gives the most significant improvement, we used this for further evaluation.

5.3 Evaluation on Utilizing Knowledge Sources

We also tested adding contextual information and H2M expert feedback network components to our slot tagging architecture. Contextual information is extracted from previous two sentences with uniform weighting. For the H2M expert model, we used the pretrained model of **Entertainment** domain for the target **Music** domain, and the **Places** domain for the target **Restaurant** domain for H2M LU.

The upper part (rows 2-4) in Table 4 shows the result of adding each. Results show that 1) adding network component from each knowledge source leads to an improvement on at least one of the domain, 2) improvement on each method varies with the domain. Adding sentence embeddings and contextual information led to significant improvements for the **Restaurant** domain while contextual information and H2M expert feedback led to significant improvements for the **Music** domain.

5.4 Evaulation on Network Ensemble Approaches

We also conducted an experiment to include all network components to see if we can improve further by considering multiple knowledge sources together. The result is shown in the lower part (row 5-7) of Table 4 with different ensembling methods introduced in Section 3.3. It shows that any of the ensemble approaches to add all of the network components leads to better results than adding either of them individually.

The result implies that each of the proposed method improves the slot tagging method from different perspectives so all of them can be considered. Also, we see that attention has the best results among ensemble approaches, with 2.62% higher F1 score for the **Restaurant** domain, and 6.09% for the **Music** domain compared to the baseline. This implies the attention model can help to find the best way to ensemble additional components by predicting the importance of each component for each sentence. Especially, we could see a statistically significant improvement on the **Music** domain compared with other methods. We believe this is because the improvement of each network component on the **Music** domain is more obvious compared to the **Restaurant** domain. We would like to test in other domains for the future work.

Model	Restaurant			Music		
	P	R	F1	P	R	F1

P, R, F1 stands for precision, recall, F1-score (%) respectively. * denotes the F1 score is statistically significant compared to the baseline. ** denotes the F1 score of ensemble model is also statistically significant compared to the concatenation ensemble model.

6 Conclusion

We studied slot tagging in H2H online text conversations. Starting from a core network with bidirectional LSTM, we proposed to use additional network components and ensemble them to augment useful knowledge from multiple sources (web data, search engine click logs, H2M expert feedback, and previous utterances). Experiments with our four-turn Twitter dataset on **Restaurant** and **Music** domains showed that our method improves up to 6.09%-points higher F1 on slot tagging compared to existing approaches. For future work, we plan to study our model on domain and intent classification, and also on additional domains.

Acknowledgement

We would like to thank Eric Mei and Soumya Batra for their help on data collection and labeling.

Abstract

This paper describes a novel approach for the task of end-to-end argument labeling in shallow discourse parsing. Our method describes a decomposition of the overall labeling task into subtasks and a general distance-based aggregation procedure. For learning these subtasks, we train a recurrent neural network and gradually replace existing components of our baseline by our model. The model is trained and evaluated on the Penn Discourse Treebank 2 corpus. While it is not as good as knowledge-intensive approaches, it clearly outperforms other models that are also trained without additional linguistic features.

1 Introduction

Shallow discourse parsing (SDP) is a challenging problem in NLP with the aim to identify local coherence relations in text. Discourse relations are used in text to connect individual segments of text logically. The Penn Discourse Treebank (PDTB) (Prasad et al., 2008a) adopts a non-hierarchical view on discourse relations. As an example from the PDTB, the sentence:

- *We would stop index arbitrage* when **the market is under stress**.

contains an explicit discourse relation which is signaled through the underlined connective (`Conn`) and further consists of two arguments (`Arg1` in italics and `Arg2` in bold). In addition, a sense is assigned to a relation, such as `Condition`.

Discourse analysis, however, does not work on a sentence-level, but takes full documents into account. Often, short paragraphs suffice to show the challenge in extracting overlapping relations. To illustrate the problem, we split the paragraphs shown in Figure 1 into small text chunks. Though our implementation works on the level of individual tokens, we here use these chunks to highlight challenges in discourse argument labeling. The chunks are delimited such that no smaller part would play exactly the same role for the various relations involved.

If you think you have stress-related problems on the job, there's good news and bad news. You're probably right, and you aren't alone.

...

Even the courts are beginning to recognize the link between jobs and stress-related disorders in compensation cases, according to a survey by the National Council on Compensation Insurance. But although 56% of the respondents in the study indicated that mental-health problems were fairly pervasive in the workplace, there is still a social stigma associated with people seeking help.

you think you have stress-related problems on the job,	`Arg2`	`Arg1`	
there's good news and bad news.	`Arg1`	`Arg1`	
You're probably right,		`Arg2`	`Arg1`
and		`Arg2`	`Conn`
you aren't alone		`Arg2`	`Arg2`

Table 1: First sample paragraph split into text chunks.

The first example (cf. Table 1) shows that (1) each relations argument contains an arbitrary number of tokens. Further, (2) chunks may have multiple functions (class labels) referring to different individual relations, e.g. the "if" of the first chunk is the connective of **R1**, while in **R2** it is part of the first argument. As a special case, (3) they can have the same class label but pointing to different relations. Finally, (4) there is no generally fixed linear order for the classes `Arg1`, `Arg2`, `Conn`, although

the connective is always syntactically integrated with the second argument.

In the second example (cf. Table 2), (5) arguments can cover whole sentences as demonstrated by **R4**. (6) Although two connectives are next to each other, they can have different arguments and thus constitute different relations. Finally, (7) arguments can also consist of non-continuous chunks as in **R5**.

SDP consists of the main tasks of identifying connectives, demarcating their arguments, assigning senses to them, and finding the senses of so-called *implicit relations* holding between adjacent text spans, which are not explicitly signaled by a connective. Lin et al. (2014) presented a full end-to-end shallow discourse parser that solves these subtasks with a sequential pipeline architecture, which served as a model for the vast majority of follow-up work. Recently, however, most work has addressed specifically the last-mentioned task of identifying the senses of implicit relations, which has been found to be by far the most challenging one.

The focus of our work, in contrast, is on identifying and delimiting the arguments of relations as well as the disambiguation of connectives. Our aim is to do this without any engineering of linguistic features, so that the approach can be easily applied to new corpora and new languages. With this perspective, we follow in particular the proposals of Wang et al. (2015) and Hooda and Kosseim (2017). The first work applies a recurrent neural network on selected sentences and labels these sentences on a token-level. The second work extends this idea and uses an LSTM on a restricted form of the argument labeling task. The authors show the feasibility of a neural model for explicit argument labeling on pre-extracted argument spans. They prepare a dataset of argument spans (extracted from their context) and train a recurrent neural network to label each token's position in such a span .

In our work, we extend this idea to make it applicable within the full SDP setting, i.e., on running text rather than on previously extracted individual relations. As a baseline approach, we use our reimplementation of the system of Lin et al. (2014). We study different applications of our neural model and substitute corresponding components for argument extraction from the baseline pipeline: First we address extracting the arguments of connectives that are already given; this is a sensible assumption since models for connective classification (Pitler and Nenkova, 2009) work quite well. Then, we extend this approach by removing the dependency on previously identified connectives. This step is not easy, because the connectives serve to identify the number of explicit relations in a document. Because the number of relations is initially not clear when connectives are missing, we adapt a sliding window approach for decomposing the text in overlapping windows. We then develop a process of identical *prediction* steps (one for each possible window within a document) and one final *aggregation* step, which combines the individual results into the final set of predicted relations. As an outlook, we study the capacity of our neural model for the joint prediction of explicit and implicit relation arguments.

The main contributions of this paper are

1. integrating a BiLSTM model into the shallow discourse pipeline architecture, and

2. addressing the problem of jointly predicting connective and arguments with a moving-window approach for handling overlapping relations in running text.

In the following, Section 2 discusses relevant related work, and Section 3 explains our method. The experiments and results are presented in Section 4, followed by a discussion in Section 5 and conclusions in Section 6.

2 Related Work

The task of shallow discourse parsing was initiated by the development of the second version

of the Penn Discourse Treebank (PDTB2) (Prasad et al., 2008b) and further by the shared tasks at CoNLL 2015 and 2016 (Xue et al., 2015, 2016). Successful systems at these competitions were those of Wang et al. (2015); Wang and Lan (2016); Oepen et al. (2016). They followed the pipeline model of (Lin et al., 2014), which consists of successive tasks of connective identification, argument labeling, and sense classification for both explicit and implicit relations. Similar to other approaches used for argument extraction (e.g., (Wang et al., 2015; Laali et al., 2016; Oepen et al., 2016)), these competing systems use standard supervised machine learning models in combination with handcrafted linguistic features, such as syntactic, positional, and lexical features.

For argument labeling (or 'extraction'), the exact boundaries of both arguments must be identified. At the CoNLL shared task 2016, Stepanov and Riccardi (2016) reported the best scores for argument extraction with F-measures of 49.64% for `Arg1` and 76.51% for `Arg2`. In contrast to the systems mentioned before, their approach involves conditional random fields (CRF) (Lafferty et al., 2001), which are generally popular for the task of sequence labeling. Also, Ghosh et al. (2011b,a) formulate argument extraction as a token-level sequence labeling problem and use a pipeline of cascaded conditional random fields to mark up each token in a window. On top of a connective classifier, they first predict `Arg2` due to the closeness to the connective. For the prediction of `Arg1`, they use the same feature set as for the former prediction and additionally take the `Arg2` predictions into account. Similar to us, they use a window around the connective (2 sentences before and after the sentence with the connective). They report scores of about 79% F-measure for `Arg2` and 57% F-measure for `Arg1` with their approach. Our approach differs from theirs in that we use tokens instead of full sentences to create windows. This is necessary because a single sentence might contain multiple connectives and participate in more than one discourse relation (cf. the examples shown in Section 1).

A moving-window approach similar to ours is used, for example, by Graves and Schmidhuber (2005) in their work on phoneme classification. The task is quite different for SDP argument labeling, however, as a word's label highly depends on the word's context and the corresponding relation the word is associated with. Thus, we cannot apply such an approach directly and hence define an aggregation procedure for combining the individual per-window predictions.

Argument labeling with recurrent neural networks was done by Wang et al. (2015) in their DCU parser. In addition to word embeddings, they also used hand-crafted features, such as POS tags, syntactic relations, and lexical features. In contrast, our aim is to explore to what extent the problem can be solved *without* feature engineering. Thus, the main inspiration for our approach is the recent work of Hooda and Kosseim (2017), who use an LSTM network on spans of text for labeling arguments. The authors examine their approach on pre-extracted argument spans where the size of spans is determined by the maximal argument pair distance. This shows the feasibility of neural networks to label discourse arguments in a restricted problem setting. Like in our work, they do not rely on additional data other than word embeddings. In contrast to them, we use the embeddings as they are provided, without further adaption throughout the training. In our experiments, we could not identify gains in performance and thus save computation time by reducing trainable parameters.

3 Method

The main goal of our work is to replace existing components in the general discourse parser pipeline framework with our neural model. Depending on which component we want to substitute, we need different methods for processing the discourse.

Our first approach is to replace the argument extraction module, which operates on the basis of previously identified connectives. After that, we introduce an extended model that jointly predicts connectives and their arguments. As demonstrated in Section 1, the main challenge in this task is that a text contains multiple, potentially overlapping, relations that have to be predicted.

Our approach is to decompose the text (and thereby the SDP task) into a series of smaller texts, viz. into a sequence of overlapping windows. For each window, the statistical model is trained to recognize a possibly partial relation. Afterwards, a final aggregation process combines the individual window predictions and thus realizes the argument extraction for a full text.

We describe the baseline discourse parser in

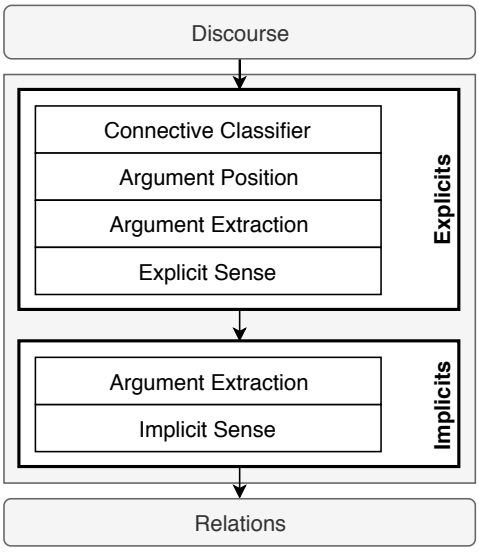

Figure 2: Baseline architecture proposed by Lin et al. (2014) that has been used throughout the experiments.

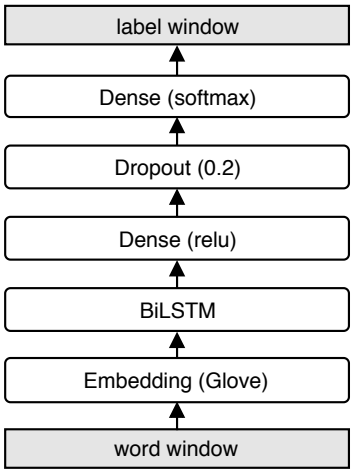

Figure 3: Bidirectional LSTM model architecture. First, tokens in a window are processed sequentially using the recurrent network. Then, each time step is transformed independently using one dense layer for transformation and one dense layer for the final prediction.

Section 3.1. The window model for predicting just arguments is explained in Section 3.2, and its extension to also handle connectives in Section 3.3. Thereafter, we turn to more training and evaluation details in Section 4.

3.1 Baseline: Shallow Discourse Parser

Our baseline discourse parser is inspired by the architecture of the (Lin et al., 2014) parser and consists of several components within a pipeline (see Figure 2). First, explicit relations are identified by classifying connectives, deciding the relative position of the first argument (whether it is contained in the previous sentence or the same sentence as the second argument), then delimiting the arguments, and finally recognizing the sense. In a second phase, implicit relations are classified between adjacent sentences where no explicit relations were found. For the argument extraction component, Lin et al. use a constituent-level approach by iterating over possible subtrees within a sentence and selecting the most likely `Arg1` and `Arg2`.

3.2 Window-based Argument Prediction

For our first approach, we propose a neural network as shown in Figure 3 to predict discourse relations given a sequence of words. Specifically, it operates on a window of words, which we build around a connective that we assume to have been identified by a previous module in the pipeline. Then, for each token the prediction task is defined as a four-way classification problem, i.e., the label is one of `None`, `Arg1`, `Arg2`, or `Conn`[1], as in the work by Hooda and Kosseim (2017) and similar to the window-based approach of Ghosh et al. (2011a).

Each word in the input sequence is embedded into lower-dimensional space. Because of the small size of the PDTB corpus, we use pretrained word embeddings, and these are further processed with a bidirectional Long Short-Term Memory network (BiLSTM). LSTMs have shown better performance compared to simple recurrent neural networks due to their higher capacity for storing important information over longer distances. Further improvements are gained through the bidirectional processing of sequential information (Graves and Schmidhuber, 2005). We keep hidden states for each time step and propagate them to the next layer. For our *BiLSTM* model, the hidden states are processed independently by a dense layer and finally are given to the top output layer (see Figure 3). Between the two dense layers, an additional dropout layer is used for better generalization.

3.3 Joint Prediction of Arguments and Connectives

To apply our model on a text without pre-identified connectives (i.e., to jointly predict connectives and their arguments), we need to adapt training and in-

[1]Notice that while the previously-given connective was used to define the position of the window, we still predict connectives in this model in order to support argument identification (but we will not evaluate the performance on connectives in this model).

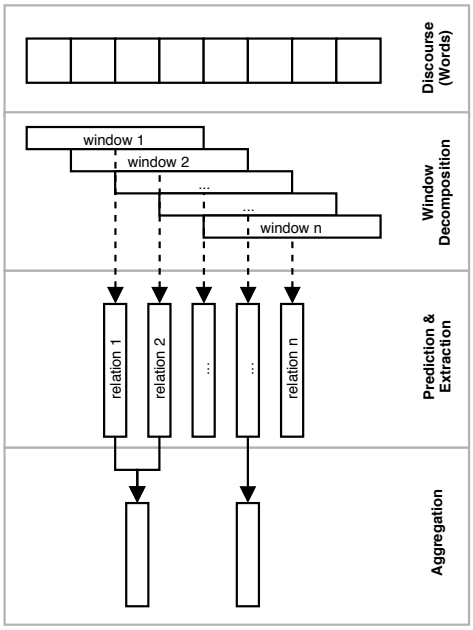

Figure 4: Overview of the proposed method consisting of decomposition, prediction, and aggregation.

ference, as the number of discourse relations and their positions are not known in this scenario. Also, as shown in the introductory example in Table 1, assigning classes to tokens is not a global decision, but has to be decided locally depending on the relation currently predicted. For this reason, we introduce the decomposition of the task into (i) handling multiple overlapping windows and (ii) a subsequent aggregation of the window-level predictions into the final set of predicted relations. The challenge in this aggregation approach is to identify valid predictions and further combine multiple possibly contradictory predictions pointing to the same relation. While we restrict our work here to explicit relations, we will show in our last experiment in Section 4.6 that this approach can also be applied to the case of implicit relations, merely by changing the data that the model is trained on.

3.3.1 Decomposition

The first part of our joint prediction method is to decompose the text into multiple overlapping windows that contain token embeddings. This is done by, first, padding the text at the beginning and at the end such that each token represents the center of one created window.

Then, for each window, we predict whether it contains a (possibly partial) relation or not, and which tokens belong to a particular part of the relation. Thus, for each token our model predicts one of four classes, `None`, `Arg1`, `Arg2`, or `Conn`.

We illustrate the process using the first example from Table 1. We cannot simply split the paragraph into windows and assign classes, because individual tokens have different labels depending on the context. Therefore, we choose the centering of the beginning of `Arg2` as a sufficient criterion (for generality to potentially cover both explicit and implicit relations, we did not choose the connective position as identifier). Thus, we extract three windows around the words "[if][you][think]", "[.][you]['re]", and "[and][you][are]". Because it is possible that a window's center is placed at the beginning or the end of a text, those have to be padded for having the same size as other complete windows.

The main challenge in jointly predicting connectives and their arguments is caused by multiple relations with overlapping arguments. To handle this, we create a unique identifier for each relation by using the position where the second argument of a relation begins. This forces the model to recognize relations only in the case when their second argument is centered in the window, and otherwise ignore them as being not in the focus of the current window.

For training the model, the data is prepared in such a way that it satisfies the properties above. For each relation instance in the PDTB, we use a fixed-size window that is placed on the text such that the relation has `Arg2` centered in this window. To further augment the data, we do not only use perfectly centered relations but additionally move the window one and two words to the left and to the right. Thus, for each relation in a text, we create five training instances. For each window, we keep the words and their argument labels, i.e., whether for a particular relation, a word belongs to one of the arguments, to the connective, or to neither of them. These windows, which correspond to a relation, are collected as positive training samples. Additionally, all windows that have not been extracted so far are gathered as negative training samples. For these negative training samples, although they might identify relations partially, all word labels are set to `None`. In this way, we want to force the model to learn to identify only relations for which `Arg2` is centered within a window.

In short, this process tries to include both arguments of the relation within a single window, but for longer arguments, this is not guaranteed. In this

approach, relations where an argument's span is beyond the window size remain incomplete for the training procedure.

3.3.2 Aggregation

After training a model for individual windows, the remaining challenge is to assemble the final set of relation predictions from all individual window predictions. We can distinguish the following cases: A window can contain

- only `None` labels (and thus no relation is to be extracted at all), or
- an invalid relation, where one or both arguments are empty, or
- a partial relation, where one or both of the arguments is incomplete, or
- a completely predicted relation.

To explain the aggregation step in detail, we define relations more formally and then describe the aggregation of individual relations based on their distance.

A relation is defined as a tuple $\mathrm{R}(a_1, a_2, c)$ of three sets, one for the first argument, the second argument, and the connective. Each of these sets contains the position indices of the included words, and hence these three sets are, by definition, disjoint. We maintain this property throughout the aggregation process of two relations.

Given two relations r_1, r_2, we define the merge of two relations, $r = r_1 \cup r_2$, as follows:

$$r^c = (r_1^c \cup r_2^c) \tag{1}$$

$$r^{a_2} = r_1^{a_2} \cup r_2^{a_2} \setminus r^c \tag{2}$$

$$r^{a_1} = (r_1^{a_1} \cup r_2^{a_1}) \setminus (r^c \cup r^{a_2}) \tag{3}$$

The crucial step is to decide whether two relations that are labeled in two consecutive windows are to be merged, i.e., to decide whether they denote the same relation. To this end, we measure the *distance* between two relations and merge them if the distance is below a certain threshold. Here we make use of the Jaccard distance as a distance metric for sets (but other metrics could be used as well). The Jaccard distance is based on the Jaccard index, which measures the similarity between finite sets by comparing the union and intersection of those sets:

$$J(A, B) = 1 - \frac{|A \cap B|}{|A \cup B|}$$

	None	Arg1	Arg2	Conn
Exp1	70.68 %	14.43 %	13.79 %	1.10 %
Exp2	85.34 %	7.21 %	6.89 %	0.56 %
Exp3	82.78 %	8.60 %	8.37 %	0.25 %

Table 3: Class label ratio calculated on the extracted training windows.

We define the distance of two relations $J_{rel}(r_1, r_2)$ as the mean of the two Jaccard distances between the relation's arguments.

$$J_{rel}(r_1, r_2) = \frac{J(r_1^{a_1}, r_2^{a_1}) + J(r_1^{a_2}, r_2^{a_2})}{2}$$

Note that for the calculation of the distances of the second arguments, we regard the connective as part of second arguments. This gives some, but not too much, influence to the connectives on the distance measure, compared to the influence of the arguments.

4 Experiments and Results

As described above, we experiment with two tasks of different complexity. The first experiment is a simplification of the general argument labeling problem, where a connective has already been classified. Because the position of the window is thus already determined, no aggregation is necessary for this scenario. For the second and third experiment, the exact positions of relations are not given and thus we follow our sliding-window approach. In all our evaluations, we use precision, recall, and F1 score of exact matches, in order to be comparable with the previous work.

All models are trained for 25 epochs on the corresponding training set, specific for a certain task. We use pretrained word embeddings with 300 dimensions as described later in Section 4.1. Each LSTM has a hidden layer of size 512. The output of each LSTM is concatenated per step, thus, the output of the BiLSTM results in 1024 dimensions per step. The dense layer with ReLU activation function on top of the BiLSTM has 64 dimensions, and the dropout works with a 0.2 probability. Finally, all models are trained using the Adam optimizer (Kingma and Ba, 2015). Because the classes are unbalanced throughout the experiments (compare Table 3) the cross-entropy loss is weighted (King and Zeng, 2001) according to the per-class occurrences in the extracted training windows.

4.1 Word Embedding

After the extraction of a vocabulary from the training corpus, we identify each token by a unique index. Every word that is not listed in the vocabulary is substituted by a special index for unknown words.

Because of the small size of the corpus, it is common to use pretrained embeddings (Mikolov et al., 2013) instead of training them solely on the given training corpus. In our experiments, we use *global vectors* for word representations (GloVe) (Pennington et al., 2014), similar as done by Hooda and Kosseim (2017). In general, GloVe embeddings have yielded promising results for a variety of related tasks. Hence, in the present study, we use GloVe without comparatively evaluating different pretrained embeddings.

Since both models, the word embedding model and ours, are trained on different corpora, the vocabularies also differ. First, we initialize all words with a random embedding. Then, for each word that is found in the set of pretrained embeddings, we replace the random embedding by its pretrained equivalent.

A minor disadvantage of word embeddings is that they are learned on a syntactic level. This means that although two words look similar in terms of characters, they might have different meanings depending on the words in their context. As a consequence, we follow the idea of using LSTMs on top of the word embeddings in order to account for the context in the individual representation.

In contrast to Hooda and Kosseim (2017), we avoid dynamically retraining the word vectors throughout the training process. Our earlier experiments showed that in our setting, training the embeddings has no positive effect on the final result, and thus, by avoiding this step, we also reduce the number of parameters that have to be trained.

4.2 Data Preparation

In our experiments, we follow the CoNLL shared task on shallow discourse parsing and work on their prepared dataset. This dataset differs slightly from the original PDTB2 corpus which is caused by the merge of a few sense labels and the cleaning of the PDTB data. For each relation in the CoNLL corpus, we extract a fixed-size window where the second argument is centered, i.e., where `Arg2` starts in the middle of the window. To produce more training data, we also extract windows that are shifted by small margins (up to two positions) to the left and to the right. Each of these windows constitutes a positive example of a discourse relation the model should learn. Conversely, every window of the same size where `Arg2` is not centered is added as a negative example. Even though a negative example may contain parts of some arguments, the words are labeled with `None` in order to force the model to only recognize relations where `Arg2` starts in the middle of the window. We keep punctuation as part of the vocabulary, as it might capture relevant discourse information.

In our evaluations, all models are trained on a window size of 100 tokens. Based on the span lengths found in the corpus, shown in Table 4, we choose this window size, as it captures a solid majority (over 80%) of the relations.

	Explicit		Implicit	
Perc.	**Span Length**	**Distance**	**Span Length**	**Distance**
min	2	0	2	0
20 %	14	2	20	2
40 %	21	2	29	2
60 %	29	3	38	2
80 %	44	4	49	3
max	1167	987	437	249

Table 4: Statistics calculated from the CoNLL2016 dataset. Overview of span lengths containing both arguments and distances of arguments for specific percentiles.

4.3 Baseline

The baseline model is inspired by Lin et al. (2014) who proposed a pipeline approach of several components. For our comparison, we focus on those

Label	Precision	Recall	F1
Arg1	46.69	44.59	45.62
Arg2	68.94	65.83	67.35
Arg1+Arg2	48.16	45.99	47.05

Table 6: Exact match of explicit arguments for a given connective.

components that are responsible for argument extraction: the connective classifier, argument position classifier and argument extractor in the explicit case, as well as the extraction of non-explicit arguments (cf. Figure 2). In contrast to our own model, which works on token level prediction, Lin et al.'s argument extraction model works on subtree level.

The performance reported in Table 5 shows the evaluation scores following the CoNLL shared task for our reimplementation of the pipeline described by Lin et al. Although these numbers are lower than those reported for the original implementation (e.g. predicting both explicit arguments is 10% worse), they may serve as a comparison and indicate that a re-implemenation of this system is not trivial. The values give different perspectives on the data, a full evaluation (**All**), and more detailed views on both parts (**Explicits** and **Non-Explicits**), which correlate with the structure of the architecture.

4.4 Connective Arguments

In the first experiment, we train a model to substitute the components for argument position and argument extraction similar to Ghosh et al. (2011a). The training data contains only positive explicit samples, since the model is never applied to other situations than these. With our procedure described above, we extract 73.610 samples from the corpus. For inference, we use a fixed-size window centered around the previously identified connective. The labeled indices for `Arg1` and `Arg2` are taken without any further processing.

The results in Table 6 show an increase of the values for `Arg1` and `Arg2` compared to our baseline.

4.5 Explicit Argument Extraction

The second experiment generalizes the window-based model and predicts arbitrary explicit relations for a text. This is challenging compared to the former experiment, because the connective is missing and therefore the model does not know the exact position of a relation. For this reason, we introduced the decomposition of a discourse with the sliding window approach and further introduce an aggregation method to get the final set of predicted relations.

Label	Precision	Recall	F1
Conn	69.25	44.56	54.23
Arg1	36.52	23.50	28.59
Arg2	62.96	40.51	49.30
Arg1+Arg2	40.29	25.93	31.55

Table 7: Exact match of explicit arguments for joint prediction of connectives and their arguments.

	Precision	Recall	F1
	Explicits		
Conn	71.35	62.73	66.76
Arg1	33.16	29.15	31.03
Arg2	52.47	46.13	49.09
Arg1+Arg2	37.25	32.75	34.86
	Non-Explicits		
Arg1	41.99	29.26	34.49
Arg2	44.32	30.88	36.40
Arg1+Arg2	40.16	27.99	32.99
	All		
Conn	71.35	62.73	66.76
Arg1	40.95	31.77	35.78
Arg2	51.47	39.94	44.98
Arg1+Arg2	41.83	32.45	36.55

Table 8: Evaluation of the joint extraction of explicit and non-explicit arguments.

The training data additionally contains negative explicit samples in contrast to the first experiment. The same amount of negative instances as positive instances is sampled from all possible negative instances. We extract twice as much training instances as before.

As shown in Table 7, the scores for connective identification are not as high as achieved with a specialized model (as in the baseline). Further, the sores for argument extraction also decrease for `Arg2` slightly and for `Arg1` even more. This is probably caused by the unbalanced data, as `None` labels occur much more often than other labels (see Table 3).

4.6 Explicit/Implicit Arguments Extraction

In the final experiment, we examine the full capacity of our model by using it for jointly predicting both explicit and implicit relation arguments. The training data consists of explicit and implicit relation instances, and for each positive sample, one negative sample is added to the training data. In sum, the model is trained on 325.350 instances.

As expected, the number for identifying non-

explicit relations is lower than the baseline (see Table 8). In contrast to our model, the baseline always selects two adjacent unlabeled sentences, which achieves good results despite its simplicity. Our models seems unable to recognize any sensible underlying pattern.

5 Discussion

Usually, different specialized models are combined to label arguments, either on a constituent-level (Lin et al., 2014; Kong et al., 2014) or on a token-level (Ghosh et al., 2011a,b). As we explained earlier, though, a crucial difference is their usage of highly-engineered linguistic features (e.g., cue words, syntactic classes, word pair relations, production rules), which our system does not use. Instead, it relies solely on word (token) sequences encoded by pretrained embeddings, which thus represent a certain amount of semantic information.

Our comparison with the re-implemented pipeline architecture is quite weak, as our implementation does not perform as good as the original work that relies on manually-engineered rules.

While our approach can obviously not compete with the knowledge-intensive approaches of Oepen et al. (2016) and Stepanov and Riccardi (2016), a fair comparison is that to the similar approach of Wang et al. (2015); here, our system clearly outperforms the earlier result. They report exact match F-measure of 36.32% for `Arg1` and 41.70% for `Arg2`. Compared to that system, our first experiment's approach where the connective was given (Section 4.4) performs much better. In comparison with our second experiment, our system's scores are lower for `Conn` and `Arg1`, but still higher for `Arg2` and both arguments extraction. A big problem in joint connective–argument extraction is the limited amount of data and the unbalanced class labels. We tried to work on the second problem by using weighted losses based on the class occurrences.

6 Conclusions and Future Work

In this work, we integrate a BiLSTM model in the shallow discourse parsing framework. We described tasks of different complexity in argument labeling and explained different ways of applying our neural model. For the general task of argument labeling, we adapt a token-level window-based approach and introduce a novel aggregation method, which is needed for combining individual predictions into the final set of relation arguments. We explored the limits of this approach by studying the joint prediction of the arguments of explicit and implicit relations.

The aggregation of partial relations is done using a distance threshold. For gaining possible improvements on the final results, it may well be worth studying different methods for merging conflicting relation predictions as well as defining different ways of computing the distances of individual predictions.

Because of the simplified nature of our architecture, we think that there are further interesting potentials for future work. Formulating the new window-training problem makes it possible to easily replace our proposed model by other architectures with more capacity. At the same time, we see this way of solving argument extraction as one step toward reducing the complexity and degree of error propagation in the more traditional SDP pipeline architecture.

We release the source code of our system[3] to promote future research.

Abstract

Content of text data are often influenced by contextual factors which often evolve over time (e.g., content of social media are often influenced by topics covered in the major news streams). Existing language models do not consider the influence of such related evolving topics, and thus are not optimal. In this paper, we propose to incorporate such topical-influence into a language model to both improve its accuracy and enable cross-stream analysis of topical influences. Specifically, we propose a novel language model called Topical Influence Language Model (TILM), which is a novel extension of a neural language model to capture the influences on the contents in one text stream by the evolving topics in another related (or possibly same) text stream. Experimental results on six different text stream data comprised of conference paper titles show that the incorporation of evolving topical influence into a language model is beneficial and TILM outperforms multiple baselines in a challenging task of text forecasting. In addition to serving as a language model, TILM further enables interesting analysis of topical influence among multiple text streams.

1 Introduction and Motivation

Language modeling plays a central role in many Natural Language Processing (NLP) tasks and applications. Neural language models have attracted much attention recently due to their superior performance (Dieng et al., 2016; Kiros et al., 2014; Kiddon et al., 2016; Ranzato et al., 2015; Devlin et al., 2018; Peters et al., 2018). One common limitation of the existing neural language models is that they cannot model the potential influence of related contextual factors on text content generation. However, as text data are produced by humans based on their observations of the real world, the content of text data are generally influenced by many contextual factors, and thus, it is necessary to model the influence of those contextual factors on the generation of text content in order to optimize language modeling. For example, the content of social media may be influenced by the popular topics in news stream; another example is that the content of research papers in one research community such as *Information Retrieval* are often influenced by the topics of research papers published in the same community in the past or research papers published in another related research community such as *Machine Learning* since the general algorithms developed in the latter may be applied to solve application problems in the former.

In this paper, we propose to incorporate such topical influence into a language model to both improve its accuracy and enable cross-stream analysis of topical influences. Specifically, we propose a novel language model called Topical Influence Language Model (TILM), which is a novel extension of a neural language model to capture the influence on the contents in one text stream by the evolving topics in another related (or possibly same) text stream. In other words, TILM is a recurrent neural network-based deep learning architecture that incorporates topical influence to model the generation of a dynamically evolving text stream. Since most text data have time stamps associated with them, which generally indicate the time when a text document was produced, text data can often be regarded as a sequence / stream of text objects ordered by their time stamps. TILM is designed to model the generation of such a text stream, i.e., the generation of text data conditioned on a given time stamp. We also assume that the distributions of words in the text data from two different timestamps are somewhat different, which allows us to capture the evolution of topics in the stream data.

TILM is comprised of three basic components. The first component is the *Sequence Generator*, which can be any current neural language model.

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 778–788
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

The second component is the *Topic Generator* which captures the trend of different topics of interest within the *influencing text stream*, which can be based on any topic models, e.g., LDA. Finally, the third component is a novel *Influence Generator*, which ensures that TILM can capture topical influence corresponding to the input timestamp and incorporate it into the generation process to ensure that the generated text is consistent with that particular timestamp from the perspective of topical influence. TILM combines these three essential components into a single unified model and learns all their optimal parameter values from a training text stream corpus with time stamps.

We conducted comprehensive experiments with six different sets of publication stream datasets to evaluate the effectiveness of TILM. These datasets contain titles of the papers published in different machine learning theory and applied machine learning conferences over 20 years, which were collected from the Open Academic Graph. Experimental results show that the incorporation of topical influence into a language model is beneficial and TILM outperforms multiple baselines by a clear margin in a challenging task of text forecasting. We found that effectively capturing the evolving topical influence is the key to improving the accuracy of language modeling. In addition to serving as a language model, TILM further enables interesting analysis of topical influence among multiple text streams.

2 Related Works

There has been a surge of research interest in the use of neural network (NN) architectures for language modeling and automatic text generation in recent years (Dieng et al., 2016; Kiros et al., 2014; Kiddon et al., 2016; Ranzato et al., 2015). The first NN-based text generator was proposed by Kukich (Kukich, 1987), although generation was done only at the phrase level. Recent advances in recurrent neural network-based language models (RNN-LM) have demonstrated the value of distributed representations and its power to model arbitrarily long dependencies (Mikolov et al., 2010, 2011). Sutskever et al. (Sutskever et al., 2011) introduced a simple variant of the RNN that can generate meaningful sentences by learning from a character-level corpus. Mao et.al. have demonstrated how Recurrent Neural Networks, specially, Long-Short-Term-Memory (LSTM) is effective in solving various text generation tasks (Mao et al., 2014). TopicRNN proposed by Dieng (Dieng et al., 2016) integrated the merits of RNNs and latent topic models to capture long-range semantic dependency. Recently, Generative Adversarial Nets (GANs) that use a discriminative model to guide the training of the generative model has shown promising results in automated text generation (Rajeswar et al., 2017; Lin et al., 2017; Che et al., 2017; Zhang et al., 2017). All these text generation techniques have also been vastly studied for generating summary for text corpora [see (Gambhir and Gupta, 2017) for a comprehensive survey]. Most recently, BERT (Devlin et al., 2018) and ELMo (Peters et al., 2018) have shown very promising performance. However, none of these existing methods can model topical influences from related contextual factors on generation of text data. While external topical influences have been studied in the context of search behavior modeling (Karmaker Santu et al., 2017, 2018), similar study has not been pursued yet for text generation modeling. Specifically, current text generation processes are static processes with no notion of time and thus, can not model dynamically evolving text stream data corresponding to evolving influences of related text streams, which the proposed TILM can do.

3 Topical Influence Language Model

We first briefly discuss some preliminaries and notations. Next, we present the three major components that are the building blocks of the proposed Topical Influence Language Model (TILM) and then present how TILM combines them into a single unified model.

3.1 Preliminaries and Notations

The goal task involves performing language modeling on each text stream within a set of text streams, $S = \{s_1, s_2, ..., s_m\}$, where, $|S| = m$. Each text stream consists of a set of tuples in the form of (document, timestamp) , e.g., $s_1 = \{(d_1, t_1), (d_2, t_2), ...\}$. Each document is a sequence of words, e.g., $d_1 = [x_1 x_2 ...]$, where, each $x_i \in V$ and V is the vocabulary set. For modeling purposes, we group the documents within each stream into different bins based on their corresponding timestamp. The time ranges $[t_{start}, t_{end}]$ used to create these bins are defined by the user and can be in varying granularity like year, month,

day or seconds. Each bin is then assigned a discrete timestamp T and all the documents in that bin share the same timestamp, e.g., all paper published in different machine learning conferences during year 2016 are assigned the timestamp $T_{2016} = [Jan_{2016}, Dec_{2016}]$.

3.2 Sequence Generator

Sequence Generator is the basic component of TILM which generates the next word x_i in the sentence given $i-1$ previous words. Thus, *Sequence Generator* is essentially a language model which generates a probability distribution over a sequence of words that can be used to predict the next word in the sequence. Any sequence modeling framework, e.g., Hidden Markov Models, Recurrent Neural Networks etc. can work as a sequence generator. For the experiments described in this paper, we chose recurrent neural network with LSTM cells as the *Sequence Generator* due to its recent promising results obtained for language modeling tasks (Kiros et al., 2014; Kim et al., 2016). Given the previous i words, i.e., $x_{1:i}$, the recurrent neural network based language models compute the conditional probability for the next word $y_i = v$ for $v \in V$, the vocabulary set, by computing a hidden state h_i and passing it through a Softmax function:

$$P(y_i = v|x_{1:i}) \equiv P(y_i = v|h_i) \quad (1)$$

$$P(y_i|h_i) \propto \exp(W^{\Omega}h_i + B^{\Omega}) \quad (2)$$

$$h_i = \Omega(h_{i-1}, x_i) \quad (3)$$

Here, Ω can be a standard RNN cell or more complicated cell like LSTM, GRU etc and W and B are linear transformation coefficients. Output at step i, i.e., y_i is fed as input for step $i+1$, thus, $x_{i+1} = y_i$.

3.3 Topic Generator

The next component of TILM is the *Topic Generator*. The primary purpose of this component is to analyze different topics across a related text stream data (let us call it s) and compute the evolution of topic distributions within that stream over time. It takes all past text stream data of s as input and applies a probabilistic topic model to infer n (a user defined parameter) different topics, each represented with a unique distribution over the entire vocabulary. Again, many different topic models can be potentially used, but in our experiments, we chose LDA (Blei et al., 2003) as the *Topic Generator* since it has been the most popular topic modeling technique in the last decade. Once n topics are identified, the *Topic Generator* takes all text content from each discrete timestamp T (defined in section 3.1) separately and computes the distribution of n topics over each timestamp, which we denote by θ_T.

The *Topic Generator* also provides a subcomponent, i.e., *History Extractor*, which, given a particular timestamp T as input, retrieves the topic distributions of previous r (a user defined parameter) timestamps computed by LDA. We mathematically denote the output of *History Extractor* by $\theta_{T-r:T-1}$, where, $\theta_{i:j}$ denotes topic distributions from timestamp i to j augmented into a single vector. This means the cardinality of vector $\theta_{T-r:T-1}$ is $r \times n$. In the case of modeling influence from multiple related text streams and assuming we have m such streams, we can simply concatenate $\theta_{T-r:T-1}$ from each stream to create a single vector of dimension $r \times n \times m$.

3.4 Influence Generator

The *Influence Generator* is a pivotal component of TILM, which models the evolving topical influence during the text generation process. Given a particular timestamp T, we represent topical influence by a real valued vector (γ_T) of dimension K (another user defined parameter), which is essentially the output of *Influence Generator*. The input to the *Influence Generator* is the $r \times n$ dimensional vector of topic distributions from previous r timestamps of a related text stream, i.e., $\theta_{T-r:T-1}$ (assuming T as the current timestamp). Thus, *Influence Generator* essentially maps a $r \times n$ dimensional topic vector to a K dimensional influence vector. Although any function that can perform this mapping can resemble as Influence Generator, we chose a feed-forward neural network for TILM due to its capability of approximating a wide family of functions. Without loss of generality, we used ReLU activation units in the hidden layers. Once the influence vector (γ_T) is computed, it is then injected as a bias into the *Sequence Generator* when generating the next word (x_i) in the sequence (More details in section 3.5).

Here, we assume that the influence vector γ_T corresponding to current timestamp T, can be approximated from the historical topic distribution $\theta_{T-r:T-1}$. This assumption is reasonable, because most text stream data do not evolve dramatically

over night, rather their topical shift happens quite gradually. Take for example some particular research community like SIGKDD. The topic distribution in papers published in a particular year is unlikely dramatically different from the previous two years, rather they are somewhat correlated.

Mathematically, let θ_T denote the topic distribution for the generated text at timestamp T, then the function of *Influence Generator* is expressed as follows ($\|$ means the concatenation operation):

$$\theta_{T-r:T-1} = \theta_{T-r} \| \theta_{T-r+1} \| .... \| \theta_{T-1} \quad (4)$$

$$\begin{aligned} \gamma_T &= \Gamma(\theta_{T-r:T-1}) \\ &= W_2^\Gamma \cdot \left[ReLU(W_1^\Gamma \cdot \theta_{T-r:T-1} + B_1^\Gamma) \right] + B_2^\Gamma \end{aligned} \quad (5)$$

3.5 TILM as a Unified Model

Now that we have presented the three building blocks of TILM, this section presents how these different components interact with each other and work as a unified architecture to model stream text data by capturing the fluctuations of topical influence over time. The process can be thought of as generating text corresponding to a particular timestamp T. Thus, the whole process starts with a timestamp T as input and the start-of-sentence marker (let's call it #) as the sequence generated so far. The next task is to generate one word at a time iteratively until the end-of-sentence marker is generated (let's call it *). The exact process of generating the next word y_i in the sequence is demonstrated in Figure 1.

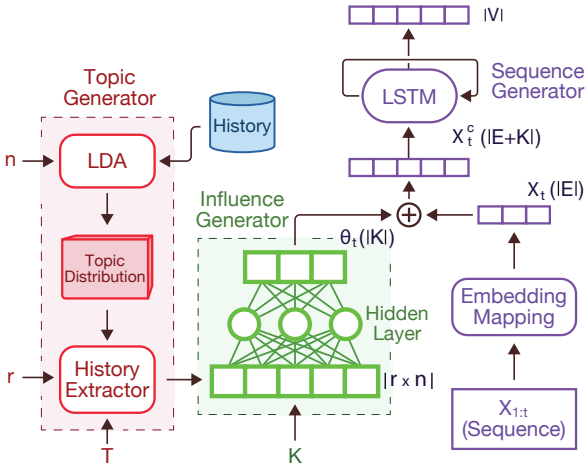

Figure 1: TILM architecture: Topic Generator (Red), Influence Generator (Green) and Sequence Generator (Purple)

The first step of generation process is to infer n different topics from a related (possibly same) historical text stream and compute the topic distributions for each unique timestamp observed in the training data. Next, given a particular timestamp T as input, the *History Extractor* Module extracts the historical topic distributions corresponding to previous r timestamps and concatenates them to generate a vector representation of the history, i.e., $\theta_{T-r:T-1}$ of dimension $r \times n$ (see the previous subsection for details). $\theta_{T-r:T-1}$ is then passed through *Influence Generator* Γ which outputs the K dimensional influence vector γ_T. For a particular timestamp T, γ_T is fixed and can be re-used for any text generation task tied to the timestamp T. The bottom middle section (Green Color) of Figure 1 shows the feed-forward neural network of *Influence Generator*.

The next trick in TILM is to concatenate the influence vector (γ_T) with the vector representation of each word in the sequence generated so far. This means, for each word in $\{x_1, x_2, ..., x_i\}$, γ_T is concatenated to each of their vector representations to create an augmented representation $\{x_1^C, x_2^C, ..., x_i^C\}$, i.e., while generating the next word $x_{i+1} = y_i$ in the sequence, all the previous words in the sequence share the same topical influence represented by vector γ_T. This augmented representation essentially allows TILM to capture the dynamic nature of text stream data as the influence vector injects evolving topical influence into the generation process. Finally, the augmented representations $\{x_1^C, x_2^C, ..., x_i^C\}$ are fed into the recurrent neural network model to compute a hidden state h_i . The final output vector Y is computed by applying a linear transformation on h_i. Note that, vector Y is a real-valued vector. We apply a Softmax function on Y to convert it into a valid probability distribution, sampling from which, the next word in the sequence is generated. The mathematical formulas behind the entire generation process is summarized below:

$$Y = W^\Omega \cdot h_i + B^\Omega, \quad (6)$$

$$h_i = \Omega(h_{i-1}, x_i^C), \quad (7)$$

$$x_i^C = x_i \| \gamma_T. \quad (8)$$

Thus, Y can be written as follows:

$$Y = W^\Omega \cdot \Omega(h_{i-1}, x_i \| \gamma_T) + B^\Omega. \quad (9)$$

Here, γ_T is obtained as follows:

$$\gamma_T = W_2^\Gamma \cdot \left[ReLU(W_1^\Gamma \cdot \theta_{T-r:T-1} + B_1^\Gamma) \right] + B_2^\Gamma. \quad (10)$$

Here, $\theta_{T-r:T-1}$ is the concatenation of topic distribution vector from previous r timestamps.

Finally, we apply a Softmax function on the output vector Y to convert it into a valid probability distribution $P(y_i|h_i)$, as follows:

$$P(y_i = v|h_i) = \frac{\exp(Y_i)}{\sum_{j=1}^{|V|} \exp(Y_j)}. \quad (11)$$

The next word $y_i = x_{i+1}$ in the sequence is generated by sampling from this conditional distribution. TILM repeats this whole process multiple times to generate new words in the sentence until a end-of-sentence marker is generated. The whole process is summarized in Algorithm 1, which describes the generation of a single sentence by TILM for a particular timestamp T.

Algorithm 1: Topical Influence Language Model (TILM)

Process TILM $(T, \Theta, \Gamma, \Omega, r, n, K, E)$;
Input : T: discrete timestamp

3.6 Estimation of TILM parameters

In this section, we present the estimation techniques for the optimal values of TILM model parameters. Close observation of Equation 6-10 reveals that TILM contains the following set of parameters:

$$\boldsymbol{W} = \left\{W^\Omega, B^\Omega, W_1^\Gamma, B_1^\Gamma, W_2^\Gamma, B_2^\Gamma\right\} \quad (12)$$

We find the optimal values for the parameter set $\boldsymbol{W}$ by maximizing the log-likelihood of the training text stream data. The optimization problem thus can be written as follows:

$$\boldsymbol{W}^* = \underset{W}{argmax} \quad \log L(x_1 x_2 ... x_n|W) \quad (13)$$

As maximizing the log-likelihood is the same as minimizing the negative of the log-likelihood function and as we know the exact word which comes next in the sequence during the training process, our optimization problem boils down to minimizing the softmax cross entropy with logits between the conditional distribution $P(y_i|h_i)$ and the one-hot encoding of the actual word that appears next in the training data. Softmax Cross Entropy with logits essentially measures the probability error in discrete classification tasks in which the classes are mutually exclusive. Thus,

$$\boldsymbol{W}^* = \underset{W}{argmin} \{-\log L(x_1 x_2 ... x_n|W)\} \quad (14)$$

$$= \underset{W}{argmin} \left\{ -\sum_{i=1}^{N} \sum_{v \in V} I(x_i, v) \cdot \log P(x_i = v|h_i(W)) \right\} \quad (15)$$

Here, N is the total number of words in the training data. $I(p, q)$ is an indicator function that returns 1 if $p = q$ and 0 otherwise.

We used back-propagation to learn the weights of the network connection edges of TILM. Specifically, we used Adaptive Moment Estimation, which is a popular stochastic gradient descent technique and commonly known as Adam Optimizer, to compute the gradient for minimizing our objective function in Equation 15. Adam Optimizer is an update to the RMSProp (Hinton et al., 2012), which is another popular optimizer. For more details, refer to (Kingma and Ba, 2014).

4 Experimental Design

4.1 Dataset

We experimented with six different sets of publication title stream data to evaluate the performance of TILM. These datasets were collected from the Open Academic Graph[1](Tang et al., 2008; Sinha et al., 2015). Here, we focused on studying how the paper titles published by different machine learning related conferences evolved over time. As community, we considered both the core machine learning community, e.g., NIPS, ICML as well as research communities that apply a fair share of machine learning, e.g, KDD, SIGIR. Specifically, we considered all the titles of papers published during the years 1996-2015 by the following six conference venues: NIPS, CVPR, ICML, KDD, SIGIR and WWW. For these datasets, the discrete timestamp corresponds to a particular year.

[1] https://www.openacademic.ai/oag/

Conf.	# of Titles	Title/ Year	Total Words	Words/ Title
KDD	5,499	274.95	49,980	9.08
NIPS	6,229	311.45	49,792	7.99
SIGIR	3,994	199.7	34,892	8.73
ICML	4,106	205.3	34,159	8.32
WWW	5,701	285.05	50,253	8.82
CVPR	10,121	506.05	90,890	8.98

Table 1: Dataset Summary

Each row in these datasets consists of a tuple <timestamp, paper-title> and altogether they contain $35,650$ paper titles in total. Again, each paper title can contribute multiple instances for predicting the next word which resulted in $309,966$ total instances (see Table 1).

4.2 Evaluation Roadmap

For a proper evaluation of TILM, we need a goal task which is both time-sensitive and requires influence modeling. To address this challenge, we evaluate TILM using a text forecasting task, where we attempt to predict the text content at future timestamps in a text stream based on the past data from related (including the same) streams.

As the setup of such a text forecasting task is essentially similar to summarizing *future* text data, we use two popular evaluation metrics from the literature of text summarization, i.e., BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004), where a score is generated by comparing the automatically generated text against some reference text written by humans. However, neither BLEU nor ROUGE considers the notion of time, thus we need a time-sensitive customization of both BLEU and ROUGE. The simplest way to do this is to compare a TILM generated text for timestamp T against the original text corresponding to the same timestamp T. This means, when TILM is asked to generate a paper title relevant to timestamp T, the ground truth paper title against which the generated title is compared must also correspond to the timestamp T. Another challenge is to match the generated title against multiple independent publication titles corresponding to timestamp T. We address it by adopting a simple greedy approach where the TILM-generated title is matched against each ground truth title corresponding to the timestamp T and paired with the most similar one in terms of BLEU or ROUGE score. The matched ground truth title is then removed from the corpus so that the next generated title cannot match with the previously matched title again. This ensures that TILM is generating a diverse set of titles rather than just memorizing one single title from each timestamp T. This way, we can use TILM to generate multiple sentences (titles) for a particular timestamp T and then average the scores of all generated sentences to get an evaluation score corresponding to timestamp T. This whole computation process is presented in Algorithm 2, where we demonstrate the case for time-sensitive BLEU score. The case for ROUGE is exactly similar. Finally, these average scores across different timestamps can be further averaged to compute the overall forecasting score[2].

Algorithm 2: Time aware BLEU score computation

Time aware BLEU (T, G, R);
Input : T: discrete timestamp
G: Generated Text set
R: Reference Text set
Output: Time sensitive BLEU
$score \leftarrow 0$
$|G| \leftarrow$ number of sentences in G
for *each sentence* g *in* G **do**
  for *each sentence* r *in* R **do**
    compute $BLEU(g, r)$
  end
  $r^* = \underset{r}{argmax} \;\; BLEU(g, r)$
  $score \leftarrow score + BLEU(g, r^*)$
  $R \leftarrow R - \{r^*\}$
end
return $\frac{score}{|G|}$

4.3 Baseline Methods

The main questions we want to answer in our experiments are whether the incorporation of topical influence (from a related stream) is beneficial for language modeling and whether the specific configuration of TILM we described earlier is an effective way to capture evolving topical influence. To answer the second question, we compare TILM with two baselines which are both variants of TILM but with different ways to capture influence. The first one is called *RILSTM* which is identical to TILM except that the influence vector of RILSTM is generated randomly as opposed to generating it by the *Influence Generator* of TILM. The second baseline is called *IILSTM* where we do not inject the influence vector as a bias into

[2]All the codes and evaluation scripts for experimentation can be found at the following link: (https://bitbucket.org/karmake2/tilm/src/master/

Acronym	Details	Nature
Bigram	Bigram Language Model	Static
LSTM	Long short-term memory	Static
RILSTM	LSTM with Random Influence	Dynamic
IILSTM	Sampling from Joint LSTM-Influence Distribution	Dynamic
TILM	Topical Influence LM	Dynamic

Table 2: Baselines for Quantitative Comparison.

the vector representation of words, rather, the *Influence Generator* directly computes a probability distribution for sampling the next word and this probability is multiplied with the probability computed independently by LSTM. To answer the first question, i.e., to verify the benefit of modeling the evolution of topical influence, we also compared TILM against two baselines representing static models: simple bigram language model and Long-Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997; Gers et al., 1999). Table 2 contains the summary of these baseline algorithms along with TILM.

5 Results

This section presents both quantitative and qualitative evaluation results for TILM. For all the results reported in this section, TILM used the following parameter settings: r was set to 3, for both *Sequence Generator* and *Influence Generator*, the number of hidden units was empirically set to 256, K (dimension of influence vector) was set to 15, batch size was set to 2000 instances and the learning rate was set to 0.01. For the *Topic Generator*, n (number of topics) was set to 15, θ_T was computed from target text stream itself and LDA was run using $\alpha = 0.1$ and $\beta = 0.05$.

5.1 Quantitative Evaluation

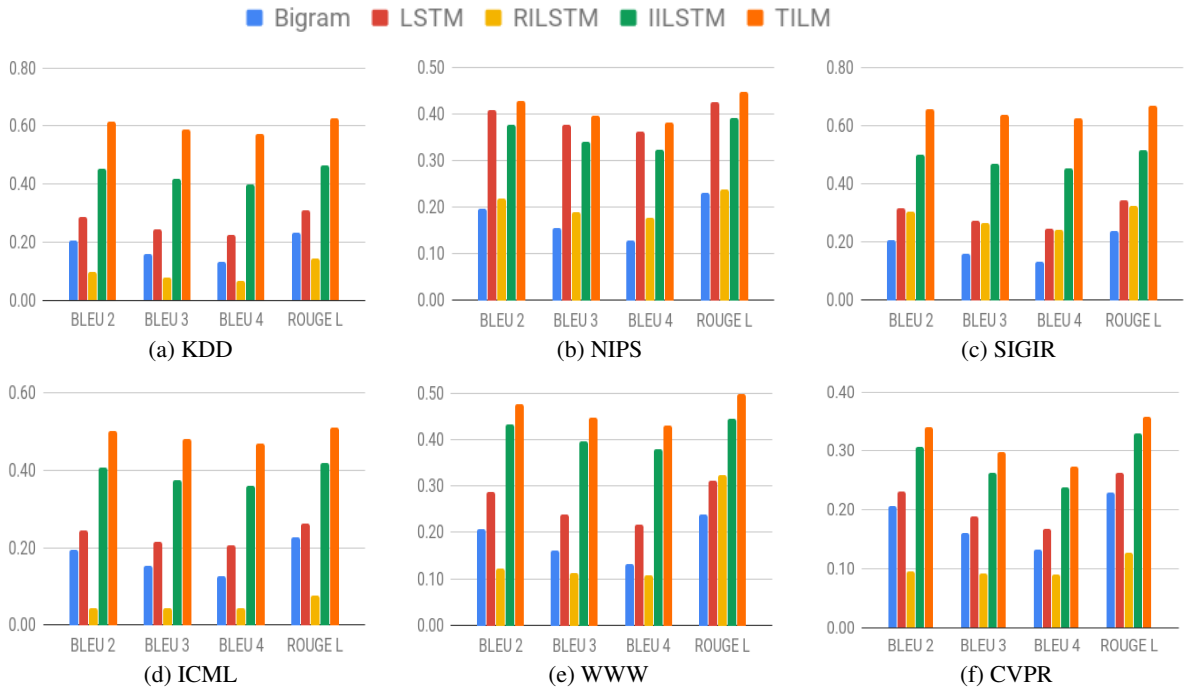

Figure 2 provides the summary of results for comparing TILM against multiple baseline methods. Close examination of Figure 2 reveals that TILM outperforms all other baselines by a clear margin for all six datasets. For example, BLEU-4 score obtained by TILM on KDD Dataset is 0.57, while LSTM obtained only a score of 0.22. ROUGE-L score obtained by TILM is 0.63, while it is 0.31 for LSTM. This clearly indicates that TILM can indeed capture the temporal evolution of KDD paper titles over time and given a input timestamp T, can generate text relevant to T. Also note that, RILSTM performs significantly worse compared to LSTM for most datasets which implies that the influence vector plays the key role in helping TILM capture the evolution of the text stream. It is also noteworthy that IILSTM is the second best performing method which confirms that injecting influence vector as a bias into the word representation works better than using the Joint LSTM-Influence distribution obtained by simply multiplying influence probabilities with LSTM probabilities.

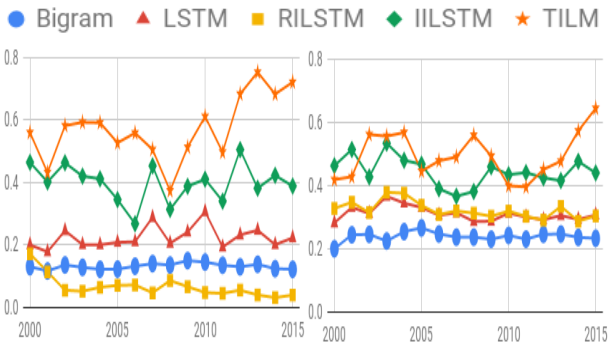
To get more insights into the performance of TILM, we plot the timestamp-wise performance of all compared methods for KDD Dataset (BLEU 4) and WWW Dataset (ROUGE L) in Figure 3 [other plots are similar and omitted due to lack of space]. A general inspection of Figure 3 also demonstrates the superiority of TILM for the text forecasting task, where, for any performance metric, TILM obtains the best score across different timestamps for most of the cases.

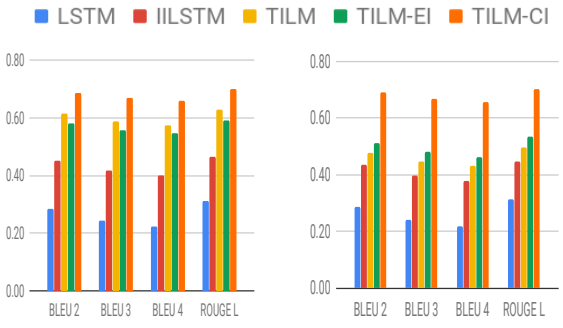
External Influence: So far, we have only considered the influence of the community for which the text generation is targeted towards. However, other related communities also pose indirect influence on the text content generated within the target community. For example, a shift in the interest of theoretical machine learning conferences like ICML often influences the research directions pursued by more applied conferences like KDD or WWW. To test this hypothesis, we conducted a series of experiments where instead of using the influence of the target community (e.g., KDD, WWW) itself, we computed the influence vector from the historical topic distribution of a core machine learning community (e.g. ICML, NIPS). We call this approach TILM-EI where EI means external influence. We conducted another set of experiments where we computed influence vectors from both the target community and a related external community and injected both influence vectors into the TILM process. We call this approach TILM-CI where CI stands for combined influence. Two sample results from these experiments are shown in Figure 4, i.e., influence of ICML on KDD and WWW, respectively. Experiments results suggest that, although TILM-EI is not always better than TILM itself, TILM-CI outperforms basic TILM as TILM-CI combines both internal and external influence.

5.2 Qualitative Evaluation



In this section, we present qualitative results to show the great potentials of TILM. We first ran LDA on paper titles from SIGIR and KDD over the year range 2000-2015. Number of topics was

(a) KDD (b) NIPS (c) SIGIR



(d) ICML (e) WWW (f) CVPR

Topic	Top Keywords
Optimization	matrix, gradient, sparse, convex, stochastic
Search Relevance	information, retrieval, search, index, document
Rule Mining	rule, discovery, association, pattern, mine
Social Networks	social, network, recommender, community, topic
SVM Classifiers	supervised, learning, support, vector, machine
User Behavior Modeling	log, behavior, personalization, click, feedback

Table 3: Sample topics Extracted from KDD and SIGIR for year range [1995-2015] Using LDA

set to 15. Table 3 shows six example topics along with top 5 keywords for each topic. Next, we did some topic trend analysis for SIGIR conference in Figure 5. For SIGIR, we considered two topics, i.e., *User Behavior Modeling* [Figure 5a, 5b] and *Search and Relevance* [Figure 5c, 5d]. Beside plotting the original topic-distribution trend computed from the real conference proceedings (Figures in red color), we also plot the simulated topic-distribution trend computed from the text generated by TILM (Figures in green color). Close observation of Figure 5 confirms that TILM can indeed generate sentences aligned with the evolution of the text stream corresponding to evolving topical influence. For example, Figure 5a shows that research interest towards *User Behavior Modeling* grew significantly within SIGIR community in the past ten years, which is also nicely reflected in the text generated by TILM [Figure 5b]. On the other hand, research on Search and relevance almost matured after 2008 within the SIGIR community [Figure 5c], which has also been captured

year	#	Sample Generated Title
2000 - 2002	1	discovering in hierarchical rules using lexical knowledge
	2	data mining criteria for tree based regression and classification
	3	mining frequent class sets in spatial databases
2007 - 2009	1	a framework for community identification in dynamic social networks
	2	learning preferences of new users in recommender systems
	3	data mining for intrusion detection from outliers
2012 - 2015	1	deep model based transfer and multi task learning for biological image analysis
	2	a bayesian framework for estimating properties of information network
	3	active learning for sparse bayesian classification

Table 4: Sample titles generated by TILM for conference KDD across different year ranges

effectively by TILM and apparent from the decaying trend of Figure 5d.

Finally, Table 4 presents some sample paper titles generated by TILM for different time ranges targeted towards KDD community. A closer look into Table 4 reveals that TILM can generate syntactically correct, semantically coherent and time-sensitive evolving text. It is worth mentioning that, TILM did not store any paper-to-year mapping information. Table 4 also nicely captures the interest shift within KDD community over the years. For example, paper titles generated for year range 2000-2002 include topics like rule mining and tree based classifications, while paper titles generated for year range 2012-2015 include topics like deep learning and active learning, which is consistent with our expectation.

6 Conclusion

We studied how to improve neural language models by incorporating topical influence from contextual factors and proposed a novel Topical Influence Language Model (TILM), which includes a novel extension of a basic neural language model by incorporating both a topic generator (based on topic modeling) and a neural network-based influence modeling component, leading to a general architecture with three major components: *Sequence Generator*, *Topic Generator* and *Influence Generator*. We quantitatively evaluated TILM using a text forecasting task on six publication stream datasets and demonstrated that it is beneficial to incorporate topical influence in language modeling and TILM outperforms multiple baseline methods by a significant margin. As a novel language model, TILM allows for leveraging related text streams to improve accuracy of language modeling of a target stream, thus potentially helping improve many applications where language models are applied. We also show that TILM is able to generate well-structured, meaningful text content corresponding to future time stamps, thus potentially allowing us to predict topical trends in the future, which would be useful for optimizing decision making. Moreover, we also showed the potential that TILM can be used as a tool to compare influences of different external streams on a particular target stream, thus facilitating cross-stream influence analysis. While it is not the focus of this paper, such analysis clearly opens up an interesting direction for analyzing multiple text streams to understand their influences in a topic-specific way, a highly promising direction for future research.

7 Acknowledgement

We sincerely thank Hao Ma, Bin Bi, Kuansan Wang and Jiawei Han for their valuable feedback during the initial phase of generating the idea for this paper. We also thank the three anonymous reviews for their unanimous recognition of the importance of this new research direction which would help promoting this direction to a greater extent.

Abstract

In this paper, we propose a novel pretraining-based encoder-decoder framework, which can generate the output sequence based on the input sequence in a two-stage manner. For the encoder of our model, we encode the input sequence into context representations using BERT. For the decoder, there are two stages in our model, in the first stage, we use a Transformer-based decoder to generate a draft output sequence. In the second stage, we mask each word of the draft sequence and feed it to BERT, then by combining the input sequence and the draft representation generated by BERT, we use a Transformer-based decoder to predict the refined word for each masked position. To the best of our knowledge, our approach is the first method which applies the BERT into text generation tasks. As the first step in this direction, we evaluate our proposed method on the text summarization task. Experimental results show that our model achieves new state-of-the-art on both CNN/Daily Mail and New York Times datasets.

1 Introduction

Text summarization generates summaries from input documents while keeping salient information. It is an important task and can be applied to several real-world applications. Many methods have been proposed to solve the text summarization problem (See et al., 2017; Nallapati et al., 2017; Zhou et al., 2018; Gehrmann et al., 2018). There are two main text summarization techniques: extractive and abstractive. Extractive summarization generates summary by selecting salient sentences or phrases from the source text, while abstractive methods paraphrase and restructure sentences to compose the summary. We focus on abstractive summarization in this work as it is more flexible and thus can generate more diverse summaries.

Recently, many abstractive approaches are introduced based on neural sequence-to-sequence framework (Paulus et al., 2018; See et al., 2017; Gehrmann et al., 2018; Li et al., 2018). Based on the sequence-to-sequence model with copy mechanism, (See et al., 2017) incorporates a coverage vector to track and control attention scores on source text. (Paulus et al., 2018) introduce intra-temporal attention processes in the encoder and decoder to address the repetition and incoherent problem.

There are two issues in previous abstractive methods: 1) these methods use left-context-only decoder, thus do not have complete context when predicting each word. 2) they do not utilize the pre-trained contextualized language models on the decoder side, so it is more difficult for the decoder to learn summary representations, context interactions and language modeling together.

Recently, BERT has been successfully used in various natural language processing tasks, such as textual entailment, name entity recognition and machine reading comprehensions. In this paper, we present a novel natural language generation model based on pre-trained language models (we use BERT in this work). As far as we know, this is the first work to extend BERT to the sequence generation task. To address the above issues of previous abstractive methods, in our model, we design a two-stage decoding process to make good use of BERT's context modeling ability. On the first stage, we generate the summary using a left-context-only-decoder. On the second stage, we mask each word of the summary and predict the refined word one-by-one using a refine decoder. To further improve the naturalness of the generated sequence, we cooperate reinforcement objective with the refine decoder.

The main contributions of this work are:

1. We propose a natural language generation

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 789–797
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

model based on BERT, making good use of the pre-trained language model in the encoder and decoder process, and the model can be trained end-to-end without handcrafted features.

2. We design a two-stage decoder process. In this architecture, our model can generate each word of the summary considering both sides' context information.

3. We conduct experiments on the benchmark datasets CNN/Daily Mail and New York Times. Our model achieves a 33.48 average of ROUGE-1, ROUGE-2 and ROUGE-L on the CNN/Daily Mail, which is state-of-the-art. On the New York Times dataset, our model achieves about 5.6% relative improvement over ROUGE-1.

2 Background

2.1 Text Summarization

In this paper, we focus on single-document multi-sentence summarization and propose a supervised abstractive model based on the neural attentive sequence-to-sequence framework which consists of two parts: a neural network for the encoder and another network for the decoder. The encoder encodes the input sequence to intermediate representation and the decoder predicts one word at a time step given the input sequence representation vector and previous decoded output. The goal of the model is to maximize the probability of generating the correct target sequences. In the encoding and generation process, the attention mechanism is used to concentrate on the most important positions of text. The learning objective of most sequence-to-sequence models is to minimize the negative log likelihood of the generated sequence as shown in following equation, where y_t^* is the t-th ground-truth summary token.

$$Loss = -\log \sum_{t=1}^{|y|} P(y_t^* | y_{<t}^*, X) \tag{1}$$

However, with this objective, traditional sequence generation models consider only one direction context in the decoding process, which could cause performance degradation since complete context of one token contains preceding and following tokens, thus feeding only preceded decoded words to the decoder so that the model may generate unnatural sequences. For example, attentive sequence-to-sequence models often generate sequences with repeated phrases which harm the naturalness. Some previous works mitigate this problem by improving the attention calculation process, but in this paper we show that feeding bi-directional context instead of left-only-context can better alleviate this problem.

2.2 Bi-Directional Pre-Trained Context Encoders

Recently, context encoders such as ELMo, GPT, and BERT have been widely used in many NLP tasks. These models are pre-trained on a huge unlabeled corpus and can generate better contextualized token embeddings, thus the approaches built on top of them can achieve better performance.

Since our method is based on BERT, we illustrate the process briefly here. BERT consists of several layers. In each layer there is first a multi-head self-attention sub-layer and then a linear affine sub-layer with the residual connection. In each self-attention sub-layer the attention scores e_{ij} are first calculated as Eq. (2) (3), in which d_e is output dimension, and W^Q, W^K are parameter matrices.

$$a_{ij} = \frac{(h_i W_Q)(h_j W_K)^T}{\sqrt{d_e}} \tag{2}$$

$$e_{ij} = \frac{\exp e_{ij}}{\sum_{k=1}^{N} \exp e_{ik}} \tag{3}$$

Then the output is calculated as Eq. (4), which is the weighted sum of previous outputs h added by previous output h_i. The last layer outputs is context encoding of input sequence.

$$o_i = h_i + \sum_{j=1}^{N} e_{ij}(h_j W_V) \tag{4}$$

Despite the wide usage and huge success, there is also a mismatch problem between these pre-trained context encoders and sequence-to-sequence models. The issue is that while using a pre-trained context encoder like BERT, they model token-level representations by conditioning on both direction context. During pre-training, they are fed with complete sequences. However, with a left-context-only decoder, these pre-trained language models will suffer from incomplete and inconsistent context and thus cannot generate good enough context-aware word representations, especially during the inference process.

3 Model

In this section, we describe the structure of our model, which learns to generate an abstractive multi-sentence summary from a given source document.

Based on the sequence-to-sequence framework built on top of BERT, we first design a refine decoder at word-level to tackle the two problems described in the above section. We also introduce a discrete objective for the refine decoders to reduce the exposure bias problem. The overall structure of our model is illustrated in Figure 1.

3.1 Problem Formulation

We denote the input document as $X = \{x_1, \ldots, x_m\}$ where $x_i \in \mathcal{X}$ represents one source token. The corresponding summary is denoted as $Y = \{y_1, \ldots, y_L\}$, L represents the summary length.

Given input document X, we first predict the summary draft by a left-context-only decoder, and then using the generated summary draft we can condition on both context sides and refine the content of the summary. The draft will guide and constrain the refine process of summary.

3.2 Summary Draft Generation

The summary draft is based on the sequence-to-sequence model. On the encoder side the input document X is encoded into representation vectors $H = \{h_1, \ldots, h_m\}$, and then fed to the decoder to generate the summary draft $A = \{a_1, \ldots, a_{|a|}\}$.

3.2.1 Encoder

We simply use BERT as the encoder. It first maps the input sequence to word embeddings and then computes document embeddings as the encoder's output, denoted by following equation.

$$H = BERT(x_1, \ldots, x_m) \tag{5}$$

3.2.2 Summary Draft Decoder

In the draft decoder, we first introduce BERT's word embedding matrix to map the previous summary draft outputs $\{y_1, \ldots, y_{t-1}\}$ into embeddings vectors $\{q_1, \ldots, q_{t-1}\}$ at t-th time step. Note that as the input sequence of the decoder is not complete, we do not use the BERT network to predict the context vectors here.

Then we introduce an N layer Transformer decoder to learn the conditional probability $P(A|H)$. Transformer's encoder-decoder multi-head attention helps the decoder learn soft alignments between summary and source document. At the t-th time step, the draft decoder predicts output probability conditioned on previous outputs and encoder hidden representations as shown in Eq. (6), in which $q_{<t} = \{q_1, \ldots, q_{t-1}\}$. Each generated sequence will be truncated in the first position of a special token '[PAD]'. The total summary draft decoder progress is shown in Stage 1 of Figure 1.

$$P_t^{vocab}(w) = f_{dec}(q_{<t}, H) \tag{6}$$

$$L_{dec} = \sum_{t=1}^{|a|} -\log P(a_t = y_t^* | a_{<t}, H) \tag{7}$$

As Eq. (7) shows, the decoder's learning objective is to minimize negative likelihood of conditional probability, in which y_t^* is the t-th ground truth word of summary.

However a decoder with this structure is not sufficient enough: if we use the BERT network in this decoder, then during training and inference, in-complete context(part of sentence) is fed into the BERT module, and although we can fine-tune BERT's parameters, the input distribution is quite different from the pre-train process, and thus harms the quality of generated context representations.

If we just use the embedding matrix here, it will be more difficult for the decoder with fresh parameters to learn to model representations as well as vocabulary probabilities, from a relative small corpus compared to BERT's huge pre-training corpus. In a word, the decoder cannot utilize BERT's ability to generate high quality context vectors, which will also harm performance.

This issue exists when using any other contextualized word representations, so we design a refine process to mitigate it in our approach which will be described in the next sub-section.

3.2.3 Copy Mechanism

As some summary tokens are out-of-vocabulary words and occurs in input document, we incorporate copy mechanism (Gu et al., 2016) based on the Transformer decoder, we will describe it briefly.

At decoder time step t, we first calculate the attention probability distribution over source document X using the bi-linear dot product of the last

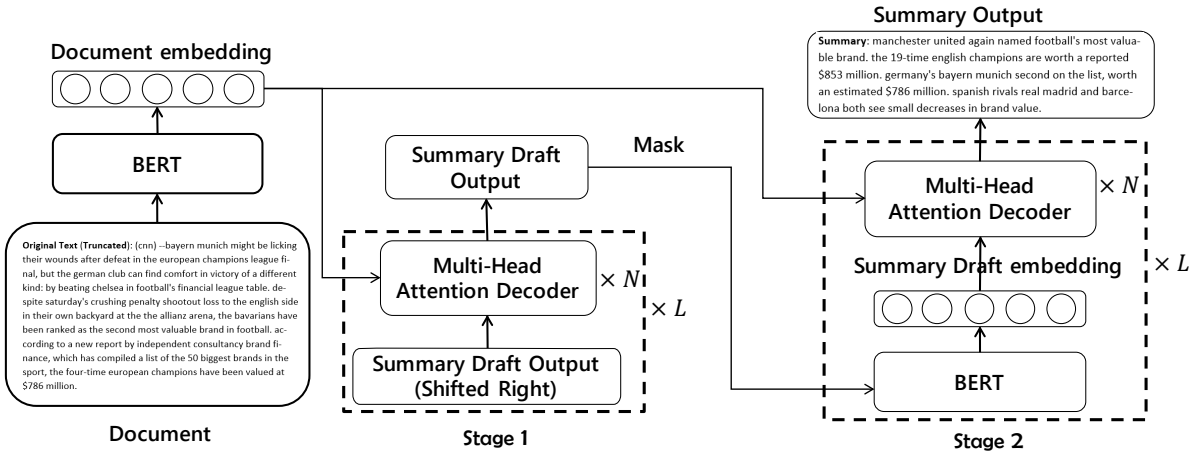

Figure 1: Model Overview, N represents decoder layer number and L represents summary length.

layer decoder output of Transformer o_t and the encoder output h_j, shown in Eq. (8) (9).

$$u_t^j = o_t W_c h_j \tag{8}$$

$$\alpha_t^j = \frac{\exp u_t^j}{\sum_{k=1}^{N} \exp u_t^k} \tag{9}$$

We then calculate copying gate $g_t \in [0, 1]$, which makes a soft choice between selecting from source and generating from vocabulary, W_c, W_g, b_g are parameters:

$$g_t = sigmoid(W_g \cdot [o_t, h] + b_g) \tag{10}$$

Using g_t we calculate the weighted sum of copy probability and generation probability to get the final predicted probability of extended vocabulary $\mathcal{V} + \mathcal{X}$, where $\mathcal{X}$ is the set of out of vocabulary words from the source document. The final probability is calculated as follow:

$$P_t(w) = (1 - g_t) P_t^{vocab}(w) + g_t \sum_{i:w_i=w} \alpha_t^i \tag{11}$$

3.3 Summary Refine Process

The main reason to introduce the refine process is to enhance the decoder using BERT's contextualized representations, so we do not modify the encoder and reuse it during this process.

On the decoder side, we propose a new word-level refine decoder. The refine decoder receives a generated summary draft as input, and outputs a refined summary. As Figure 1 Stage 2 shows, it first masks each word in the summary draft one by one, then feeds the draft to BERT to generate context vectors. Finally it predicts a refined summary word using an N layer Transformer decoder which is the same as the draft decoder. At t-th time step the t-th word of input summary is masked, and the decoder predicts the refined word given other words of the summary.

The learning objective of this process is shown in Eq. (12), y_t is the t-th summary word and y_t^* for the ground-truth summary word, and $a_{\neq t} = \{a_1, \ldots, a_{t-1}, a_{t+1}, \ldots, a_{|y|}\}$.

$$L_{refine} = \sum_{t=1}^{|y|} -\log P(y_t = y_t^* | a_{\neq t}, H) \tag{12}$$

From the view of BERT or other contextualized embeddings, the refine decoding process provides a more complete input sequence which is consistent with their pre-training processes. Intuitively, this process works as follows: first the draft decoder writes a summary draft based on a document, and then the refine decoder edits the draft. It concentrates on one word at a time, based on the source document as well as other words.

We design the word-level refine decoder because this process is similar to the cloze task in BERT's pre-train process, therefore by using the ability of the contextual language model the decoder can generate more fluent and natural sequences.

The parameters are shared between the draft decoder and refine decoder, as we find that using individual parameters the model's performance degrades a lot. The reason may be that we use teach-forcing during training, and thus the word-level refine decoder learns to predict words given all the

other ground-truth words of summary. This objective is similar to the language model's pre-train objective, and is probably not enough for the decoder to learn to generate refined summaries. So in our model all decoders share the same parameters.

3.3.1 Mixed Objective

For summarization, ROUGE is usually used as the evaluation metric, however during model training the objective is to maximize the log likelihood of generated sequences. This mis-match harms the model's performance. Similar to previous work (Kryściński et al., 2018), we add a discrete objective to the model, and optimize it by introducing the policy gradient method. The discrete objective for the summary draft process is as shown in Eq. (13), where a^s is the draft summary sampled from predicted distribution, and $R(a^s)$ is the reward score compared with the ground-truth summary, we use ROUGE-L in our experiment. To balance between optimizing the discrete objective and generating readable sequences, we mix the discrete objective with maximum-likelihood objective. Eq. (14) shows the final objective for the draft process, note here L_{dec} is $-logP(a|x)$. In the refine process we introduce similar objectives.

$$L^{rl}_{dec} = R(a^s) \cdot [-\log(P(a^s|x))] \quad (13)$$

$$\hat{L}_{dec} = \gamma * L^{rl}_{dec} + (1-\gamma) * L_{dec} \quad (14)$$

3.4 Learning and Inference

During model training, the objective of our model is sum of the two processes, jointly trained using "teacher-forcing" algorithm. During training we feed the ground-truth summary to each decoder and minimize the following objective.

$$L_{model} = \hat{L}_{dec} + \hat{L}_{refine} \quad (15)$$

At test time, each time step we choose the predicted word by $\hat{y} = argmax_{y'} P(y'|x)$, use beam search to generate the draft summaries, and use greedy search to generate the refined summaries.

4 Experiment

4.1 Settings

In this work, all of our models are built on $BERT_{BASE}$, although another larger pre-trained model with better performance ($BERT_{LARGE}$) has published but it costs too much time and GPU memory. We use WordPiece embeddings with a 30,000 vocabulary which is the same as BERT. We set the layer of transformer decoders to 12(8 on NYT50), and set the attention heads number to 12(8 on NYT50), set fully-connected sub-layer hidden size to 3072. We train the model using an Adam optimizer with learning rate of $3e-4$, $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 10^{-9}$ and use a dynamic learning rate during the training process. For regularization, we use dropout (Srivastava et al., 2014) and label smoothing (Szegedy et al., 2016) in our models and set the dropout rate to 0.15, and the label smoothing value to 0.1. We set the RL objective factor γ to 0.99.

During training, we set the batch size to 36, and train for 4 epochs(8 epochs for NYT50 since it has many fewer training samples), after training the best model are selected from last 10 models based on development set performance. Due to GPU memory limit, we use gradient accumulation, set accumulate step to 12 and feed 3 samples at each step. We use beam size 4 and length penalty of 1.0 to generate logical form sequences.

During inference, we filter repeated tri-grams in beam-search process by setting word probability to zero if it will generate an tri-gram which exists in the existing summary. It is a nice method to avoid phrase repetition since the two datasets seldom contains repeated tri-grams in one summary.

4.1.1 Datasets

To evaluate the performance of our model, we conduct experiments on CNN/Daily Mail dataset, which is a large collection of news articles and modified for summarization. Following (See et al., 2017) we choose the non-anonymized version of the dataset, which consists of more than 280,000 training samples and 11490 test set samples.

We also conduct experiments on the New York Times(NYT) dataset which also consists of many news articles. The original dataset can be applied here.[1] In our experiment, we follow the dataset splits and other pre-process settings of (Durrett et al., 2016). We first filter all samples without a full article text or abstract and then remove all samples with summaries shorter than 50 words. Then we choose the test set based on the date of publication(all examples published after January 1, 2007). The final dataset contains 22,000 train-

ing samples and 3,452 test samples and is called NYT50 since all summaries are longer than 50 words.

We tokenize all sequences of the two datasets using the WordPiece tokenizer. After tokenizing, the average article length and summary length of CNN/Daily Mail are 691 and 51, and NYT50's average article length and summary length are 1152 and 75. We truncate the article length to 512, and the summary length to 100 in our experiment(max summary length is set to 150 on NYT50 as its average golden summary length is longer).

4.1.2 Evaluation Metrics

On CNN/Daily Mail dataset, we report the full-length F-1 score of the ROUGE-1, ROUGE-2 and ROUGE-L metrics, calculated using PyRouge package[2] and the Porter stemmer option. On NYT50, following (Paulus et al., 2018) we evaluate limited length ROUGE recall score(limit the generated summary length to the ground truth length). We split NYT50 summaries into sentences by semicolons to calculate the ROUGE scores.

4.2 Results and Analysis

Table 1 gives the results on CNN/Daily Mail dataset, we compare the performance of many recent approaches with our model. We classify them to two groups based on whether they are extractive or abstractive models. As the last line of the table lists, the ROUGE-1 and ROUGE-2 score of our full model is comparable with DCA, and outperforms on ROUGE-L. Also, compared to extractive models NeuSUM and MASK-LM^{global}, we achieve slight higher ROUGE-1. Except the above four scores, our model outperforms these models on all the other scores, and since we have 95% confidence interval of at most $\pm$ 0.20, these improvements are statistically significant. The test set outputs of our model are released for further study.[3]

4.2.1 Ablation Analysis

As the last four lines of Table 1 show, we conduct an ablation study on our model variants to analyze the importance of each component. We use three ablation models for the experiments. One-Stage: A sequence-to-sequence model with copy mechanism based on BERT; Two-Stage: Adding the refine decoder to the One-Stage model; Two-Stage

+ RL: Full model with refine process cooperated with RL objective.

First, we compare the Two-Stage+RL model with Two-Stage ablation, we observe that the full model outperforms by 0.30 on average ROUGE, suggesting that the reinforcement objective helps the model effectively. Then we analyze the effect of refine process by removing it from the Two-Stage model, we observe that without the refine process the average ROUGE score drops by 1.69. The ablation study proves that each module is necessary for our full model, and the improvements are statistically significant on all metrics.

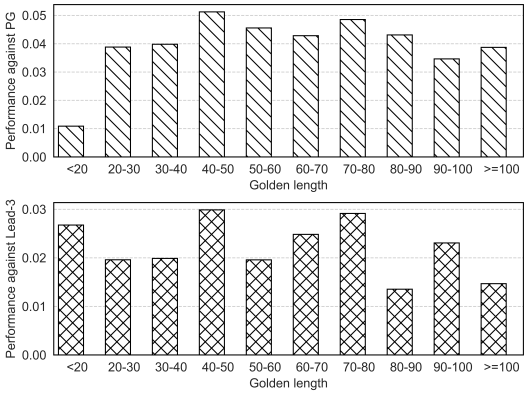

Figure 2: Average ROUGE-L improvement on CNN/Daily mail test set samples with different golden summary length.

4.2.2 Effects of Summary Length

To evaluate the impact of summary length on model performance, we compare the average rouge score improvements of our model with different length of ground-truth summaries. As the above sub-figure of Figure 2 shows, compared to Pointer-Generator with Coverage, on length interval 40-80(occupies about 70% of test set) the improvements of our model are higher than shorter samples, confirms that with better context representations, in longer documents our model can achieve higher performance.

As shown in the below sub-figure of Figure 2, compared to extractive baseline: Lead-3 (See et al., 2017), the advantage of our model will fall when golden summary length is greater than 80. This probably because that we truncate the long documents and golden summaries and cannot get full information, it could also because that the training data in these intervals is too few to train an abstractive model, so simple extractive method will not fall too far behind.

4.3 Additional Results on NYT50

Table 2 reports experiment results on the NYT50 corpus. Since the short summary samples are filtered, NYT50 has average longer summaries than CNN/Daily Mail. So the model needs to catch long-term dependency of the sequences to generate good summaries.

The first two lines of Table 2 show results of the two baselines introduced by (Durrett et al., 2016): these baselines select first n sentences, or select the first k words from the original document. Also we compare performance of our model with two recent models, we see 2.39 ROUGE-1 improvements compared to the ML+RL with intra-attn approach(previous SOTA) carries over to this dataset, which is a large margin. On ROUGE-2, our model also get an improvement of 0.51. The experiment proves that our approach can outperform competitive methods on different data distributions.

5 Related work

5.1 Text Summarization

Text summarization models are usually classified to abstractive and extractive ones. Recently, extractive models like DeepChannel (Shi et al., 2018), rnn-ext+RL (Chen and Bansal, 2018) and NeuSUM (Zhou et al., 2018) achieve higher performances using well-designed structures. For example, DeepChannel propose a salience estimation network and iteratively extract salient sentences. (Zhang et al., 2018) train a sentence compression model to teach another latent variable extractive model.

Also, several recent works focus on improving abstractive methods. (Gehrmann et al., 2018) design a content selector to over-determine phrases in a source document that should be part of the summary. (Hsu et al., 2018) introduce inconsistency loss to force words in less attended sentences(which determined by extractive model) to have lower generation probabilities. (Li et al., 2018) extend seq2seq model with an information selection network to generate more informative summaries.

Model	R-1	R-2
First sentences	28.60	17.30
First k words	35.70	21.60
Full (Durrett et al., 2016)	42.20	24.90
ML+RL+intra-attn (Paulus et al., 2018)	42.94	26.02
Two-Stage + RL (Ours)	**45.33**	**26.53**

Table 2: Limited length ROUGE recall results on the NYT50 test set.

5.2 Pre-trained language models

Pre-trained word vectors (Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2017) have been widely used in many NLP tasks. More recently, pre-trained language models (ELMo, GPT and BERT), have also achieved great success on several NLP problems such as textual entailment, semantic similarity, reading comprehension, and question answering (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2018).

Some recent works also focus on leveraging pre-trained language models in summarization. (Radford et al., 2017) pretrain a language model and use it as the sentiment analyser when generating reviews of goods. (Kryściński et al., 2018) train a language model on golden summaries, and then use it on the decoder side to incorporate prior knowledge.

In this work, we use BERT(which is a pre-trained language model using large scale unlabeled data) on the encoder and decoder of a seq2seq model, and by designing a two stage decoding structure we build a competitive model for abstractive text summarization.

6 Conclusion and Future Work

In this work, we propose a two-stage model based on sequence-to-sequence paradigm. Our model utilize BERT on both encoder and decoder sides, and introduce reinforce objective in learning process. We evaluate our model on two benchmark datasets CNN/Daily Mail and New York Times, the experimental results show that compared to previous systems our approach effectively improves performance.

Although our experiments are conducted on summarization task, our model can be used in most natural language generation tasks, such as machine translation, question generation and paraphrasing. The refine decoder and mixed objective can also be applied on other sequence generation tasks, and we will investigate on them in future work.

Abstract

Hierarchical neural networks are often used to model inherent structures within dialogues. For goal-oriented dialogues, these models miss a mechanism adhering to the goals and neglect the distinct conversational patterns between two interlocutors. In this work, we propose *Goal-Embedded Dual Hierarchical Attentional Encoder-Decoder (G-DuHA)* able to center around goals and capture interlocutor-level disparity while modeling goal-oriented dialogues. Experiments on dialogue generation, response generation, and human evaluations demonstrate that the proposed model successfully generates higher-quality, more diverse and goal-centric dialogues. Moreover, we apply data augmentation via goal-oriented dialogue generation for task-oriented dialog systems with better performance achieved.

1 Introduction

Modeling a probability distribution over word sequences is a core topic in natural language processing, with language modeling being a flagship problem and mostly tackled via recurrent neural networks (RNNs) (Mikolov and Zweig, 2012; Melis et al., 2017; Merity et al., 2018).

Recently, dialogue modeling has drawn much attention with applications to response generation (Serban et al., 2016a; Li et al., 2016b; Asghar et al., 2018) or data augmentation (Yoo et al., 2019). It's inherently different from language modeling as the conversation is conducted in a turn-by-turn nature. (Serban et al., 2016b) imposes a hierarchical structure on encoder-decoder to model this utterance-level and dialogue-level structures, followed by (Serban et al., 2016c; Chen et al., 2018; Le et al., 2018a).

However, when modeling dialogues involving two interlocutors center around one or more goals, these systems generate utterances with the greatest likelihood but without a mechanism sticking to the goals. This makes them go off the rails and fail to model context-switching of goals. Most of the generated conversations become off-goal dialogues with utterances being non-relevant or contradicted to goals rather than on-goal dialogues. The differences are illustrated in Figure 1.

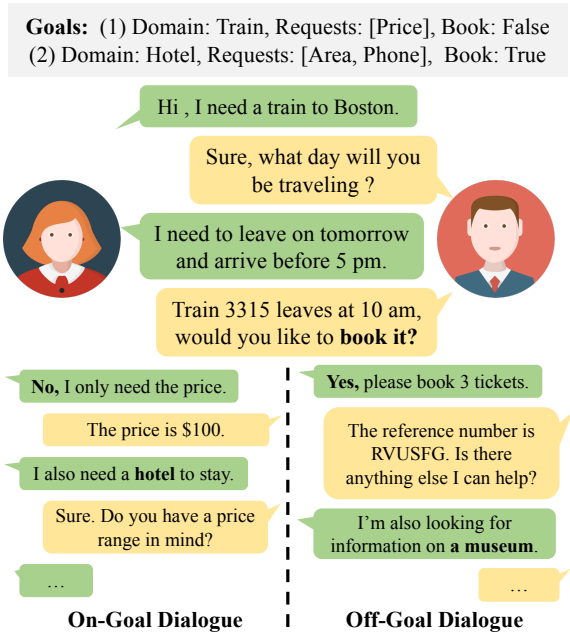

Figure 1: On-goal dialogues follow the given goals such as no booking of train tickets and a hotel reservation. Off-goal dialogues have context switches to other domains non-relevant to goals.

Besides, two interlocutors in a goal-oriented dialogue often play distinct roles as one has requests or goals to achieve and the other provides necessary support. Modeled by a single hierarchical RNN, this interlocutor-level disparity is neglected and constant context switching of roles could reduce the capacity for tracking conversational flow and long-term temporal structure.

To resolve the aforementioned issues when modeling goal-oriented dialogues, we propose

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 798–811
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

the Goal-Embedded Dual Hierarchical Attentional Encoder-Decoder (G-DuHA) to tackle the problems via three key features. First, the goal embedding module summarizes one or more goals of the current dialogue as goal contexts for the model to focus on across a conversation. Second, the dual hierarchical encoder-decoders can naturally capture interlocutor-level disparity and represent interactions of two interlocutors. Finally, attentions are introduced on word and dialogue levels to learn temporal dependencies more easily.

In this work, our contributions are that we propose a model called goal-embedded dual hierarchical attentional encoder-decoder (G-DuHA) to be the first model able to focus on goals and capture interlocutor-level disparity while modeling goal-oriented dialogues. With experiments on dialogue generation, response generation and human evaluations, we demonstrate that our model can generate higher-quality, more diverse and goal-focused dialogues. In addition, we leverage goal-oriented dialogue generation as data augmentation for task-oriented dialogue systems, with better performance achieved.

2 Related Work

Dialogues are sequences of utterances, which are sequences of words. For modeling or generating dialogues, hierarchical architectures are usually used to capture their conversational nature. Traditionally, language models are also used for modeling and generating word sequences. As goal-oriented dialogues are generated, they can be used in data augmentation for task-oriented dialogue systems. We review related works in these fields.

Dialogue Modeling. To model conversational context and turn-by-turn structure of dialogues, (Serban et al., 2016b) devised hierarchical recurrent encoder-decoder (HRED). Reinforcement and adversarial learning are then adopted to improve naturalness and diversity (Li et al., 2016b, 2017a). Integrating HRED with the latent variable models such as variational autoencoder (VAE) (Kingma and Welling, 2014) extends another line of advancements (Serban et al., 2016c; Zhao et al., 2017; Park et al., 2018; Le et al., 2018b). However, these systems are not designed for task-oriented dialogue modeling as goal information is not considered. Besides, conversations between two interlocutors are captured with a single encoder-decoder by these systems.

Language Modeling. A probability distribution of a word sequence $w_{1:T} = (w_1, w_2, ..., w_T)$ can be factorized as $p(w_1)\prod_{t=2}^{T} p(w_t|w_{1:t-1})$. To approximate the conditional probability $p(w_t|w_{1:t-1})$, counted statistics and smoothed N-gram models have been used before (Goodman, 2001; Katz, 1987; Kneser and Ney, 1995). Recently, RNN-based models have achieved a better performance (Mikolov et al., 2010; Józefowicz et al., 2016; Grave et al., 2017; Melis et al., 2018). As conversational nature is not explicitly modeled, models often have role-switching issues.

Task-Oriented Dialogue Systems. Conventional task-oriented dialog systems entails a sophisticated pipeline (Raux et al., 2005; Young et al., 2013) with components including spoken language understanding (Chen et al., 2016; Mesnil et al., 2015; Gupta et al., 2019), dialog state tracking (Henderson et al., 2014; Mrksic et al., 2017), and dialog policy learning (Su et al., 2016; Gašić and Young, 2014). Building a task-oriented dialogue agent via end-to-end approaches has been explored recently (Li et al., 2017b; Wen et al., 2017). Although several conversational datasets are published recently (Gopalakrishnan et al., 2019; Henderson et al., 2019), the scarcity of annotated conversational data remains a key problem when developing a dialog system. This motivates us to model task-oriented dialogues with goal information in order to achieve controlled dialogue generation for data augmentation.

3 Model Architecture

Given a set of goals and the seed user utterance, we want to generate a goal-centric or on-goal dialogue that follows the domain contexts and corresponding requests specified in goals. In this section, we start with the mathematical formulation, then introduce our proposed model, and describe our model's training objective and inference.

At training time, K dialogues $\{D_1, ..., D_K\}$ are given where each D_i associates with N_i goals $\mathbf{g_i} = \{g_{i1}, g_{i2}, ..., g_{iN_i}\}$. A dialogue D_i consists of M turns of utterances between a user $\mathbf{u}$ and a system agent $\mathbf{s}$ $(\mathbf{w_{u1}}, \mathbf{w_{s1}}, \mathbf{w_{u2}}, \mathbf{w_{s2}}, ...)$, where $\mathbf{w_{u1}}$ is a word sequence $w_{u1,1}, w_{u1,2}, ..., w_{u1,N_{u1}}$ denoting the user's first utterance.

The task-oriented dialogue modeling aims to approximate the conditional probability of user's or agent's next utterance given previous turns and goals. It can be further decomposed over gener-

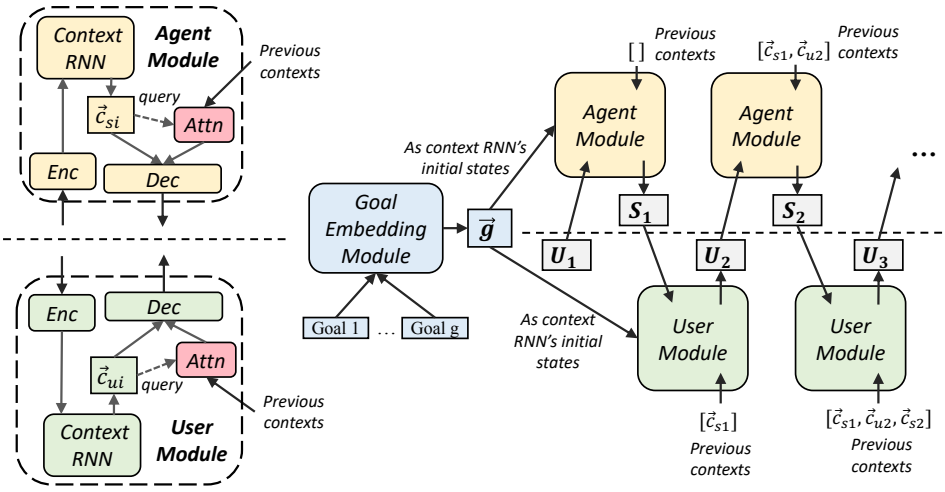

Figure 2: G-DuHA architecture. The goal embedding module embeds goals as priors for context RNNs. Dual hierarchical RNNs naturally model two interlocutors. An attention over previous contexts captures long-term dependencies. For encoders, word attentions are used to summarize local importance of words. (Enc: Encoder, Dec: Decoder, Attn: Attention, U_i: User's utterance, S_i: Agent's utterance)

ated words, e.g.

$$P(\mathbf{w_{um}}|\mathbf{w_{u1}}, \mathbf{w_{s1}}, ..., \mathbf{w_{s(m-1)}}, \mathbf{g_i}) = \prod_{n=1}^{N_{um}} P(w_{um,n}|w_{um,<n}, \mathbf{w_{u1}}, ...) \quad (1)$$

To model goal-oriented dialogues between two interlocutors, we propose Goal-embedded Dual Hierarchical Attentional Encoder-Decoder (G-DuHA) as illustrated in Fig. 2. Our model comprises goal embedding module, dual hierarchical RNNs, and attention mechanisms detailed below.

3.1 Goal Embedding Module

We represent each goal in $\{g_{i1}, g_{i2}, ...\}$ using a simple and straightforward binary or multi-one-hot encoding followed by a feed-forward network (FFN). A goal could have a specific domain such as hotel or a request such as price or area, Table 2 shows a few examples. Our goal embedding module, a FFN, then converts binary encoding of each goal into a goal embedding, where the FFN is learned during training. If multiple goals present, all goal embeddings are then added up element-wisely to be the final goal embedding:

$$\overrightarrow{g_i} = \sum_{j=1}^{|g_i|} FFN(Encode(g_{ij})) \quad (2)$$

The output of the goal embedding module has the same number of dimensions as context RNN's hidden state and is used as initial states for all layers of all context RNNs to inform the model about a set of goals to focus on.

3.2 Dual Hierarchical Architecture

The hierarchical encoder-decoder structure (Serban et al., 2016b) is designed for utterance level and context level modeling. With a single encoder, context RNN, and decoder, the same module is used to process input utterances, track contexts, and generate responses for both interlocutors.

In task-oriented dialogues, however, roles are distinct as the user aims to request information or make reservations to achieve goals in mind and the system agent provides necessary help. To model this interlocutor-level disparity, we extend it into a dual architecture involving two hierarchical RNNs, each serves as a role in a dialogue.

3.3 Attention Mechanisms

At the utterance level, as importance of words can be context dependent, our model uses first hidden layer's states of the context RNN as the query for attention mechanisms (Bahdanau et al., 2015; Xu et al., 2015) to build an utterance representation. A feed-forward network is involved to computed attention scores, whose input is the concatenation of the query and an encoder output.

At the dialogue level, for faster training, our model has a skip connection to add up context RNN's raw output with its input as the final output c_t. To model long-term dependencies, an attention module is applied to summarize all previous

contexts into a global context vector. Specifically, a feed-forward network takes the current context RNN's output c_t as the query and all previous context outputs from both context RNNs as keys and values to compute attention scores. The global context vector is then concatenated with c_t to form our final context vector for decoder to consume.

3.4 Objective

For predicting the end of a dialogue, we exploit a feed-forward network over the final context vector for a binary prediction. Thus our training objective can be written as

$$L = \sum_{i=1}^{K} \Big[-\log p_{\boldsymbol{\theta}}(D_i) + \sum_{t}^{M_i} -\log p_{\boldsymbol{\theta}}^{end}(e_{it}) \Big], \tag{3}$$

where our model $p_{\boldsymbol{\theta}}$ has parameters $\boldsymbol{\theta}$, M_i is the number of turns, e_{it} is 0 as the dialogue D_i continues and 1 if it terminates at turn t.

3.5 Generation

At dialogue generation time, a set of goals $\{g_{i1}, g_{i2}, ...\}$ and a user utterance $\mathbf{w_{u1}}$ as a seed are given. Then our model will generate conversations simulating interactions between a user and an agent that seek to complete all given goals. The generation process terminates as the end of dialogue prediction outputs a positive or the maximum number of turns is reached.

4 Experiments

We evaluate our approach on dialogue generation and response generation as well as by humans. Ablation studies and an extrinsic evaluation that leverages dialogue generation as a data augmentation method are reported in the subsequent section.

4.1 Dataset

Experiments are conducted on a task-oriented human-human written conversation dataset called MultiWOZ (Budzianowski et al., 2018), the largest publicly available dataset in the field. Dialogues in the dataset span over diverse topics, one to more goals, and multiple domains such as `restaurant`, `hotel`, `train`, etc. It consists of 8423 train dialogues, 1000 validation and 1000 test dialogues with on average 15 turns per dialogue and 14 tokens per turn.

4.2 Baselines

We compare our approach against four baselines:

(i) LM+G: As long-established methods for language generation, we adopt an RNN language model (LM) with 3-layer 200-hidden-unit GRU (Cho et al., 2014) incorporating our goal embedding module as a baseline, which has goal information but no explicit architecture for dialogues.

(ii) LM+G-XL: To show the possible impact of model size, a larger LM that has a 3-layer 450-hidden-unit GRU is adopted as another baseline.

(iii) Hierarchical recurrent encoder-decoder (HRED) (Serban et al., 2016b): As the prominent model for dialogues, we use HRED as the baseline that has a dialogue-specific architecture but no goal information. The encoder, decoder, and context RNN are 2-layer 200-hidden-unit GRUs.

(iv) HRED-XL: We also use a larger HRED with 350 hidden units for all GRUs as a baseline to show the impact of model size.

4.3 Implementation Details

In all experiments, we adopt the delexicalized form of dialogues as shown in Table 2 with vocabulary size, including slots and special tokens, to be 4258. The max number of turns and sequence length are capped to 22 and 36, respectively.

G-DuHA uses 2-layer, 200-hidden-unit GRUs as all encoders, decoders, and context RNNs. All feed-forward networks have 2 layers with non-linearity. FFNs of encoder attention and end of dialogue prediction have 50 hidden units. The FFNs of context attention and goal embedding gets 100 and 200 hidden units. We simply use greedy decoding for utterance generation.

All models initialize embeddings with pre-trained fast-text vectors on wiki-news (2018) and are trained by the Adam optimizer (2015) with early-stopping to prevent overfitting. To mitigate the discrepancy between training and inference, we pick predicted or ground-truth utterance as the current input uniformly at random when training.

4.4 Evaluation Metrics

We employ a number of automatic metrics as well as human evaluations to benchmark competing models on quality, diversity, and goal focus:

Quality. BLEU (Papineni et al., 2002), as BLEU-4 by default, is a word-overlap measure against references and commonly used by dialogue generation works to evaluate quality (2015;

Model	Size	BLEU	B1	B2	B3	D-1	D-2	D-U	P	R	F1	L-D	L-U
LM+G	4.2 M	6.34	23.24	12.89	8.76	0.16	0.88	23.75	89.52	82.39	**84.89**	15.1	13.0
LM+G-XL	8.2 M	6.22	23.10	12.75	8.63	0.16	0.93	**26.38**	**90.03**	81.62	84.71	14.7	14.4
HRED	5.1 M	5.40	21.91	11.58	7.66	0.09	0.38	3.94	69.69	66.22	65.35	17.3	14.1
HRED-XL	8.8 M	5.08	20.45	10.90	7.22	0.11	0.50	5.51	68.25	65.93	65.09	15.9	16.9
G-DuHA	7.8 M	**7.48**	**24.38**	**14.44**	**10.12**	**0.17**	**0.99**	**25.98**	86.21	**83.18**	83.76	14.3	15.0

S: you are welcome . have a great day !

Table 2: Dialogue qualitative comparison. Reqt: Requests. U: User, S: Agent. **Goal hit or miss**. **Role confusion**. Extensive qualitative comparisons of dialogues are presented in the appendix.

2016b; 2016a; 2017; 2018). Lower N-gram B1, B2, B3 are also reported.

Diversity. D-1, D-2, D-U: The distinctiveness denotes the number of unique unigrams, bigrams, and utterances normalized by each total count (Li et al., 2016a; Xu et al., 2018). These metrics are commonly used to evaluate the dialogue diversity.

Goal Focus. A set of slots such as address are extracted from reference dialogues as multi-label targets. Generated slots in model's output dialogues are the predictions. We use the multi-label precision, recall, and F1-score as surrogates to measure the goal focus and achievement.

Human Evaluation. The side-by-side human preference study evaluates dialogues on *goal focus*, *grammar*, *natural flow*, and *non-redundancy*.

5 Results and Discussion

5.1 Dialogue Generation Results

For dialogue generation (Li et al., 2016b), a model is given one or more goals and one user utterance as the seed inputs to generate entire dialogues in an auto-regressive manner.

Table 1 summarizes the evaluation results. For quality measures, G-DuHA significantly outperforms other baselines, implying that it's able to carry out a higher-quality dialogue. Besides, goal-embedded LMs perform better than HREDs, showing the benefits of our goal embedding module. No significant performance difference is observed with respect to model size variants.

For diversity evaluations, G-DuHA is on par with goal-embedded LMs and both outperform HRED significantly. Of 1000 generated dialogues, HRED delivers highly repetitive outputs with only 4 to 6% distinct utterances, whereas 25% of utterances are unique from G-DuHA.

For recovering slots in reference dialogues, precision denotes a degree of goal deviation, recall entails the achievement of goals, and F1 measures the overall focus. Goal-embedded LM is the best on precision and F1 with G-DuHA having com-

Goals	Contexts (Reference)	Response
Domain: train User: [destination, departure, arriveBy, day] Reqt:[duration,price] Book: False Domain: restaurant User: [area, food, pricerange] Reqt: [] Book: True	U: hey i am looking for a train from [value_place] to [value_place] . mind helping out ? S: many trains are leaving on [value_day] . mind choosing the time ? U: i want to leave on [value_day] and arrive by [value_time] . S: i have train [train_id] that leaves [value_place] at [value_time] and arrives in [value_place] at [value_time] . would you like to make reservations ? U: could you give me the travel time and price of that train please ? S: the cost is [value_price] pounds . the duration of the trip is [value_count] minutes , leaving [value_place] at [value_time] and arriving at [value_time] in [value_place] .	**LM+G**: thanks . i am also looking for a restaurant in the [value_area] . **HRED**: i am also looking for a place to stay . i would like a [value_count] star hotel . **G-DuHA**: thank you . i am also looking for a restaurant in the [value_area] of town .
Domain: train User: [destination, departure, arriveBy, day] Reqt: [] Book: False	U: i need a train that leaves on [value_day] with an arrival of [value_time] . S: where will you be travelling to and from ?	**LM+G**: i will be departing from [value_place] . **HRED**: i will be leaving from [value_place] . **G-DuHA**: i am departing from [value_place] and need to arrive by [value_time] .

Table 5: Qualitative comparison of generated responses. Reqt: Requests. U: User, S: Agent.

parable performance. However, even thought LM can better mention the slots in dialogue generation, utterances are often associated with a wrong role. That is, role confusions are commonly seen such as the user makes reservations for the agent as in Table 2. The reason could be that LM handles the task similar to paragraph generation without an explicit design for the conversational hierarchy.

Overall, G-DuHA is able to generate high-quality dialogues with sufficient diversity and still adhere to goals compared to baselines.

Qualitative Comparison. Table 2 compares generated dialogues from different models given one to three goals to focus on. It's clear that models with the goal embedding module are able to adhere to given goals such as "book" or "no book", requesting "price" or "entrance fee" while HRED fails to do so. They can also correctly covering all required domain contexts without any diversion such as switching from attraction inquiry to restaurant booking, then to taxi-calling. For HRED, without goals, generated dialogues often detour to a non-relevant domain context such as shifting to train booking while only hotel inquiry is required.

For goal-embedded LM, a serious issue revealed is role confusions as LM often wrongly shifts between the user and agent as shown in Table 2. The issue results from one wrong `EndofUtterance` prediction but affects rest of dialogue and degrades the overall quality. More generated dialogues are reported in the appendix.

5.2 Response Generation Results

For response generation (Sordoni et al., 2015; Serban et al., 2016c; Park et al., 2018), a set of goals as well as the previous context, i.e. all previous

	Wins	Losses	Ties
Goal Focus	**82.33%**	6.00%	11.67%
Grammar	6.00%	5.00%	89.00%
Natural Flow	**26.00%**	15.00%	59.00%
Non-redundancy	**35.34%**	6.33%	58.33%

Table 6: Human evaluations, G-DuHA vs HRED. 100 pairs of generated dialogues along with goals are given to three domain experts for side-by-side comparisons.

reference utterances, are given to a model to generate the next utterance as a response.

Table 3 and 4 summarize the results. G-DuHA outperforms others on quality and goal focus measures and rivals LM-goal on diversity on both agent and user responses. For goal focus, LM-goal performs good on precision but short on recall. This could because it generates much shorter user and agent responses on average.

Interestingly, as previous contexts are given, LM-goal performs only slightly better than HRED. This implies hierarchical structures capturing longer dependencies can make up the disadvantages of having no goal information for response generation. However, as illustrated in Table 12, HRED could still fail to predict the switch of domain contexts, e.g. from `train` to `restaurant`, which explains performance gaps. Another intriguing observation is that when incorporating the goal embedding module, response diversity and goal focus can be boosted significantly.

Comparing the performance between agent and user response generation, we observe that models can achieve higher quality and diversity but lower goal focus when modeling agent's responses. These might result from the relatively consistent utterance patterns but diverse slot types used by an agent. More generated responses across different models are presented in the appendix.

5.3 Human Evaluation Results

For human evaluation, we conduct side-by-side comparisons between G-DuHA and HRED, the widely used baseline in literature, on dialogue generation task. We consider the following four criteria: *goal focus*, *grammar*, *natural flow*, and *non-redundancy*. *Goal focus* evaluates whether the dialogue is closely related to the preset goals; *grammar* evaluates whether the utterances are well-formed and understandable; *natural flow* evaluates whether the flow of dialogue is logical and fluent; and *non-redundancy* evaluates whether the dialogue is absent of unnecessary repetition of mentioned information. 100 pairs of generated dialogues from G-DuHA and HRED along with their goals are randomly placed against each other. For each goal and pair of dialogues, three domain experts were instructed to set their preferences with respect to each of the four criteria, marked as *win / lose / tie* between the dialogues.

Table 6 presents the results. G-DuHA shows substantial advantages on goal focus, with 82.33% wins over HRED, confirming the benefits of our goal embedding module. G-DuHA also outperforms HRED significantly on natural flow and non-redundancy. These might result from G-DuHA's ability to generating much more diverse utterances while concentrating on current goals. An especially interesting observation is that in cases where multiple goals are given, G-DuHA not only stays focused on each individual goal but also generates intuitive transitions between goals, so that the flow of a dialogue is natural and coherent. An example is shown in Table 2, where the G-DuHA-generated dialogue switches towards the `taxi` goal while maintaining reference to the previously mentioned `attraction` and `restaurant` goals: *"... i also need a taxi to commute between the 2 places ..."*. We also observe that both G-DuHA and HRED performed well on grammaticality. The generated samples across all RNN-based models are almost free from grammar error as well.

5.4 Ablation Studies

The ablation studies are reported in Table 7 for dialogue generation and in Table 8 for response generation to investigate the contribution of each module. Here we evaluate user and agent response generation together.

Goal Embedding Module. First, we examine the impact of goal embedding module. When unplugging the goal embedding module, we observe significant and consistent drops on quality, diversity, and goal focus measures for both dialogue and response generation tasks. For dialogue generation task, the drops are substantially large which resonates with our intuition as the model only has the first user utterance as input context to follow.

With no guideline about what to achieve and what conversation flow to go around with, dialogues generated from HRED often have the similar flow and low diversity. These results demon-

Model	BLEU	B1	D-1	D-2	D-U	P	R	F1

strate that our goal embedding module is critical in generating higher-quality and goal-centric dialogues with much more diversity.

Dual Hierarchical Architecture. We also evaluate the impact of dual hierarchical architecture. Comparisons on both dialogue and response generation tasks show a consistent trend. We observe that applying dual architecture for interlocutor-level modeling leads to a solid increase in utterance diversity as well as moderate improvements on quality and goal focus.

The results echo our motivation as two interlocutors in a goal-oriented dialogue scenario exhibit distinct conversational patterns and this interlocutor-level disparity should be modeled by separate hierarchical encoder-decoders.

For the dialogue-level attention module, there is no significant effect on diversity and goal focus on both tasks but it marginally improves the overall utterance quality as BLEU scores go up by a bit.

6 Data Augmentation via Dialogue Generation

As an exemplified extrinsic evaluation, we leverage the goal-oriented dialogue generation as data augmentation for task-oriented dialogue systems. Dialogue state tracking (DST) is used as our evaluation task which is a critical component in task-oriented dialogue systems (Young et al., 2013) and has been studied extensively (Henderson et al., 2014; Mrksic et al., 2017; Zhong et al., 2018).

In DST, given the current utterance and dialogue history, a dialogue state tracker determines the state of the dialogue which comprises a set of *requests* and *joint goals*. For each user turn, the user informs the system a set of turn goals to fulfill, *e.g. inform(area=south)*, or turn requests asking for more information, *e.g. request(phone)*. The joint goal is the collection of all turn goals up to the current turn.

We use the state-of-the-art Global-Locally Self-Attentive Dialogue State Tracker (GLAD) (Zhong et al., 2018) as our benchmark model and the WoZ restaurant reservation dataset (Wen et al., 2017; Zhong et al., 2018) as our benchmark dataset, which is commonly used for the DST task.

The dataset consists of 600 train, 200 validation and 400 test dialogues. We use the first utterances from 300 train dialogues and sample restaurant-domain goals to generate dialogues, whose states are annotated by a rule-based method.

Table 9 summarizes the augmentation results. Augmentation with G-DuHA achieved an improvement over the vanilla dataset and outperform

HRED on turn requests while being comparable on joint goal. For goal-embedded LM, as it struggles with role confusion, the augmentation actually hurts the overall performance.

7 Conclusion

We introduced the goal-embedded dual hierarchical attentional encoder-decoder (G-DuHA) for goal-oriented dialogue generation. G-DuHA is able to generate higher-quality and goal-focused dialogues as well as responses with decent diversity and non-redundancy. Empirical results show that the goal embedding module plays a vital role in the performance improvement and the dual architecture can significantly enhance diversity.

We demonstrated one application of the goal-oriented dialogue generation through a data augmentation experiment, though the proposed model is applicable to other conversational AI tasks which remains to be investigated in the future.

As shown in experiments, a language model coupled with goal embedding suffers from role-switching or confusion. It's also interesting to further dive deep with visualizations (Kessler, 2017) and quantify the impact on quality, diversity, and goal focus metrics.

Acknowledgments

The authors would like to acknowledge the entire AWS Lex Science team for thoughtful discussions, honest feedback, and full support. We are also very grateful to the reviewers for insightful comments and helpful suggestions.

A Appendix

A.1 More Generated Dialogues for Qualitative Comparison

In Table 10 and Table 11, we list and compare more generated dialogues of different models given a variable number of goals to focus on.

The domains, what slots to request such as phone or postcode, and when should the user make a reservation or not are specified in goals. We use bold style to emphasize whether the assigned goals are achieved or missed such as requests of a correct slot or a wrong domain. The underline and bold style denotes the role confusions.

A.2 More Generated Responses for Qualitative Comparison

Responses are generated by a model given the goals and all the previous utterances. In Table 12, we present more generated responses for qualitative comparison. We observe that HRED is unable to correctly switch beteen goal contexts illustrated by the second example.

Abstract

Automatic question generation (QG) is a useful yet challenging task in NLP. Recent neural network-based approaches represent the state-of-the-art in this task. In this work, we attempt to strengthen them significantly by adopting a holistic and novel generator-evaluator framework that directly optimizes objectives that reward semantics and structure. The *generator* is a sequence-to-sequence model that incorporates the *structure* and *semantics* of the question being generated. The generator predicts an answer in the passage that the question can pivot on. Employing the copy and coverage mechanisms, it also acknowledges other contextually important (and possibly rare) keywords in the passage that the question needs to conform to, while not redundantly repeating words. The *evaluator* model evaluates and assigns a reward to each predicted question based on its conformity to the *structure* of ground-truth questions. We propose two novel QG-specific reward functions for text conformity and answer conformity of the generated question. The evaluator also employs structure-sensitive rewards based on evaluation measures such as BLEU, GLEU, and ROUGE-L, which are suitable for QG. In contrast, most of the previous works only optimize the cross-entropy loss, which can induce inconsistencies between training (objective) and testing (evaluation) measures. Our evaluation shows that our approach significantly outperforms state-of-the-art systems on the widely-used SQuAD benchmark as per both automatic and human evaluation.

1 Introduction

Automatic question generation (QG) is a very important yet challenging problem in NLP. It is defined as the task of generating syntactically correct, semantically sound and relevant questions from various input formats such as text, a structured database or a knowledge base (Mannem et al., 2010). More recently, neural network based techniques such as sequence-to-sequence (Seq2Seq) learning have achieved remarkable success on various NLP tasks, including question generation. A recent deep learning approach to question generation (Serban et al., 2016) investigates a simpler task of generating questions only from a triplet of subject, relation and object. Learning to ask (referred to as L2A hereinafter) (Du et al., 2017) proposes a Seq2Seq model with attention for question generation from text. (Song et al., 2018) (in an approach referred to as NQG$_{LC}$ hereafter) encoded ground-truth answers and employed bi-directional LSTMs in a Seq2Seq setting. In addition, they use the *copy* mechanism (See et al., 2017) and context matching to capture interactions between the given ground-truth answer and its context within the passage.

In the context of QG from paragraphs, (Zhao et al., 2018) proposed maxout pointer network to keep track of word *coverage*. Our previous work (Kumar et al., 2018) (referred to as AutoQG hereinafter) generates *candidate answers* from text using Pointer Networks (Vinyals et al., 2015) and *encodes the answer* in the question decoder for improved performance.

We first present a framework in which a *generator* mechanism (the horse) that is employed for generating a question-answer pair invokes or pulls the *evaluator* mechanism (the cart) that is employed for evaluating the generated pair. Our clearly delineated *generator-evaluator* framework lets us (a) easily incorporate several best practices from the above referred previous models in the *generator* while (b) also letting us employ in the *evaluator*, other complex non-decomposable rewards that are consistent with performance measures (such as BLEU and ROUGE) on test data. We also propose some novel reward functions that

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 812–821
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

evaluate the syntax of the question and semantics of the question-answer pair in its entirety. More specifically, since the generated question is in anticipation of some specific answer, we find it most natural to incorporate candidate answer generation (using Pointer Networks) alongside QG right in our generator module, so that the evaluator can optionally take into cognizance the conformity of the generated answer to the ground-truth answer, along with text conformity. Likewise, we also incorporate copy and coverage mechanisms for QG into the generator module so that they can be specifically trained by leveraging a suite of holistically designed and structure-sensitive reward functions in the evaluator module.

The Generator

In Table 1, in rows 1 through 4, we illustrate through examples, the incremental benefits of introducing answer prediction and the copy and coverage mechanisms (See et al., 2017) in the generator. The evaluator associated with the corresponding three generator models employs the conventional and simplistic cross-entropy loss. The motivation for answer prediction in the generator module is obvious and will be further discussed in Section 2.1. In row 3 we illustrate the influence of our copy mechanism, where a rare phrase 'new amsterdam' has been rightly picked up in association with the name of the city.

We however note that in row 3, the word 'new' has been erroneously repeated twice, since an encoder-decoder based model could generate questions with meaningless repetitions.

We introduce a mechanism for discouraging such repetitions in our generator by quantitatively emphasizing the *coverage* of sentence words while decoding. Row 4 shows the improved and relevant question generated by our model trained by incorporating both the copy and coverage mechanisms.

Evaluator

In row 5 of Table 1, we observe the high-quality question that is generated when the simplistic cross-entropy loss in the evaluator is replaced with the more complex and non-decomposable (across words) BLEU reward that accounts for proximity of 'founded' to 'new york'.

In Table 2, we further illustrate the effect of employing other reward functions (described in Section 2.2) in the evaluator. As can be seen, the model that incorporates QG-specific reward functions (QSS and ANSS) generates a significantly better question when compared to the question generated without these rewards.

Limitations of simple decomposable losses: A Seq2Seq model trained using a vanilla cross-entropy loss function (decomposable over words in the question) generates the question *"what year was new york named ?"* (row 1 in Table 1), which is not addressed in the sentence. The passage talks only about the founding of the city and its naming two years later. The inaccuracy of the question is possibly caused by the use of a loss that is agnostic to sequence information. In other words, given its decomposable nature, the cross-entropy loss on the ground-truth question or any of its (syntactically invalid) anagrams will be the same. Moreover, use of the cross-entropy loss in the sequence prediction model could make the process brittle, since the model trained on a specific distribution over words is used on a test dataset with a possibly different distribution to predict the next word given the current predicted word. This creates exposure bias (Ranzato et al., 2015) during training, since the model is only exposed to the data distribution and not the model distribution. Thus, performance suffers due to inadequately evaluating the *structure* of the generated question against the ground-truth question.

The standard metrics for evaluating the performance of question generation models such as BLEU (Papineni et al., 2002), GLEU, and ROUGE-L (Lin, 2004) are based on degree of n-gram overlaps between a generated question and the ground-truth question. It would be desirable to be able to directly optimize these *task-specific metrics*. However, these n-gram based metrics do not decompose over individual words and are therefore hard to optimize. We explicitly employ an evaluator that rewards each generated question based on its conformance to one (or more than one using decomposable attention) questions in the ground-truth set using these possibly non-decomposable reward functions. We find such learning to be a natural instance of reinforcement learning (RL) (Sutton and Barto, 1998) that allows us to use policy gradient to directly optimize task-specific rewards (such as BLEU, GLEU and ROUGE-L), which are otherwise non-differentiable and hard to optimize. In Table 2 we illustrate questions generated using different reward functions. It can be observed that ques-

Table 2: Sample text and questions generated using different reward functions, with and without our new QG-specific rewards QSS+ANSS.

tions generated using combination of standard reward functions with reward functions specific to QG quality (QSS+ANSS) exhibit higher quality.

Contributions We summarize our main contributions as follows:

- A comprehensive, end-to-end **generator-evaluator framework** naturally suited for automated question generation. Whereas earlier approaches employ some mechanism (the horse) for generating the question, intertwined with an evaluation mechanism (the cart), we show that these approaches can benefit from a much clearer separation of the generator of the question from its evaluator.

- A *generator* founded on the **semantics** and **structure** of the question by (a) identifying target/pivotal answers (Pointer Network), (b) recognizing contextually important keywords in the answer (copy mechanism), and (c) avoiding redundancy (repeated words) in the question (coverage mechanism).

- An *evaluator* that (a) directly optimizes for conformity to the **structure** of ground-truth sequences (BLEU, GLEU, etc.), and (b) matches against appropriate questions from a set of ground-truth questions (Decomposable Attention).

- Novel reward functions that ensure that the generated question is relevant to the text and conforms to the encoded answer.

When evaluated on the benchmark SQuAD dataset (Rajpurkar et al., 2016), our system considerably outperforms state-of-the-art question generation models (Du et al., 2017; Kumar et al., 2018; Song et al., 2018) in automatic and human evaluation.

2 Our Approach

Our framework for question generation consists of a generator and an evaluator. From the reinforcement learning (RL) point of view, the generator is the *agent* and the generation of the next word is an *action*. The probability of decoding a word $P_\theta(word)$ gives a stochastic *policy*. On every token that is output, an evaluator assigns a reward for the output sequence predicted so far using the current policy of the generator. Based on the reward assigned by the evaluator, the generator updates and improves its current policy. Let us denote the reward (*return*) at time step t by r_t. The cumulative reward, computed at the end of the generated sequence is represented by $R = \sum_{t=0}^{T} r_t$. The goal of our framework is to determine a generator

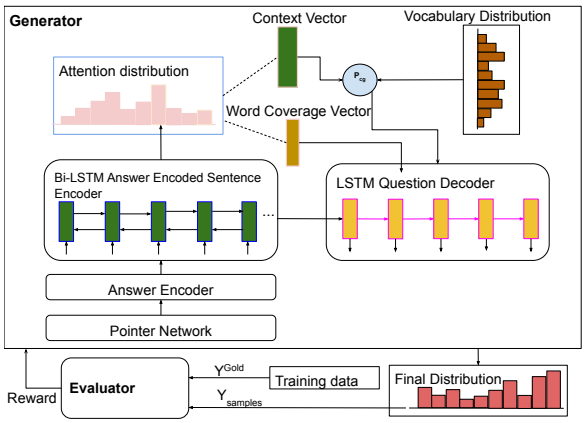

Figure 1: Our generator-evaluator framework for question generation. p_{cg} is the probability which determines whether to copy a word from source text or sample it from vocabulary distribution.

(policy) that maximizes the expected return:

$$Loss_{RL}(\theta) = -\mathrm{E}_{P_\theta(Y_{0:T}|\mathbf{X})} \sum_{t=0}^{T} r_t(Y_t; \mathbf{X}, Y_{0:t-1}) \tag{1}$$

where X is the current input and $Y_{0:t-1}$ is the predicted sequence until time $t-1$. This supervised learning framework allows us to directly optimize task-specific evaluation metrics (r_t) such as BLEU.

The generator is a sequence-to-sequence model, augmented with (i) an encoding for the potentially best pivotal answer, (ii) the copy mechanism (Gu et al., 2016) to help generate contextually important words, and (iii) the coverage mechanism (Tu et al., 2016) to discourage word repetitions. The evaluator provides rewards to fine-tune the generator. The reward function can be chosen to be a combination of one or more metrics. The high-level architecture of our question generation framework is presented in Figure 1.

2.1 Generator

Similar to AutoQG (Kumar et al., 2018), we employ attention and boundary pointer network to identify pivotal answer spans in the input sentence. The generator then takes as input the sequence of words in the sentence, each augmented with encoding of most probable pivotal answer, along with a set of linguistic features such as POS tag, NER tag, *etc.* At each step, the generator outputs a word with the highest probability, to eventually produce a word sequence. Additionally, as we will see, the generator employs copy and coverage mechanisms.

Sentence Encoder: Each word in the input text is fed sequentially into the encoder along with its linguistic features as well as with the encoded pivotal answer (identified by the boundary pointer network). Our encoder is a two-layer bidirectional LSTM network, consisting of $\overrightarrow{h_t} = \overrightarrow{LSTM_2}(x_t, \overrightarrow{h_{t-1}})$ and $\overleftarrow{h_t} = \overleftarrow{LSTM_2}(x_t, \overleftarrow{h_{t-1}})$, which generates a sequence of hidden states. Here x_t is the given input word at time step t, and $\overrightarrow{h_t}$ and $\overleftarrow{h_t}$ are the hidden states at time step t for the forward and backward passes respectively.

Question Decoder: Our question decoder is a single-layer LSTM network, initialized with the state $s = [\overrightarrow{h_t}; \overleftarrow{h_t}]$, which is concatenation of hidden state from forward and backward passes.

We also model the attention (Bahdanau et al., 2014) distribution over words in the source text. We calculate the attention (a_i^t) over the i^{th} source word as $a_i^t = softmax(e_i^t)$, where

$$e_i^t = v^t tanh(W_{eh} h_i + W_{sh} s_t + b_{att}) \tag{2}$$

Here v^t, W_{eh}, W_{sh} and b_{att} are model parameters to be learned, and h_i is the concatenation of forward and backward hidden states of the encoder. We use this attention a_i^t to generate the *context vector* c_t^* as a weighted sum of encoder hidden states: $c_t^* = \sum_i a_i^t h_i$. We further use the c_t^* vector to obtain a probability distribution over the words in the vocabulary as: $P = softmax(W_v[s_t, c_t^*] + b_v)$, where W_v and b_v are model parameters. Thus during decoding, the probability of a word is $P(qword)$. During the training process for each timestamp, the loss is calculated as $L_t = -\log P(qword_t)$. The loss associated with the generated question is:

$$Loss = \frac{1}{T}\sum_{t=0}^{T} L_t = -\frac{1}{T}\sum_{t=0}^{T} \log P(qword_t) \tag{3}$$

2.1.1 The Copy and Coverage Mechanisms:

The copy mechanism facilitates the copying of important entities and words from the source sentence to the question. We calculate $p_{cg} \in [0, 1]$ as the decision of a binary classifier that determines whether to generate (sample) a word from the vocabulary or to copy the word directly from the input text, based on attention distribution a_i^t:

$$p_{cg} = sigmoid(W_{eh}^T c_t^* + W_{sh}^T s_t + W_x x_t + b_{cg}) \tag{4}$$

Here W_{eh}, W_{sh}, W_x and b_{cg} are trainable model parameters. The final probability of decoding a word is specified by the mixture model:

$$p^*(qword) = p_{cg} \sum_{i:w_i=qword} a_i^t + (1-p_{cg})p(qword) \tag{5}$$

Where $p^*(qword)$ is the final distribution over the union of the vocabulary and the input sentence.

As discussed earlier, Equation (5) addresses the rare words issue, since a word not in vocabulary will have probability $p(qword) = 0$. Therefore, in such cases, our model will replace the <unk> token for out-of-vocabulary words with a word in the input sentence having the highest attention obtained using attention distribution a_i^t.

To discourage meaningless multiple repetitions of words in the question (as illustrated in row 3 of Table 1), we maintain a word coverage vector (wcv) for the words already predicted as the sum of all the attention distributions ranging over timesteps 0 until $t-1$. Specifically, at time step t, $wcv = \sum_{t'=0}^{t-1} a^{t'}$.

No word is generated before timestep 0, and hence *wcv* will be a zero vector then. After storing the word coverage vector until $t-1$, while attending to the next word, we will need to inform our attention mechanism about words covered until then. Hence, equation (2) is now modified to be:

$$e_i^t = v^t tanh(W_{wcv} wcv_i^t + W_{eh} h_i + W_{sh} s_t + b_{att}) \tag{6}$$

Here W_{wcv} are trainable parameters that inform the attention mechanism about words that have been previously covered while choosing to attend over the next word. Following the incorporation of the copy and coverage mechanism in our generator, the generator's final loss function will be:

$$Loss_{copy+cov} = -\frac{1}{T}\sum_{t=0}^{T} \log P^*(w_t) + \lambda_c L_{cov} \tag{7}$$

where λ_c is the coverage hyperparameter and the coverage loss L_{cov} is defined as:

$$L_{cov} = \sum_i min(a_i^t, wcv_i^t) \tag{8}$$

We note that this cross-entropy based loss function still does not include task-specific metrics such as BLEU that were motivated earlier. We employ an evaluator to refine the model pre-trained on this loss function to directly optimize the task specific reward. We also empirically show that the refinement of maximum likelihood models using task-specific rewards such as BLEU improves results considerably. In the next subsection we describe our evaluator.

2.2 Evaluator

The evaluator fine-tunes the parameters of the generator network by optimizing task-specific reward functions through policy gradient. It takes as input the predicted sequence and the gold sequence, evaluates a policy, and returns a reward (a score between 0 and 1) that reflects the quality of the question generated. For question generation, the choice of reward functions include task-specific metrics BLEU, GLEU and ROUGE-L (Du et al., 2017; Kumar et al., 2018), as well as the decomposable attention (Parikh et al., 2016) described below. More importantly, we present two new reward functions that are specifically designed for question generation, QSS and ANSS, for the conformity of questions and answers respectively.

Combining Equation (7) with a reward function R (BLEU, GLEU, ROUGE, DAS, QSS and ANSS), we obtain the overall loss function using the expected reward objective as follows:

$$L_{overall} = \alpha * Loss_{copy+cov} - \beta * \sum_{i=0}^{N} \sum_{y \in \mathcal{Y}} P_\theta(y|X^{(i)}) R(y, y^{*(i)}) \tag{9}$$

where $R(y, y^{*(i)})$ denotes per sentence score (reward), $\mathcal{Y}$ is a set of sequences sampled from the final distribution, and α and β are tunable hyperparamters.

2.2.1 Decomposable attention based evaluator

The use of a lexical similarity based reward function such as BLEU or ROUGE does not provide the flexibility to handle multiple possible versions of the ground truth. For example, the questions *"who is the widow of ray croc?"* and *"ray croc was married to whom?"* have almost the same meaning, but due to word order mismatch with the gold question, at most one of them can be rewarded using the BLEU score at the cost of the other(s). Empirically, we find this restriction leading to models that often synthesize questions with

poor quality. We therefore, design a novel reward function, a decomposable attention (Parikh et al., 2016) based similarity scorer (DAS). Denoting by $\hat{q}$ a generated question and by q the ground-truth question, we compute a cross attention based similarity using the following steps:

Cross Attention: The generated question $\hat{q}$ and the ground-truth question q are inter-attended as:

$$\hat{q}_i^* = \sum_{j=0}^{L_q} a_{ji} e(q_j),\ a_{ji} = \frac{\exp(e(\hat{q}_i)^T e(q_j))}{\sum_{k=0}^{L_{\hat{q}}} \exp(e(\hat{q}_i)^T e(q_k))},$$
$$q_j^* = \sum_{i=0}^{L_{\hat{q}}} b_{ji} e(\hat{q}_i),\ b_{ji} = \frac{\exp(e(\hat{q}_i)^T e(q_j))}{\sum_{k=0}^{L_q} \exp(e(\hat{q}_k)^T e(q_j))} \tag{10}$$

where $e(.)$ is the word embedding of dimension size d, $\hat{q}^*$ is the cross attention vector for a generated question $\hat{q}$, and q^* is the cross attention vector for a question q in the ground truth.

Comparison: Each n-gram $\hat{q}_i$ in the generated question (through its embedding $e(\hat{q}_i)$) is compared with its associated cross-attention vector $\hat{q}^*$ using a feed forward neural network N_1. Similarly, each n-gram q_j in the ground-truth question (through its embedding $e(q_j)$) is compared with its associated attention vector q^* using another network N_2 having the same architecture as N_1. The motivation for this comparison is that we would like to determine the soft alignment between n-grams in the generated question and the gold question. As an illustration, while comparing the gold question "*why do rockets look white?*" with a generated question "*why are rockets and boosters painted white?*", we find that an n-gram "*rockets and boosters*" is softly aligned to "*rockets*" while "*look*" is softly aligned to "*painted*".

$$\boldsymbol{\hat{q}_{1,i}} = N_1([e(\hat{q}_i), \hat{q}^*]),\ \boldsymbol{q_{2,j}} = N_2([e(q_j), q^*]) \tag{11}$$

where $\boldsymbol{\hat{q}_{1,i}}$ and $\boldsymbol{q_{2,j}}$ are vectors containing comparison scores of aligned phrases in generated question and gold question respectively and N_1 and N_2 are the feed forward neural nets.

Matching Score: The vectors $\boldsymbol{\hat{q}_{1,i}}$ and $\boldsymbol{q_{2,j}}$ are aggregated over each word or phrase in the predicted question and gold question respectively before feeding them to a linear function (L):

$$DAS = L(\sum_{i=1}^{L_q} \boldsymbol{\hat{q}_{1,i}}, \sum_{j=1}^{L_{\hat{q}}} \boldsymbol{q_{2,j}}) \tag{12}$$

This matching score between the predicted question and the gold question is the reward returned by the decomposable attention based evaluator.

2.2.2 QG quality specific reward functions

We introduce two new reward functions that specifically designed to evaluate the conformity of the generated question (QSS) and answer (ANSS) against the ground truth.

Question sentence overlap score (QSS): This reward function is specific to QG. We compute the sentence overlap score as the number of common n-grams between predicted question and the source sentence. This reward ensures that generated question is relevant to the given sentence. Thus, if $precision_n(s, q)$ computes the $n-$gram precision match between sentence and question,

$$QSS = (\prod_{i=1}^{n} precision_i(sentence, question))^{\frac{1}{n}} \tag{13}$$

Predicted and encoded answer overlap score (ANSS): In order to ensure that the generated question is about the pivotal answer/ground truth answer we calculate answer overlap score. Answer overlap score is the number of common n-grams between the encoded answer and the answer predicted (ans_{qa}) for the generated question using the best performing question answering model over SQuAD[1]

$$ANSS = (\prod_{i=1}^{n} precision_i(\text{ans}_{qa}, pivotal_answer))^{\frac{1}{n}} \tag{14}$$

3 Experimental Setup

In this section, we present our evaluation framework on the publicly available SQuAD (Rajpurkar et al., 2016) dataset. We first explain various reward functions employed in our experiments. We then describe our baseline and the evaluation methods.

Reward Functions: We experimented with the five reward functions discussed in Section 2.2: (1) BLEU, (2) GLEU, (3) ROUGE-L, (4) DAS, and (5) the QG-specific reward QSS+ANSS. In our

[1] https://github.com/huggingface/pytorch-pretrained-BERT

experiments we considered BLEU for up to 4-grams. For the GLEU score, we recorded all subsequences of up to 4-grams.

Baselines and Evaluation Methods: We reimplemented two state-of-the-art question generation models as baselines for comparison: L2A (Du et al., 2017) and AutoQG (Kumar et al., 2018). A direct (and fair) comparison with another recent technique, NQG_{LC} (Song et al., 2018), is not feasible, as unlike us, NQG_{LC} requires ground-truth answers, whereas both AutoQG and our model predict pivotal answers. L2A does not consider answers. Moreover, their context (input is sometimes more than one sentence) is different also the train/test split is different from ours. Hence, we only report the original numbers reported in their paper. We also did not perform human evaluation on NQG_{LC} as their source code has not been made available for reimplementation.

We also use an existing implementation of a recent RL-based abstractive summarization technique (Paulus et al., 2018) to train baseline models SUM_{BLEU} (with BLEU as reward function) and $\text{SUM}_{\text{ROUGE}}$ (with ROUGE as reward function). This comparison studies the effectiveness of state-of-the-art abstractive summarization techniques applied to question generation as-is, as the two are conceptually similar tasks.

We report automatic and human evaluation results on eight variants of our model, each of which is equipped with the copy and coverage mechanism, the pointer network, as well as one of the four reward functions: BLEU, GLEU, ROUGE-L, DAS or one of the four rewards in combination with QG quality specific rewards (QSS+ANSS). Hence, our models are named GE_{BLEU}, etc.

For automatic evaluation, we employ BLEU, ROUGE-L and METEOR, which are standard evaluation measures used to evaluate sequence prediction tasks. We use the evaluation scripts released by (Chen et al., 2015) that was originally used to evaluate the image captioning task.

We also performed human evaluation to further analyze the quality of questions generated for their syntactic correctness, semantic correctness and relevance. Syntactic correctness measures the grammatical correctness of a generated question, semantic correctness measures meaningfulness and naturalness of the question, and relevance measures how relevant the question is to the text. We perform human evaluation for each model on a randomly selected subset of 100 sentences. Each of the three judges is presented the 100 sentence-question pairs for each model and asked for a binary response on each quality parameter. The responses from all the judges for each parameter is then averaged for each model.

3.1 Ablation Analysis

We conducted an ablation analysis to study the effect of removing the copy and coverage mechanisms. Table 4 summarizes the drop in performance for GE_{ROUGE}. Without the copy mechanism, there is a drop overall in every evaluation measure, with BLEU-4 registering the largest drop of 13.8% as against 13.4%, 6.9% and 4.7% in BLEU-3, BLEU-2 and BLEU-1 respectively. On the other hand, without the coverage mechanism, we see a consistent but sufficiently lower drop (1-2%) in each evaluation measure for GE_{ROUGE}.

4 Results and Discussion

We show and compare results on automatic evaluation in Table 3. Note the numbers in parentheses for L2A (Du et al., 2017), AutoQG (Kumar et al., 2018), and NQG_{LC} (Song et al., 2018) are those reported in their original papers. The slight difference of up to 1.7% in the original and reproduced numbers can be attributed to reimplementation and different versions of various libraries used. As can be seen, all our eight models outperform L2A and AutoQG on all evaluation metrics. Two of our models, GE_{GLEU} and GE_{ROUGE}, also outperform NQG_{LC}. Hence, using evaluation metrics as the reward function during reinforcement based learning improves performance for all metrics. We also observe that $\text{GE}_{\text{ROUGE+QSS+ANSS}}$, the model reinforced with ROUGE-L (that measures the longest common sequence between the ground-truth question and the generated question) as the reward function in combination with QG quality specific rewards(QSS+ANSS), is the best performing model on all metrics, outperforming existing baselines considerably. For example, it improves over AutoQG on BLEU-4 by 29.98%, on METEOR by 13.15%, and on ROUGE-L by 8.67%.

In Table 5 we present human evaluation results for the models evaluated on three quality parameters (a) syntactic correctness, (b) semantic correctness, and (c) relevance.

Consistent with automatic evaluation results

Model	BLEU-1	BLEU-2	BLEU-3	BLEU-4	METEOR	ROUGE-L
L2A (Du et al., 2017)	43.21 (43.09)	24.77 (25.96)	15.93 (17.50)	10.60 (12.28)	16.39 (16.62)	38.98 (39.75)
AutoQG (Kumar et al., 2018)	44.68 (46.32)	26.96 (28.81)	18.18 (19.67)	12.68 (13.85)	17.86 (18.51)	40.59 (41.75)
NQG$_{LC}$ (Song et al., 2018)	-	-	-	- (13.98)	- (18.77)	- (42.72)
SUM$_{\text{BLEU}}$ (Paulus et al., 2018)	11.20-	3.50-	1.21-	0.45-	6.68-	15.25-
SUM$_{\text{ROUGE}}$ (Paulus et al., 2018)	11.94-	3.95-	1.65-	0.082-	6.61-	16.17-
GE$_{\text{BLEU}}$	46.84	29.38	20.33	14.47	19.08	41.07
GE$_{\text{BLEU+QSS+ANSS}}$	46.59	29.68	20.79	15.04	19.32	41.73
GE$_{\text{DAS}}$	44.64	28.25	19.63	14.07	18.12	42.07
GE$_{\text{DAS+QSS+ANSS}}$	46.07	29.78	21.43	16.22	19.44	42.84
GE$_{\text{GLEU}}$	45.20	29.22	20.79	15.26	18.98	43.47
GE$_{\text{GLEU+QSS+ANSS}}$	47.04	30.03	21.15	15.92	19.05	43.55
GE$_{\text{ROUGE}}$	47.01	30.67	21.95	16.17	19.85	43.90
GE$_{\text{ROUGE+QSS+ANSS}}$	**48.13**	**31.15**	**22.01**	**16.48**	**20.21**	**44.11**

Table 3: Experimental results on the test set on automatic evaluation metrics. Best results for each metric (column) are **bolded**. The numbers in parentheses for L2A, AutoQG and NQG$_{LC}$ are those from the best models reported in their respective original papers. The slight difference of up to 1.7% from our reproduced numbers can be attributed to reimplementation and different versions of various libraries used. Models with new QG-specific reward functions (QSS+ANSS) are highlighted in gray for easy comparison.

Model (GE$_{\text{ROUGE}}$)	**Δ BLEU-1 (47.01)**	**Δ BLEU-2 (30.67)**	**Δ BLEU-3 (21.95)**	**Δ BLEU-4 (16.17)**	**Δ METEOR (19.85)**	**Δ ROUGE-L (43.90)**
W/o copy	2.09 (4.7%)	2.13 (6.9%)	2.94 (13.4%)	2.23 (13.8%)	2.21 (11.1%)	2.58 (5.9%)
W/o coverage	0.31 (0.7%)	0.57 (1.9%)	0.94 (4.2%)	0.28 (1.7%)	0.84 (4.2%)	1.01 (2.3%)

Table 4: Ablation analysis results after removing (a) copy mechanism and (b) coverage mechanism from the system (GE$_{\text{ROUGE}}$). Both absolute performance drop and percentage of drop (in parentheses) are reported.

shown in Table 3, seven of our eight models outperform the two baselines, with GE$_{\text{DAS+QSS+ANSS}}$ being the best model on syntactic correctness and semantic correctness quality metrics, outperforming all the other models by a large margin. However, model GE$_{\text{BLEU+QSS+ANSS}}$ generates highly relevant questions and is the best model on relevance metrics.

It is noteworthy that for each of our models (e.g. GE$_{\text{BLEU}}$), adding QG-specific rewards (e.g. GE$_{\text{BLEU+QSS+ANSS}}$) significantly improves question quality in human evaluation, even though there is less noticeable improvements in automatic evaluation. This clearly demonstrates the effectivess of our new QG-specific reward functions.

We measure inter-rater agreement using Randolph's free-marginal multirater kappa (Randolph, 2005). This helps in analyzing level of consistency among observational responses provided by multiple judges. It can be observed that our quality metrics for all our models are rated as *moderate agreement* (Viera et al., 2005).

4.1 Analyzing Choice of Reward Function

BLEU(Papineni et al., 2002) measures precision and ROUGE(Lin, 2004) measures recall, we believe that cross-entropy loss was already accounting for precision to some extent and using it in conjunction with ROUGE (which improves recall) therefore gives best performance.

Model	Syntax		Semantics		Relevance	
	Score	Kappa	Score	Kappa	Score	Kappa
L2A	39.2	0.49	39	0.49	29	0.40
AutoQG	51.5	0.49	48	0.78	48	0.50
GE$_{\text{BLEU}}$	47.5	0.52	49	0.45	41.5	0.44
GE$_{\text{BLEU+QSS+ANSS}}$	82	0.63	75.3	0.68	**78.33**	0.46
GE$_{\text{DAS}}$	68	0.40	63	0.33	41	0.40
GE$_{\text{DAS+QSS+ANSS}}$	**84**	0.57	**81.3**	0.60	74	0.47
GE$_{\text{GLEU}}$	60.5	0.50	62	0.52	44	0.41
GE$_{\text{GLEU+QSS+ANSS}}$	78.3	0.68	74.6	0.71	72	0.40
GE$_{\text{ROUGE}}$	69.5	0.56	68	0.58	53	0.43
GE$_{\text{ROUGE+QSS+ANSS}}$	79.3	0.52	72	0.41	67	0.41

Table 5: Human evaluation results (column "Score") as well as inter-rater agreement (column "Kappa") for each model on the test set. The scores are between 0-100, 0 being the worst and 100 being the best. Best results for each metric (column) are **bolded**. The three evaluation criteria are: (1) syntactically correct (Syntax), (2) semantically correct (Semantics), and (3) relevant to the text (Relevance). Models with new QG-specific reward functions (QSS+ANSS) are highlighted in gray for easy comparison.

DAS calculates semantic similarity between generated question and the gound-truth question. As discussed in section 2.2.1 DAS will give high reward even though the generated question has low BLEU score. Thus, the performance of the

model on automatic evaluation metrics does not improve with DAS as the reward function, though the quality of questions certainly improves. Further, ROUGE in conjunction with the cross entropy loss improves on recall as well as precision whereas every other combination overly focuses only on precision.

Error analysis of our best model reveals that most errors can be attributed to intra-sentence dependencies such as co-references, concept dependencies *etc.* In a camera ready version of the paper, we will share link to a detailed report containing extensive experiments that include ablation tests. Also link to the source code will be provided then.

5 Related Work

Neural network-based methods represent the state-of-the-art in automatic question generation (QG) from text. Motivated by neural machine translation, Du et al (2017) proposed a sequence-to-sequence (Seq2Seq) architecture for QG. In our previous work, we (2018) proposed to augment each word with linguistic features and encode the most relevant *pivotal answer* to the text while generating questions. Similarly, Song et al (2018) encode ground-truth answers (given in the training data), use the copy mechanism and additionally employ context matching to capture interactions between the answer and its context within the passage. They encode ground truth answer for generating questions which might not be available for test set in contrast we train a Pointer Network based model to predict the pivotal answer to generate question about. In our work (Kumar et al., 2019a) we proposed a transformer based architecture to automatically generate complex multi-hop questions from knowledge graphs. In (Kumar et al., 2019b) we proposed a cross lingual training method for automatically generating questions from text in low resource languages.

Very recently deep reinforcement learning has been successfully applied to natural language generation tasks such as abstractive summarization (Paulus et al., 2018; Celikyilmaz et al., 2018) and dialogue generation (Li et al., 2016). In summarization, one generates and paraphrases sentences that capture salient points of the text. On the other hand, generating questions additionally involves determining question type such as what, when, etc., being selective on which keywords to copy from the input into the question, leaving remaining keywords for the answer. This also requires the development of a specific probabilistic generative model. (Yao et al., 2018) proposed generative adversarial network (GAN) framework with modified discriminator to predict question type. Recently Fan et al (2018) proposed a bi-discriminator framework for visual question generation. They formulate the task of visual question generation as a language generation task with some linguistic and content specific attributes.

6 Conclusion

We presented a novel, holistic treatment of question generation (QG) using a generator-evaluator framework. Our generator provisions for explicitly factoring in question syntax and semantics, identifies pivotal answers, recognizes contextually important words and avoids meaningless repetitions. Our evaluator allows us to directly optimize for conformity towards the structure of ground-truth question(s). We propose two novel reward functions account for conformity with respect to ground-truth questions and predicted answers respectively. In conjunction, the evaluator makes use of task-specific scores, including BLEU, GLEU, ROUGE-L, and decomposable attention (DAS) that are naturally suited to QG and other seq2seq problems. Experimental results on automatic evaluation and human evaluation on the standard benchmark dataset show that our framework, especially with the incorporation of the new reward functions, considerably outperforms state-of-the-art systems.

Abstract

Various Seq2Seq learning models designed for machine translation were applied for abstractive summarization task recently. Despite these models provide high ROUGE scores, they are limited to generate comprehensive summaries with a high level of abstraction due to its degenerated attention distribution. We introduce Diverse Convolutional Seq2Seq Model(DivCNN Seq2Seq) using Determinantal Point Processes methods(Micro DPPs and Macro DPPs) to produce attention distribution considering both quality and diversity. Without breaking the end to end architecture, DivCNN Seq2Seq achieves a higher level of comprehensiveness compared to vanilla models and strong baselines. All the reproducible codes and datasets are available online[1].

1 Introduction

Given an article, abstractive summarization aims at generating one or several short sentences that cover the main idea of original article, which is a combination of Natural Language Understanding(NLU) and Natural Language Generation(NLG).

Abstractive summarization uses Seq2Seq models (Sutskever et al., 2014) which consist of an encoder, a decoder and attention mechanism (Mnih et al., 2014). With attention mechanism the decoder can choose a weighted context representation at each generation step so it can focus on different parts of encoded information. Seq2Seq with attention achieved remarkable results on machine translation (Bahdanau et al., 2014) and other text generation tasks such as abstractive summarizaiton (Rush et al., 2015).

Unlike machine translation that emphasizes attention mechanism as a method of learning word level alignments between source text and target text, attention in summarization should be soft and diverse. Many works noticed that attention may be over concentrated for summarization and hence cause problems like generating duplicate words or duplicate sentences. Researchers try to solve these problems by introducing various attention structures, including local attention (Luong et al., 2015), hierarchical attention (Nallapati et al., 2016), distraction attention (Chen et al., 2016) and coverage mechanism (See et al., 2017) etc. But all these works ignore another repeat problem, as we call it, "Original Text Repetition". We define and explain this problem in section 3.

In this paper we propose a novel Diverse Convolutional Seq2Seq Model(DivCNN Seq2Seq) based on Micro Determinantal Point Processes(Micro DPPs) and Macro Determinantal Point Processes(Macro DPPs). Our contributions are as fol-

Article: marseille , france the french prosecutor leading an investigation into the crash of germanwings flight 9525 insisted wednesday that he was not aware of any video footage from on board the plane . marseille prosecutor brice robin told cnn that so far no videos were used in the crash investigation ..... of a cell phone video showing the harrowing final seconds from on board germanwings flight 9525 as it crashed into the french alps . .....paris match and bild reported that the video was recovered from a phone at the wreckage site . ..... cnn 's frederik pleitgen , pamela boykoff , antonia mortensen , sandrine amiel and anna-maja rappard contributed to this report .
CNN Seq2Seq: french prosecutor UNK robin says he was not aware of any video .

lows:

- We define and describe the Original Text Repetition problem in abstractive summarization and identify the cause behind it, which are degenerated attention distributions. We have also introduced three article-related metrics for the Original Text Repetition estimation and applied them in our experiments.

- We suggest a solution to this problem in the form of introducing DPPs into deep neural network (DNN) attention adjustment and propose DivCNN Seq2Seq. In order to adapt DPPs to large scale computing, we propose two kinds of methods: Micro DPPs and Macro DPPs. To the best of our knowledge, this is the first attempt to adjust attention distributions considering both quality and diversity.

- We evaluate our models on six open datasets and show its superiority on improving the comprehensiveness of generated summaries without losing much training and inference speed.

2 Convolutional Seq2Seq Learning

Usually encoder and decoder in Seq2Seq architecture are recurrent neural network(RNN) or its variants like Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit (GRU) (Chung et al., 2014) network. Recently, a Seq2Seq architecture based entirely on convolutional neural networks (CNN Seq2Seq) (Gehring et al., 2017) was proposed. It has better hierarchical representation of natural language and can be computed in parallel. In this paper we choose CNN Seq2Seq as our baseline system because it performs better on capturing long-term dependency, which is important for summarization.

Both encoder and decoder in CNN Seq2Seq consist of convolutional blocks. Each block contains a one dimensional convolution (Conv1d), a gated linear unit (GLU) (Dauphin et al., 2017) and several fully connected layers for dimension transformation. Residual connection (He et al., 2016) and batch normalization (Ioffe and Szegedy, 2015) are used in each block. Each block receives an input I of size $\mathbb{R}^{B*T*C}$, where B, T, and C are respectively batch size, length of text and number of channels (the same as embedding size). Conv1d pads the sentence first and then generates a tensor $[O_1, O_2]$ of size $\mathbb{R}^{B*T*2C}$, doubling the channel. The extra channels are used in a simple nonlinearity gated mechanism:

$$O_1, O_2 = Conv1d(I) \quad (1)$$

$$GLU([O_1, O_2]) = O_1 \otimes \sigma(O_2) \quad (2)$$

Multi-step attention (Gehring et al., 2017) are used in CNN Seq2Seq. Each convolutional block in decoder has its own attentive context. Followed on query-key-value definition of attention, queries $Q \in \mathbb{R}^{B*T_g*C}$ are different decoder block outputs, where T_g stands for summary length; keys $K \in \mathbb{R}^{B*T_s*C}$ are encoder last block outputs, where T_s stands for article length; values are sum of encoder input embeddings $E \in \mathbb{R}^{B*T_s*C}$ and K. Because of the parallel architecture, attention for all decoder time steps can be calculated at once. Such architecture can speed up training and give convenience for our DPPs calculation. Using the simplest dot product attention, all the calculations can be done with an efficient batch matrix multiplication (BMM).

$$score_{attn} = BMM(Q, K) \quad (3)$$

$$weight_{attn} = Softmax(score_{attn}) \quad (4)$$

$$context = BMM(weight_{attn}, K + E) \quad (5)$$

3 Original Text Repetition

Original Text Repetition(OTR) problem means that each sentence in generated summaries are repetitions of article sentences. The abstractive summarization hence degenerates to extractive summarization. The ROUGE metric can not detect this problem since it only measures the n-grams concurrence between generated summaries and gold summaries without taking articles into consideration. The word repeat problem (See et al., 2017) or the lack of abstraction problem (Kryściński et al., 2018) can be seen as extreme condition or alternative description of OTR. Behind this phenomenon is the degenerated attention distribution learned by model which we define as:

- **Narrow Word Attention** for each summary word, the attention distribution narrows to one word position in article.

- **Adjacent Sentence Attention** for all words in each summary sentence, their positions of

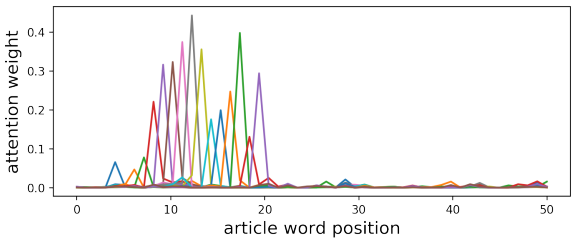

Figure 1: Degenerated attention distribution behind OTR problem. The generated summary repeats the first sentence in article. We select the first 16 words of summary and show their attention over first 50 words of article.

attention peaks are adjacent or semantically adjacent, which means that attended article parts have similar features.

As shown in the Figure 1, sentence attention degenerates to several adjacent peaks on the repeated article positions. Usually each sentence in gold summaries considers multiple article sentences and induct to one, not simply copying one article sentence. The gap between generated summaries(copy) and gold summaries(induce) means that model just learned to find article sentences that has the maximum similarity to gold summaries not the relation between article facts and summaries. Degenerated attention mechanism misleads the model.

4 Diverse Convolutional Seq2Seq Model

To prevent Seq2Seq model from attention degeneration, we introduce DPPs as a method of regularization in CNN Seq2Seq and propose DivCNN Seq2Seq.

4.1 Quality and Diversity Decomposition of Determinantal Point Processes

DPPs have been widely used in recommender systems, information retrieval and extractive summarization systems. It can generate subsets with both high quality and high diversity (Kulesza and Taskar, 2011).

Given a discrete, finite point process P and a ground set D, if for every $A \in D$ and a random subset $\boldsymbol{Y}$ drawn according to P, there is:

$$P(A \in \boldsymbol{Y}) = det(K_A) \tag{6}$$

where K is a real symmetric matrix that indexed by the elements of D, then P is a determinantal point process and K is the marginal kernel of DPPs. Marginal kernel merely gives marginal probability of one certain item to be selected in one particular sampling process, hence we use L-ensemble (Kulesza and Taskar, 2011) to model atomic probabilities for every possible instantiation of Y:

$$K = L(L+I)^{-1} = I - (L+I)^{-1} \tag{7}$$

$$P_L(\boldsymbol{Y} = Y) \propto det(L_Y) \tag{8}$$

$$P_L(\boldsymbol{Y} = Y) = \frac{det(L_Y)}{det(L+I)} \tag{9}$$

L-ensemble is also one kind of DPPs and can be constructed directly using the quality(q) and similarity(sim) of point set:

$$L_{i,j} = q(i) * sim(i,j) * q(j) \tag{10}$$

Equation 9 is a probability that subset Y being chosen, which is actually a quantitative indicator for the score of the subset considering both its quality and diversity(QD-score). Summarization follows the same principle: a good summary should consider both information significance and redundancy. In extractive summarization set of sentences with high score (quality) and diversity is chosen to a summary, using DPPs sampling algorithm (Li et al., 2017).

In Figure 2 we show the difference between quality-only sampling and DPPs sampling. We first generate a simulated attention distribution for testing. Then we use word position distance as similarity measure and attention as quality to construct the L matrix(L-ensemble) for DPPs. Point subset is sampled based on quality (green) or DPPs (blue), then a gaussian mixture distribution was generated around these points to soften and reweight the attention. Both samplings approximate the distribution of original attention distribution (orange), but DPPs approximate it better and have more scattering peaks. Sampling only considering attention weight (quality) generates less peaks, which means many adjacent points with low diversity are sampled.

In actual experiments we choose attention weight as quality. The model learns attention distribution to score different parts of article and obviously higher attention means higher quality. In original CNN Seq2Seq the sum of encoder output and encoder input embeddings are encoded feature vectors. We follow this setting and use the feature vectors to calculate cosine similarity.

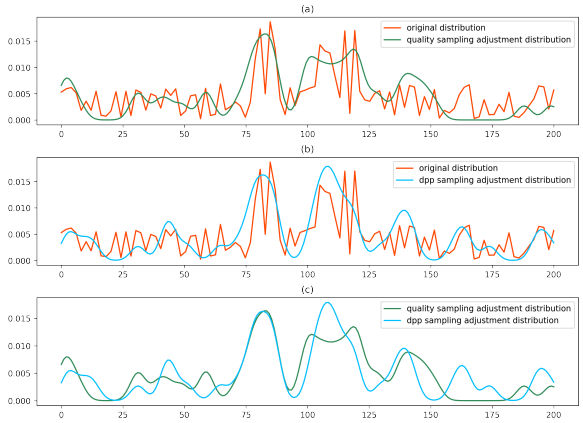

Figure 2: Comparison of different reweighting methods on a simulated distribution. DPPs sampling reweighting approximates original distribution better since it catches the high attention area around position 160. It also samples less adjacent points around position 110.

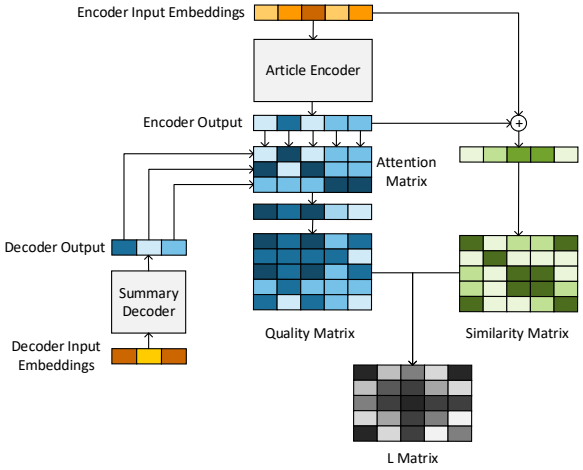

Figure 3: Construction of L matrix

Specifically, the encoder output are tree-like semantic features extracted by CNN encoder while the encoder input embedding provides point information about a specific input element before encoding (Gehring et al., 2017). Hence feature vectors contain both highly abstract semantic features and specific grammatical features when calculating diversity. Compared to extractive summarization, DPPs in abstractive summarization use status of DNN as quality and diversity which can be optimized dynamically during training.

The computation of L matrix is shown in Figure 3. For each sample in a batch(128 in our experiments), the encoder input embeddings $E \in \mathbb{R}^{T_s * C}$ multiply its transpose to produce similarity matrix $S \in \mathbb{R}^{T_s * T_s}$. The weight vectors of Multi-step Attention average over decoder layers and summary length, then do the same operation to generate quality matrix $Q \in R^{T_s * T_s}$. Then we use the hadamard product of Q and S as $L \in R^{T_s * T_s}$.

4.2 Macro DPPs

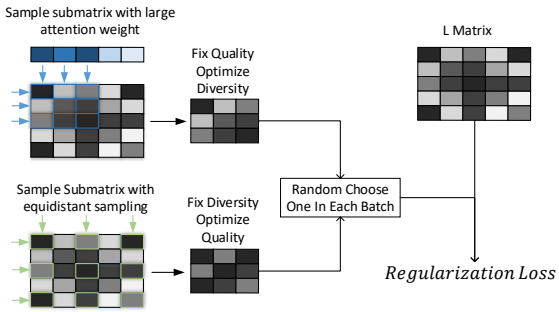

Figure 4: Conditional sampling in Macro DPPs

The idea of Macro DPPs is to pick subsets under some restriction and evaluate QD-score of subset using equation 9. The ideal attention distribution should have subsets with high QD-score.

We do not use DPPs sampling since the purpose of Macro DPPs is to evaluate subsets not to sample subsets with high QD-score. The attention distribute over the ground set so we introduce conditional sampling to sample a subset that has high quality or high diversity, then improve the other metric as follows:

- **Improve Diversity in High Quality Subset** Select points with high attention weight to construct subset and require no gradient for quality matrix, just optimize diversity.

- **Improve Quality in High Diversity Subset** Sampling point subset with high diversity is hard to realize, so we just make equidistant(equidistant on word positions) sampling to approximate it. Contrary to the previous method, we require no gradient for similarity matrix and just optimize quality.

We randomly choose one condition in each batch. After the point subset was chosen, the submatrix L_Y can be built by selecting elements in L indexed by point subset. Then we calculate the QD-score of the submatrix and add it into model loss as a regularization. We calculate the logarithmic summation of eigenvalues to prevent numeri-

cal underflow.

$$loss_{QD} = \sum \log \lambda_{L_Y} - \sum \log \lambda_{L+I} \quad (11)$$

$$\propto \frac{det(L_Y)}{det(L+I)} \quad (12)$$

$$loss_{model} = \gamma loss_{MLE} + (1-\gamma) loss_{QD} \quad (13)$$

4.3 Micro DPPs

The idea of Micro DPPs is to sample a subset Y with large QD-score from all article positions and to use these sampled points as adjusted attention focus points. Then a Gaussian Mixture (GM) distribution around these points is generated as ideal attention distribution($weight_{ideal}$). The whole process can be seen as a selection and softening on attention. The Kullback-Leibler divergence of the ideal distribution and attention distribution ($weight$) then is added into the loss function as regularization.

$$P = BFGMInference(L, t) \quad (14)$$

$$weight_{ideal} = GM_{\mu \in P}(\mu, \sigma, \pi) \quad (15)$$

$$loss_{KL} = KLdiv(weight_{ideal}, weight_{attn}) \quad (16)$$

$$loss_{model} = \gamma loss_{MLE} + (1-\gamma) loss_{KL} \quad (17)$$

Classic sampling algorithm for DPPs (Kulesza and Taskar, 2011) runs slow when the size of L matrix is large and it can not be computed in batch. In the DivCNN Seq2Seq model we need to construct an L matrix for every sample and every layer in the decoder, which is ultimately large. To optimize DPPs runtime for this large-scale computation, we introduce a Batch computation version of Fast Greedy Maximum A Posteriori Inference (Chen et al., 2018)(BFGMInference) to sample a subset with high QD-score.

BFGMInference uses a greedy method to approximate the MAP result $Y_{map} = argmax_{Y \in D}\, det(L_Y)$: each time we select j that has maximum QD-score improvements and add it to Y.

$$f(Y) = \log det(L_Y) \quad (18)$$

$$j = \underset{i \in D \setminus Y}{argmax}\, f(Y \cup \{i\}) - f(Y) \quad (19)$$

Algorithm 1 BFGMInference

Input: matrix $L \in \mathbb{R}^{B*T_s*T_s}$, size of sampled subset t
Output: Sampled subset $Y \in \mathbb{R}^{B*t}$

Initialize $D_i = L_{ii}$; $mask = 1^{B*T_s}$; $J = argmax(\log(D * mask))$; $C \in 0^{B*T_s*1}$
$mask_{j \in J} = 0$
$count = 1$
while $count < t$ **do**
  $candidate = \{i | mask_i = 1\}$
  $ctemp = 0^{B*T_s*1}$, $dtemp = 0^{B*T_s}$
  for $idx = 0; idx < Ts - count; idx++$ **do**
    $i = candidate[:, idx]$, $j = J$
    $e_i = (L_{j,i} - \langle c_j, c_i \rangle)/d_j$
    $ctemp_i = e_i$, $dtemp_i = {e_i}^2$
  end for
  $C = [C, ctemp]$, $D = D - dtemp$
  $J = argmax(\log(D * mask))$
  $mask_{j \in J} = 0$
  $count = count + 1$
end while
$Y = \{i | mask_i = 0\}$
return Y

By using Cholesky decomposition we have:

$$L_Y = VV^T \quad (20)$$

$$L_{Y \cup \{i\}} = \begin{bmatrix} V & 0 \\ c_i & d_i \end{bmatrix} \begin{bmatrix} V & 0 \\ c_i & d_i \end{bmatrix}^T \quad (21)$$

$$Vc_i^T = L_{Y,i} \quad (22)$$

$$d_i^2 = L_{ii} - ||c_i||_2^2 \quad (23)$$

Then we can transform equation 19 into:

$$j = \underset{i \in D \setminus Y}{argmax} \log(d_i^2) \quad (24)$$

The c and d can be updated incrementally according to equation 22 and 23. The complete algorithm is described in Algorithm 1. BFGMInference algorithm gains significant speed improvements when the size of L matrix is large as shown in Figure 5.

5 Experimental Setup

Datasets We test DivCNN Seq2Seq model on the widely used CNN-DM dataset (Hermann et al., 2015) and give detailed analysis on diversity and quality. Also we tried our model on other five abstractive summarization datasets which are NEWSROOM corpus (Grusky et al., 2018), TLDR (Völske et al., 2017), BIGPATENT (Sharma et al., 2019), WIKIHOW (Koupaee and Wang, 2018) and REDDIT (Kim et al., 2018). For CNN-DM corpus we truncate articles to 600 words and summaries to

Dataset	# Docs	Type	Average Document Words	Average Summary Words
CNN-DM	287227/13368/11490	News	789/777/768	55/59/62
NEWSROOM	995041/108862/108837	News	659/654/652	26/26/26
REDDIT	34000/4000/4000	Social Media	418/445/451	20/23/25
BIGPATENT	1207222/67068/67072	Documentation	699/699/699	116/116/116
TLDR	960000/20000/20000	Social Media	197/195/204	19/19/19
WIKIHOW	180000/10000/20000	Knowledge Base	475/488/418	62/60/74

Table 2: Dataset overview(train/valid/test).

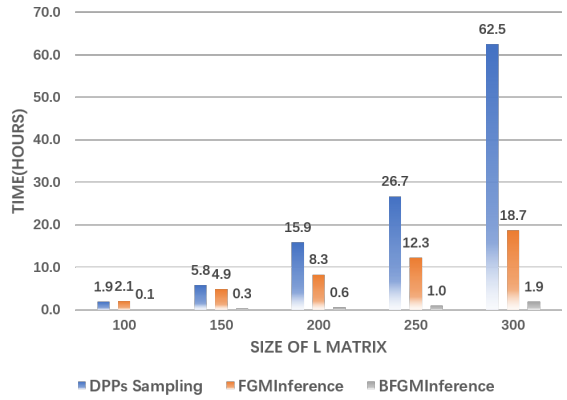

Figure 5: Speed comparison of classical DPPs sampling (blue), FGMInference (red) and BFGMInference (gray) with a batch size of 100.

70 words. For other corpus we only keep articles and summaries that have length around its average length. Specially we only use the TIFU-long version of REDDIT and non-anonymized version of CNN-DM dataset. If the raw datasets were not divided into train/dev/test then we divide the shuffled datasets manually. Details of all six datasets are shown in Table 2.

Hyperparameters and Optimization All the CNN models use a 50000 words article dictionary and 20000 words summary dictionary with byte pair encoding (BPE) (Sennrich et al., 2015). Word embeddings are pretrained on training corpus using Fasttext (Bojanowski et al., 2017; Joulin et al., 2016). We do not train models with large parameters to increase ROUGE results since what we try to improve is the comprehensiveness of each sentence in summary. The total parameters of whole CNN seq2seq Model are about 3800w and the DivCNN Seq2Seq does not change the parameters amount. All the models set embedding dimensionality and CNN channels to 256. The encoder has 20 blocks with kernel size 5 and the decoder has 4 blocks with kernel size 3. Such scale of model parameters are enough for the model to generate fluent summaries. The γ is 0.6 for Macro DPPs and 0.7 for Micro DPPs. In Macro DPPs we choose top 30 points when optimizing diversity and a stride of 20 for equidistant. In Micro DPPs for each summary we sample 20 points to generate gaussian mixture distributions. We train the model with Nesterov's accelerated gradient method using a momentum of 0.99 and renormalized gradients when the norm exceeded 0.1 (Sutskever et al., 2013). The beam search size is 5 and we apply a dropout of 0.1 to the embeddings and linear transform layers. We did not fix training epoches. The model was trained until the average epoch loss can not be lower anymore. The DPPs regularization only works when training and does not bring extra parameters into model. During test the model has learned proper attention so the generation is the same as vanilla CNN Seq2Seq Model.

Article-Related Metrics It is hard to evaluate a summary since summarization itself is very subjective. ROUGE compares generated summaries and gold summaries in checking concurrence of n-grams that results in a very limited evaluation in a word level. We set three article-related metrics to evaluate the comprehensiveness of summaries:

- **Jaccard Similarity Upper Bound (JS)** For each summary sentence, we compute its jaccard similarity with every article sentence. The largest jaccard similarity for each summary sentence is selected as JS. It measures the extent to which summaries copy articles. The worst situation is 1.

- **Sentence Coverage (SC)** We define those article sentences that have a jaccard similarity higher than the gold summaries JS value as covered sentence. Then the average counts of covered article sentences for each summary sentence is a ratio that can be used to measure the coverage of the article by the summaries. The worst situation is less than or equal to 1.

- **Novel Bigram Proportion (NOVEL)** The percentage of bigrams in summaries that did

not appear in the article. It reflects the abstraction of summaries. The worst situation is 0.

Strong Baseline We chose four strong baselines which reported high ROUGE scores. BottomUp (Gehrmann et al., 2018), sumGAN (Liu et al., 2018) and RL Rerank (Chen and Bansal, 2018) are complicate systems that have additional modules or post-processings and partially relieved the OTR problem. The Pointer Generator (See et al., 2017) reaches best ROUGE result in single end to end model but suffers greatly from repetition problem.

Various Possible Causes of the OTR problem We had supposed several other reasons for the repetition problems besides attention degeneration including overfitting, bad usage of translation-style attention mechanism, lack of decoding ability and high variance attention distribution. Respectively, we designed comparative experiments as follows:

- **Overfitting** We set dropout ratio to 0.1 (SMALL) and 0.5 (LARGE) for testing overfitting.
- **Direct Attention** Remove the encoder input embedding in attention value so the decoder looks at highly abstract features directly (DIRECT).
- **Lack of Decoding Ability** We double (DOUBLE) or half (HALF) the vanilla (VANILLA) decoder layers to adjust the decoding ability.
- **High Variance Attention** We scale down the attention distribution manually when training (SCALE), lowering the variance of the distribution.

6 Results

Various Possibilities As shown in Table 4, scaled attention has the lowest jaccard similarity upper bound, which confirms our idea that over-concentrated attention makes model to copy article sentences. As for sentence coverage, small decoder with large drop out ratio performs the best, proving that large and overfitted models may have degenerated attention. Although the scaled attention has the best JS score, its SC score is the worst (SC less than 1.0 means duplicate sentences are generated). So, we may conclude that directly scaling down attention breaks the value of attention. The ideal attention is not about erasing the peak or the variance of attention but to have multiple peaks in sentence attention and have high diversity at the same time. Neither aggregative nor scattering attention distributions do good to summary generation. Direct attention model has the maximum NOVEL score which means point information about a specific input element makes model prefer copying article words instead of generating new words.

CNN-DM Results With large model parameters and dictionaries, four models in strong baselines reach nearly 40 points in ROUGE-1 but they perform poorly on article-related metrics. Single end to end systems like Pointer Generator performs poorly on JS value and NOVEL proportion which means most of its summaries are copied from articles. As for three models with multiple modules or post-processing, the BottomUp model has relatively good jaccard similarity upper bound and the best ROUGE result but its article-related metrics are still far away from gold summaries level. RL Rerank model has better score on JS and sumGAN has better NOVEL score but none of these model reached a balanced good performance on three article-related metrics. Compared to vanilla CNN Seq2Seq, DivCNN Seq2Seq improves the JS and NOVEL points and raises the ROUGE score at the same time, proving that proper attention distribution can help reaching a better local optima. Compared with strong baselines, DivCNN Seq2Seq achieves the best in NOVEL, second and third in JS and SC, respectively. Empirically we suggest that γ for both Micro and Macro DPPs should be set to make average loss change less than 10% compared to vanilla models. We also observed that Micro DPPs is more sensitive to γ compared to Macro DPPs and is easier to converge but may degenerate to vanilla CNN Seq2Seq. Macro DPPs usually can reach better results but it needs more time to train since eigenvalue calculation is expensive and can not be accelerated through fp16 tensor computing.

Novel Bigram NOVEL is a tricky metric which is used in many researches about abstractive summarization. There are many possibilities on explaining a high NOVEL score: first, the summary get a high Novel Bigram ratio because it has many Novel unigrams, which may be good or bad; second, the model may be underfitting and can

Model	JS	SC	NOVEL	R1	R2	RL
gold	0.326	–	0.575	–	–	–
(Liu et al., 2018) sumGAN	0.709	1.136	0.118	39.92	17.65	27.25
(Gehrmann et al., 2018) BottomUp	**0.541**	1.015	0.098	**41.53**	**18.76**	**27.92**
(Chen and Bansal, 2018) RL Rerank	0.585	1.181	0.105	39.38	16.03	24.95

Table 4: Explore various possible causes of OTR.

not generate fluent sentences; third, the generated summary use novel bigrams to conclude the original text and generate readable sentences, which is the best condition. From the table 3 we can see that Bottom Up has the best ROUGE and JS results but worst NOVEL score. Our DivCNN Models have just the opposite metric scores. These three metrics shouldn't be ambivalent since gold summaries can reach high NOVEL and low JS at the same time. Base on these facts we make the following conjectures:

- Good summaries model learned have styles differ from human-write summaries. Model tend to copy bigrams from original article and reorganize them into short summary sentences. Human tend to use brand new bigrams to paraphrase facts contained in original article. The model use a rewrite(compress and extract) way while human-write is overwrite style.

- Though we use human-write summaries as gold summaries for model to learn and the MLE loss is steadily descending during training but it learned summaries with different style. It implicates that model may not have a "NLU+NLG" process like human do but be restrained in a sentence-level rewrite framework. For Bottom Up and RL Rerank it is not a problem because these two systems are designed to rewrite. They only send parts of article into Seq2Seq. Such design can gain high ROUGE score but it is not the way in which human write gold summaries.

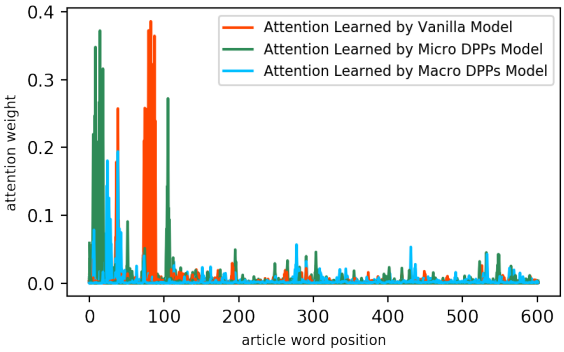

Figure 6: Actual attention distribution learned by vanilla model and DPPs models.

Extractive Summarization based on Learned Attention We also extract article sentences based on sentence attention learned by DPPs models to generate summaries. The attention of a sentence is the sum of the attention weights of the words in the sentence. Table 3 shows that extractive summarization reaches better ROUGE values, implicating that both vanilla and DivCNN models learned appropriate sentence attention. Extractive summarization uses accumulated sentence attention instead of specific distribution, so the results of vanilla models are almost the same as DivCNN.

Sample Visualization We randomly choose one sample in the test set of CNN-DM corpus to visualize and analyze. As shown in Table 1 we

Datasets	Baseline	Baseline	Micro DPPs	Macro DPPs
NEWSROOM	LEAD-3 Baseline	30.63/21.41/28.57	38.33/25.01/35.3	**40.10/26.71/37.24**
TLDR	-	-	65.94/56.97/64.65	**66.93/57.84/65.71**
BIGPATENT	(Chen and Bansal, 2018)	**37.12/11.87/32.45**	33.21/10.47/24.86	34.55/11.65/25.96
WIKIHOW	(See et al., 2017)	**28.53/9.23/26.54**	24.52/6.49/20.56	27.58/8.01/22.61

Table 5: ROUGE F1 results(R1/R2/RL) on different datasets

highlighted attentive parts in the article for different models. The vanilla model just generates one sentence which only focuses on one part of article. The Micro DPPs model generates two sentences considering three parts of the article. Macro DPPs considered article spans that both vanilla model and Micro DPPs model paid attention to. We also checked the attention distribution of this sample. As shown in Figure 6, vanilla model (red) learned only several peaks over article position 70 to 90, which suggests that it only focuses on one sentence and repeats this sentence in a summary. Attention learned by Micro DPPs model (green) still narrows to several peaks but explores more positions compared to vanilla. Macro DPPs (blue) has more natural design of loss function and it optimize quality and diversity directly so it has a more scattering attention distribution.

More Datasets We test our model on other five newly-released abstractive summarization datasets which have various compression ratio, different professional field and more flexible human-write summaries. Only ROUGE results are collected since no baseline generated summaries are provided for us to calculate article-related metrics. Table 5 shows that DivCNN performs better than best baselines on NEWSROOM, REDDIT and reaches incredible ROUGE scores more than 60 (but no baseline is reported in the dataset paper so the result is not comparable). The compression ratio and article length have little impact on the performance of DivCNN. The results show that DivCNN prefers short summaries.

Attention & Representation Degeneration In order to solve attention degeneration we introduce DPPs to improve the diversity of features where model paid high attention to. This solution is consistent with the Presentation Degeneration Problem in NLG (Gao et al., 2018). As shown in Figure 7, Macro DPPs have more diverse embedding presentation compared to vanilla model. (Gao et al., 2018) directly add a regularization loss of diversity to increase the representation power of word embeddings while we aim at generating attention distribution considering both quality and diversity, resulting in learning word embeddings with rich representation power.

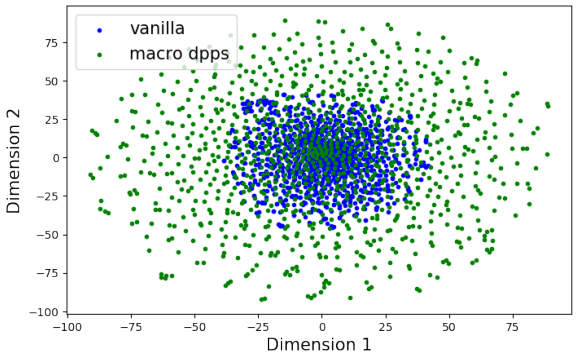

Figure 7: Presentation Degeneration Problem in NLG. We use tSNE (Maaten and Hinton, 2008) to reduce the dimension of word embeddings learned in the model.

7 Conclusions and Future Works

We have defined the "OTR" problem that leads to incomplete summaries and revealed the cause behind it, which is attention degeneration. We also introduce three article-related metrics to evaluate this problem. DPPs are applied directly on attention generation and we propose Macro and Micro DPPs versions of DivCNN Seq2Seq model to adjust attention considering both quality and diversity. Results on CNN-DM and other five open datasets show that DivCNN Seq2Seq can improve the comprehensiveness of summaries.

Due to the hardware limitation we only train a small-parameters version of DivCNN. Also we lost some precision when approximating L matrix and accelerating sampling. These drawbacks lead to limited performance improvements. In the future we hope to explore further on following directions: Quantifiable and controllable quality/diversity in DPPs; better approximation in conditional sampling, such as dynamic sampling stride adjustment; try to apply DPPs-optimized attention on another student model to improve generation.

Abstract

Abstractive text summarization aims at generating human-like summaries by understanding and paraphrasing the given input content. Recent efforts based on sequence-to-sequence networks only allow the generation of a single summary. However, it is often desirable to accommodate the psycho-linguistic preferences of the intended audience while generating the summaries. In this work, we present a reinforcement learning based approach to generate formality-tailored summaries for an input article. Our novel input-dependent reward function aids in training the model with stylistic feedback on sampled and ground-truth summaries together. Once trained, the same model can generate formal and informal summary variants. Our automated and qualitative evaluations show the viability of the proposed framework.

1 Introduction

Efficient content consumption is not only driven by the contained information but also by the tone/style of the presentation. The style in text is its non-informational or non-factual aspect and usually drives the quality of response from its audience. A *persuasive* snippet or a teaser might drive up sales for a marketing message and a piece of *formal* text will appeal better to corporate executives as against informal communication. Similarly, not all long form content is easy to read. A succinct representation of the content, i.e. the summary, plays an important role for its quick and efficient consumption. While, text summarization and to some extent *style-understanding* have been independently studied, approaches to generate style-tailored summaries are limited.

Models for style predictions (Pavlick and Tetreault, 2016; Brooke et al., 2010; Danescu-Niculescu-Mizil et al., 2013) are limited to measuring style in text. There have been multiple attempts towards transfer of style (Artetxe et al., 2017; Han et al., 2017; Shen et al., 2017; Tikhonov and Yamshchikov, 2018). Rao and Tetreault (2018) introduced a parallel corpus for formality style transfer with neural machine translation benchmarks. Niu et al. (2017) generate automatic translations tailored towards formality. However, none of these approaches account for the length/succinctness of the created content, and hence do not address the stylized summarization task. In this work, we propose an approach to generate summaries while simultaneously tailoring towards formality preferences (Table 1).

Tunable or controlled summary generation has picked up pace in recent times. Algorithms allow for controlling various dimensions of the output summary such as the length or entities (Fan et al., 2017) and topics (Krishna and Srinivasan, 2018). Since these approaches primarily rely on the diversity in the given dataset, extending these approaches for formality tailored summarization would require a diverse summarization corpus that captures subtleties in various formal variants. Since such a dataset is difficult to curate, it is non-trivial to use these methods as is. Reinforcement learning (RL) based loss functions have recently shown promise in tuning the output on rewards such as ROUGE (Paulus et al., 2018). In such methods, the model receives explicit feedback on the sampled sequences while training. If directly applied for controlling stylistic parameters like formality, such a method would need two separately trained models for generating formal and informal summaries and thus, may miss out on the common learnings.

In this work, we propose a method to incor-

porate formality in abstractive text summarization. To build a formality-rich training dataset, we merge data from two domains: news and social media - the first one representing more formal language and the latter, informal. We define a novel input-dependent reward function which aids in training the model with stylistic feedback on sampled and ground-truth summaries together. Once trained, the same model can generate formal and informal summary variants. We show the effectiveness of our approach through automated and crowd-sourced experiments, evaluating both the quality and formality levels of the generated summaries. Table 1 shows sample formal and informal summary variants, generated from our approach on an instance from the testset.

Input Article: katrina had been expressing anxiety for a while now about how worried she was about the bridal shower and being the center of attention of a bunch of people she did n't know . that 's completely normal . she has been so worried that she determined to send him a short email outlining what she would do if she were in his shoes . that absolutely counts as meddling . that 's literally the definition of meddling sticking your nose where it does n't belong . katrina talked to my mom for about five minutes and then sat about twenty feet away from her during this tournament while my mom sat alone . and katrina is n't obligated to entertain your mother . your mom could 've talked to other people instead ...
Informal: katrina had been so worried that she was abt the bridal shower & being the center of attention of a bunch of people she did n't know . katrina 's n't obligated to entertain ur mom .
Formal: katrina had been expressing anxiety for the bridal shower and being the center of attention of a bunch of people she did not know . she has been therefore worried that she determined to transmit him a short email outlining what she were in his shoes .

Table 1: Example formal and informal summary variants generated on an instance from our testset.

2 Related Work

Early abstractive summarization efforts were either template-based (Wang and Cardie, 2013; Genest and Lapalme, 2011) or employed ILP-based sentence compression (Filippova, 2010; Berg-Kirkpatrick et al., 2011; Banerjee et al., 2015). With the advent of deep sequence-to-sequence models (Sutskever et al., 2014), attention-based neural models have been proposed for long text summarization (Rush et al., 2015; Chopra et al., 2016). Recent approaches (Nallapati et al., 2017; See et al., 2017) have focused on larger datasets such as the CNN/DailyMail corpus (Hermann et al., 2015; Nallapati et al., 2016). Gulcehre et al. (2016) introduced the ability to copy out-of-vocabulary words from the article to incorporate rarely seen words like names in the generated text. Tu et al. (2016) included the concept of coverage, to prevent the models from repeating the same phrases while generating a sentence. See et al. (2017) proposed a pointer-generator framework which incorporates these improvements, and also learns to switch between generating new words and copying them from the source article. We use this pointer-generator framework as the underlying architecture.

2.1 Incorporating additional constraints

Controlled summary generation has only recently gained popularity. Variational auto-encoders (Hu et al., 2017) or adversarial training (Shen et al., 2017) have been explored for non-parallel stylistic text generation. Sennrich et al. (2016) propose modifications to neural machine translation to tune the level of politeness in the generated text. Ficler and Goldberg (2017) use a conditional language model to control variations like descriptiveness and sentiment simultaneously during generation. Efforts for constrained text summarization are rather limited with no efforts attempting to incorporate psycho-linguistic preferences. Krishna and Srinivasan (2018) incorporate input topic information in the output summary using a topic-vector along with the input word sequence.

Fan et al. (2017) control length and entity in textual summaries using explicit input indicators or tokens. Paulus et al. (2018) directly control the ROUGE evaluation metric using the Self Critical Sequence Training (SCST) (Rennie et al., 2017) algorithm. We build on these approaches and show through our experiments that our approach is able to generate better formality-tuned summaries in comparison to these methods.

2.2 Incorporating Formality

Formality is an important style or tone dimension in written text. Although there are existing works which model formality in text (Brooke et al., 2010; Lahiri, 2015; Pavlick and Tetreault, 2016; Chhaya et al., 2018), there have been limited attempts to incorporate it in text generation. Sheikha and Inkpen (2011) used a predefined set of rules based on formal-informal parallel lists to generate formal and informal sentences. More recently, a parallel corpus of formality style transfer (Rao and Tetreault, 2018) was released with NMT-based benchmarks. To the best of our knowledge, we are the first to introduce formality in the space of abstractive text summarization.

Generating text with varying levels of formality was studied recently in Machine Translation (Niu et al., 2017, 2018). A re-ranking mechanism on

the decoded hypotheses is used to control the formality of the generated translations. We augment our decoding module with a similar, but simpler re-ranking method to enhance our approach.

3 Pointer-Generator Framework

Our approach uses the pointer generator network (See et al., 2017) as the underlying architecture. This section explains this framework briefly for the sake of completion. The model is based on an encoder-decoder setup. The bi-directional LSTM encoder takes the article x as an input and computes a sequence of encoder hidden states $h_1, h_2, ..h_n$. The last state h_n becomes the initial state of the LSTM decoder which uses an attention mechanism to generate the output summary word by word. Further, at each time step, the decoder network computes p_{gen}, the probability of generating a new word from the vocabulary,

$$p_{gen} = \sigma(w_h^T h_t^* + w_s^T s_t + w_x^T x_t + b_{gen}) \quad (1)$$

where w_h, w_s, w_x, b_{gen} are trainable parameters. h_t^* is the context vector capturing the attention distribution, s_t is the decoder internal state and x_t is the decoder input at t^{th} time step. The total probability of w being the next word generated in the summary, $p(w)$, is given by,

$$p(w) = p_{gen} P_{vocab}(w) + (1 - p_{gen}) \sum_{i:w_i=w} a_i^t \quad (2)$$

where p_{gen} provides a switch between generating a new word from $P_{vocab}(w)$ or copying a word from the input based on the attention distribution. The training loss is set to be the average negative log-likelihood of the ground truth summary:

$$L_{nll} = -\frac{1}{T} \sum_{t=1}^{T} \log \left[p(y_t^* | y_1^*, ..., y_{t-1}^*, x) \right] \quad (3)$$

where y^* is the ground-truth word sequence. We propose to modify the above training objective in order to incorporate psycho-linguistic preferences of the target audience, with a focus on formality.

4 Generating (In)formal Summaries

A major challenge in incorporating formality into the summarization system is the lack of a formality-diverse dataset. To the best of our knowledge, there exists no data which either has both formal and informal ground-truth summaries for the same input article or where the provided ground-truth summaries are diverse on the formality scale. This makes the direct use of explicit indicators ineffective (Section 6.2), which have been shown to capture this diversity in the given dataset well (Fan et al., 2017; Krishna and Srinivasan, 2018). To address this, we work off a dataset mixed from two different domains: news and social, making it more formality-diverse (Section 5).

While diversity in the data helps the model to learn the (in)formal parts in the text, we further employ a modified reinforcement learning approach which teaches the decoder module to write (in)formally through explicit feedback. The model is trained using feedback on the formality of both sampled and ground-truth summaries together. The pointer-generator model is trained using the negative log-likelihood loss L_{nll} as given in Equation 3. We make the use of policy gradients by introducing an additional loss term L_{rl} in the training objective:

$$L_{rl} = -\left[r(y^s) \right] \sum_{t=1}^{T} \log \left[p(y_t^s | y_1^s, .., y_{t-1}^s, x) \right], \quad (4)$$

where r is the formality-based reward function. y^s is a sampled word sequence generated by sampling from the $p(y_t^s | y_1^s, y_2^s, .., y_{t-1}^s, x)$ distribution at each time step. In essence, optimizing L_{rl} improves the expected reward of the generated output. The final loss is a linear combination of negative log-likelihood loss with the RL loss,

$$L = (1 - \alpha) \cdot L_{nll} + \alpha \cdot L_{rl}, \quad (5)$$

where α governs the strength of the RL-based loss term.As we will show in Section 4.2, we define L_{rl} based on the input tokens and thus the same trained model can generate formal and informal summary variants for a given input article.

While decoding, our framework employs a beam search algorithm to explore plausible outputs (or hypotheses) for generating the final summary. It finally outputs the hypothesis with the maximum probability of generation. However, we observe a reasonable difference in the formality scores among hypotheses with similar generation probabilities. As a part of post-processing, we therefore employ hypotheses re-ranking to further strengthen our generation following Niu et al. (2017). We pick the hypothesis with the maximum formality score among the k hypotheses with

highest generation probabilities. We also perform word-replacement using parallel formal-informal word lists curated from (Sheikha and Inkpen, 2011). This helps to tackle unwanted formal or informal words which must have been copied directly from the input article by the pointer generator frameworks (See et al., 2017). As we show later, this helps our model to better capture formality oracle.

4.1 Measuring Formality in Text

The first step towards defining our reward function is to construct an oracle to measure formality. We define formality using lexical scores (Brooke et al., 2010; Brooke and Hirst, 2014) leveraging the implementation by Niu et al. (2017) who incorporate formality into Machine Translation[1]. They report best performance using a combination of a Support Vector Machine (SVM) model with Word2Vec representations on the CTRW (Hayakawa and Ehrlich, 1994) and BEAN (Lahiri, 2015; Pavlick and Tetreault, 2016) datasets, obtaining 84.4% accuracy on the former and a Spearman's ρ of 0.662 on the latter.

First, two sets of seed words are chosen, which represent formal and informal language respectively. We use the lists curated by Sheikha and Inkpen (2011). They contain various abbreviations with their full forms and 'informal:formal' semantically similar word pairs such as 'about:approximately', 'copy:replica', 'risk:jeopardy', and 'tasty:palatable'. We combine these word lists to create a total of 667 formal and informal seeds. Next, an SVM model is trained to find a separating hyperplane between vector space representations (coming from Word2Vec model trained on Google News corpus) of these formal and informal seeds. Once the model is trained, for any given word, Euclidean distance to this hyperplane is used as a measure of word level formality. To compute the formality of a word sequence y, we use the weighted average function from Niu et al. (2017):

$$F(y) = \frac{\sum_{w_i \in y} |L(w_i)|.L(w_i)}{\sum_{w_i \in y} |L(w_i)|}, \qquad (6)$$

where $L(w_i)$ is the lexical formality score from the SVM model described above.

$F(y)$ represents the formality of the word sequence y, where larger positive values correspond to higher levels of formality and negative values represent informality in text. Using this measure for formality as an oracle, our objective now is to teach the model the intricacies of high and low levels of formality and ultimately, taking this into consideration while summary generation. This is achieved through the reward function r, which is described next.

4.2 Defining the reward function r

We propose an indicator-based rewarding setup to simultaneously benefit from the common learnings of the two models (formal and informal summaries) and incorporate feedback on the ground-truth summaries in the dataset, as against using the formality oracle $F(y)$ described in Section 4.1 directly as separate reward function for formal and informal models.

We use explicit indicators along with the input sequence and set the reward function accordingly. For training, first the oracle $F(y)$ from equation 6 is used to classify ground-truth summaries in the dataset into informal, neutral, or formal classes. We then assign two vocabulary ids (called tokens or indicators) to each class. While training, these tokens are added to the beginning and end of the input article, based on the formality class of the corresponding ground-truth summary. For instance, for a given (article, summary) pair (a, s) in the training dataset, if s is classified as formal, we add the corresponding two tokens at the beginning and end of the input a. The usage of tokens in this manner acts as indicators, providing the model with feedback on the ground-truth summary in the training stage. The usage of two tokens keeps the input **symmetric**, making it easier for both the forward and backward LSTM encoder networks to absorb the formality information at the start of generating their half of the encoding states. We then determine our reward function for RL loss L_{rl} based on the formality class of the ground-truth summary:

$$r(y^s) = \begin{cases} F(y^s) & \text{for formal } y^* \\ 0.0 & \text{for neutral } y^* \\ -F(y^s) & \text{for informal } y^* \end{cases} \qquad (7)$$

where y^* is the ground-truth summary sequence and $F(.)$ is the score from Equation 6. If the ground-truth summary is formal (as denoted by the corresponding tokens), our reward works to maximize the expected formality of the output sum-

[1] https://github.com/xingniu/computational-stylistic-variations

mary and minimize it in case of informal ground-truth summaries. Given an unseen input article, the two tokens can be added to the input sequence based on the type of output summary required. An input-dependent reward function allows the same model to generate both the summary variants, unlike the vanilla framework, which loses the opportunity to learn the commonalities in the two spaces.

4.3 Similarity to SCST method

Equation 4 employs REINFORCE algorithm (Williams, 1992) and can be seen as a modification to the Self Critical Sequence Training (SCST) (Rennie et al., 2017) which was applied to successfully optimize on ROUGE in summarization (Paulus et al., 2018). In SCST, the word with the maximum probability is greedily chosen from the output distribution at each time step, forming a greedy sequence y^b. The model uses the reward of y^b as a baseline in the loss function. Instead, our formulation can be seen as using the baseline reward of 0. This compares the formality level of the sampled sequence y^s with the perfectly neutral summary (with formality score 0.0), penalizing any sequences lying on the opposite side of the desired formality levels.

5 Experimental Setup

We evaluate our approach on its ability to generate formal and informal summaries for an input article. We compare it with several baselines using both automated metrics and crowd-sourcing experiments.

Dataset: A combined dataset from 2 domains: news and social media is used. For the former, we use the CNN/DailyMail news dataset (Hermann et al., 2015; Nallapati et al., 2016), widely used for the task of abstractive text summarization. For the latter, we use the Webis-TLDR-17 corpus (Völske et al., 2017), automatically created using $TL;DR$ tags on Reddit[2]. Figure 1 shows the distribution of lexical formality scores over these and the complete dataset (based on Equation 6). As depicted, the combination allows us to ensure that the dataset contains formality-diverse 'article:summary' pairs. For CNN/DM, the average formality is -0.097, with minimum as -2.451 and maximum as 2.62. For Reddit dataset, the average formality is -1.068, minimum -2.653 and maximum is 2.783. While the average values are negative, through a manual analysis, we found the summaries with more than -0.5 to be reasonably formal in general. We refer the readers to Section A in Supplementary material where we show some sample ground-truth summaries in the dataset along with their formality scores.

The news dataset contains $287,226$ training instances, $13,368$ validation and $11,490$ test instances. The articles have an average length of 781 tokens and multi-sentence summaries with average length of 56 tokens. We use these average values to extract a similar-sized subset of 4 million data points in the Reddit dataset and merge them with the news dataset. We filtered out poor summaries in Reddit dataset heuristically. Several summaries which contain edit: actually refer to additional information not in the article. We filter out summaries containing such keywords. Keeping only the most formal and informal pairs, the training dataset reduces to $286,358$ input-output pairs. $10,000$ pairs are held out for validation and testing, each containing data points from both domains.

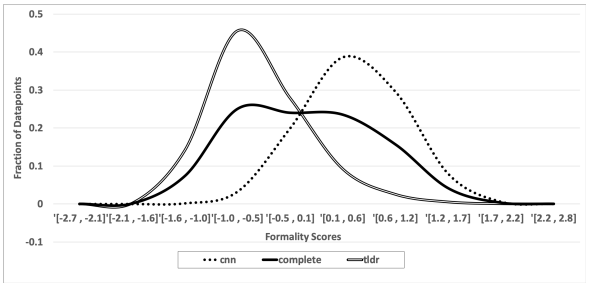

Figure 1: Distribution of lexical formality (Equation 6) in CNN/Daily Mail, Reddit and the complete dataset. Positive values on the X-axis indicate high formality and negative values indicate informality.

Hyperparameters: All methods are implemented using the pointer-generator framework described in Section 3. Following See et al. (2017), the network uses 256 hidden dimensions, embedding size as 128, vocabulary size as $50,000$, 400 maximum encoding steps and 100 maximum decoding steps. We use these hyper-parameters for all the approaches. All our models train for approximately $50,000$ iterations using a batch of size 16.

6 Automated Evaluation

We report the F1 scores for ROUGE-1, ROUGE-2, and ROUGE-L metrics, evaluating how close the generated summaries are to the reference sum-

[2]https://www.reddit.com/

	Informal Summaries					Formal Summaries				
Method	**ROUGE F-score**			**Formality**	**Improvement**	**ROUGE F-score**			**Formality**	**Improvement**
	1	**2**	**L**		(%) vs **PGen**	**1**	**2**	**L**		(%) vs **PGen**
SymVoTo (A)	**26.95**	**8.23**	**23.28**	-0.560 ± 0.902	$+6.66$	**27.00**	**8.15**	**23.23**	-0.432 ± 0.822	$+17.71$
ZeroRL (B)	24.03	6.90	21.08	-0.581 ± 0.925	$+10.66$	24.42	6.93	20.90	-0.358 ± 0.760	$+31.80$

Table 3: Performance based on Automated Evaluation Metrics for Generating Informal and Formal Summaries. Formality score is computed from the oracle (Eq. 6), averaged over the testset. All the prior approaches were adapted for formality, as described in Section 6.2.

maries. To evaluate the efficacy of the methods in capturing formality, we report the average formality in the output summaries and corresponding percentage improvements in average formality, relative to **PGen** (See et al., 2017).

6.1 Ablation study

We performed an ablation study over our approach to analyze the effect in performance by the use of two symmetric vocabulary tokens (**SymVoTo**) and a zero-reward baseline (**ZeroRL**) separately.

For training in **SymVoTo**, three levels of formality are defined based on the scores from the formality oracle $F(y)$ (Equation 6): informal (less than -0.2), neutral (between -0.2 and $+0.2$), and formal (greater than 0.2). In our training dataset, $169,628$ summaries were tagged as informal, $31,129$ as neutral and $85,601$ as formal. While training, the two tokens are added to the input article based on the formality level of the ground-truth summary. To generate the formal or informal summaries for an unseen article, we add the corresponding two tokens to the input and pass it through the trained model.

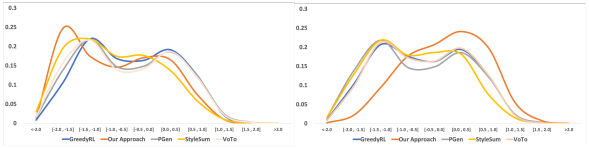
The **ZeroRL** method is trained using the joint objective in Equation 5. However, instead of using the input-dependent reward function in Equation 7, it directly optimizes on the formality oracle. Due to the slow training speeds with policy learning, we first pre-train our network with pointer-generator method (Section 3). We further train the model with policy learning for 3000 iterations. We use a fixed weight of 0.9 for L_{rl} in Equation 5 and 0.1 for negative log likelihood loss L_{nll}. To generate formal and informal summaries in this case, we train two separate models, one where the reward function is $F(y)$ to maximize the expected formality, and second, in which the reward function is $-F(y)$, to minimize the expected formality.

Training for our own approach is similar to the vanilla RL method described above, but with three differences. First, in order to use input-dependent rewards (Equation 7), we first pre-train the model with **SymVoTo** model instead of the pointer-generator method. Secondly, once pre-trained, we optimize on our input-dependent reward function instead of directly using the formality oracle. Finally, once completely trained, the same model can be used to generate formal and informal summaries by supplying the corresponding tokens at the input. While decoding these respective summaries, we use k=4 for hypothesis reranking.

The results of this study are shown in Table 2. The models **SymVoTo** and **ZeroRL** are independently able to beat the baseline from Table 3 in capturing formality. Our approach which combines these two methods using input-dependent rewards and further employs post-processing is able to better capture the formality oracle.

6.2 Evaluation against existing baselines

Multiple style transfer and summarization models are adapted for this task as baselines. Our first baseline is the vanilla, pointer-generator network described in Section 3. It generates a single, generic summary, without using any formality information. We refer to it as **PGen**.



We next implement the use of single vocabulary tokens from Fan et al. (2017) in the same manner as **SymVoTo** except with the usage of one token instead of two. We refer to this method as **VoTo**.

In order to show the benefit of incorporating formality directly into the generation process, we also implement a style-transfer pipeline where we first summarize the input article and then transfer its formality to the desired level. For this purpose, we leverage the sequence to sequence implementation from Jhamtani et al. (2017) and train it on GYAFC parallel formality dataset (Rao and Tetreault, 2018). We build two models, one for formal to informal style transfer and one for informal to formal. Using the output from **PGen** method as an input to these two models, gives us the corresponding informal and formal summaries. We refer to this approach as **StyleSum**.

Next, we compare our method against the vanilla RL baseline, adapted from Paulus et al. (2018). The implementation here is similar to **ZeroRL** (Section 6.1) but with the usage of greedy baseline rewards instead of 0. We refer to this approach as **GreedyRL**.

Table 3 summarizes the results of our experiment for generating informal and formal summaries. First, we observe that as we generate more formal and informal variants, they deviate from the ground-truth summaries at lexical level, as visible in the decreasing ROUGE scores. As we later show (Section 7) through our human evaluation, this lexical difference does not affect the performance of our approach in comparison to other baselines in terms of their correctness, meaning and suitability. Secondly, we observe the desired shift in average formality scores. For both the variants, our approach better captures formality over the baseline methods. While the average formality is still on the negative spectrum for formal summaries, our method is better able to capture the oracle as compared to other baseline approaches.

The **StyleSum** method, although produces formality-diverse summaries, it fails to preserve the content of the input article, as visible by huge decline in ROUGE. This behaviour can be attributed to only a 40% overlap between the vocabulary on which the summarization and style transfer modules were trained. One of the main disadvantages for such an approach is the lack of availability of parallel corpora with the same vocabulary, for both summarization and style transfer-indicating the challenges in cascading such models and curating such corpora for these tasks.

(a) Informal summaries (b) Formal summaries

Figure 2: Distribution of formality scores of the generated summaries. Y-Axis: Fraction of datapoints, X-Axis: Intervals of formality scores.

We compare the distributions of above approaches in Figure 2. For visualization, we divide the formality score from -2.0 (more informal) to 2.0 (more formal) into 10 buckets and plot the fraction of test data points falling into these bins. The desired shifts in the distributions are visible for generating both formal and informal variants, being more profound for our approach.

Metric	Description
Formality	How formal is the given summary
Meaning Similarity	How close or similar is the meaning of the given summary with respect to the reference (ground-truth) summary
Semantic Correctness	How correct is the information present in the summary with respect to the given input article
Suitability	How well the summary suits the input article, how well it captures the key idea behind it

Table 4: Metrics considered for the qualitative analysis of the summaries generated by our approach.

7 Qualitative Evaluation

The automated evaluation is limited to comparing the summaries to a single ground-truth summary based on ROUGE metric. Hence, we further performed a crowd-sourced experiment to evaluate the quality of the generated summaries while also evaluating their formality. We compare the summaries generated by our model with those generated by **VoTo** and **GreedyRL** baseline methods. We did not consider the **Pgen** and **StyleSum** for this comparison since the former only generates a single, generic summary and the latter deviates too

Method	Informal Summaries (in %)				Formal Summaries (in %)			
	Formality	Meaning Similarity	Semantic Correctness	Suitability	Formality	Meaning Similarity	Semantic Correctness	Suitability
	All instances							
VoTo	40	62	54	52	52	56	66	54
GreedyRL	52	54	66	62	62	66	66	54
	CNN/DM instances							
VoTo	37.5	70.8	45.8	54.2	54.1	58.3	66.7	50
GreedyRL	54.2	54.2	79.2	58.3	62.5	66.7	58.3	54.2
	TL;DR instances							
VoTo	42.3	53.8	61.5	50	50	53.8	65.4	57.7
GreedyRL	50	53.8	53.8	65.4	61.5	65.4	73.1	53.8

Table 5: Percentage improvement of the proposed approach w.r.t. baseline methods for formal and informal summary generation. Each value indicates the %age of cases where the summary by our approach was rated equal to or higher in comparison to the baseline summary. For example, in 62% of the cases (All instances), the informal summary generated by our method was rated as being closer to the reference summary in meaning (**Meaning Similarity**) with respect to the summary generated by **VoTo** method. For Informal summaries, lower score on formality is desirable and for all other comparisons, a higher score is more desirable. For all the metrics, our method either performs at par or outperforms the two baselines.

much from the content in the article, as depicted by the ROUGE scores. Table 4 describes the metrics on which we perform the comparison.

The crowd-sourced experiment is conducted via Amazon Mechanical Turk[3]. 50 samples were randomly chosen from our test data, with 24 coming from CNN/DM dataset and 26 coming from Reddit dataset. The annotators were asked to rate the summaries on a discrete scale of 1 to 5 for all our requested metrics. To avoid any inter-annotator bias, we get every annotator to rate all variants of the summary generated for each test case. In total, the summaries for each sample were rated by 5 annotators. Our comparisons between any two summary variants for the same article are based on the majority opinion of these 5 annotators. To ensure the quality of the annotations, we also ask the annotators to mark all the summaries which they saw during the survey. We reject all those assignments where this question was answered incorrectly and those with less than 150 seconds work time.

Intra-Model Comparison: The annotators rate the formality of a given summary, with 1 being the least and 5, most formal. We perform a comparative analysis between the formal and informal summaries generated by the same model. For our approach, the formal summary was rated as more formal in comparison to it's informal counterpart in 76% of the cases. For **VoTo** and **GreedyRL** method, this number drops down to 66%. Being consistent with the average formality scores in Table 3, this shows that our approach is able to produce better formality-diverse summaries.

Inter-Model Comparison: In order to measure the quality of our generated summaries, we also compare them with baseline outputs on Meaning Similarity, Semantic Correctness, and Suitability (Table 4), all being key requirements in any summarization system. We compare the (in)formal summaries generated by our system with the corresponding (in)formal summaries generated by the two baseline systems. For all these metrics, higher values are more desirable for both formal and informal variants. However, for comparison on Formality, when comparing informal summaries, lesser values are desirable and while comparing formal summaries, higher are more desirable. The results of our comparative study for these metrics are presented in Table 5. All the values represent the percentage of cases where our summary is rated to be better than the corresponding baseline summary by the majority of annotators. We also report the values for each dataset separately. While our method does show a decline in ROUGE scores in comparison to these methods (Table 3), probably due to diversion from the ground-truth summaries, this decline does not translate to the quality metrics in our human evaluation. We observe that our summaries either perform at par or outperform the baseline summaries on all four metrics. We conclude that our approach produces better formality-diverse summaries, while still surpassing other methods on summarization quality.

8 Conclusion

We presented a framework to generate formality-tailored abstractive summaries for a given input article. Our approach employs reinforcement learning to train the model with formality feedback on both ground-truth and sampled summaries to-

[3]https://www.mturk.com/

gether. Automatic and human evaluations show that although we observe some deviation from the ground-truth summaries with respect to baseline methods, the approach is effective in generating formality-diverse summaries while still preserving the meaning, semantic correctness and suitability. Given a suitable oracle, the proposed methodology can be easily extended to other psycho-linguistic preferences such as politeness. We plan to perform this incorporation of other such preferences that can arise in textual content.

Abstract

Large neural language models trained on massive amounts of text have emerged as a formidable strategy for Natural Language Understanding tasks. However, the strength of these models as Natural Language *Generators* is less clear. Though anecdotal evidence suggests that these models generate better quality text, there has been no detailed study characterizing their generation abilities. In this work, we compare the performance of an extensively pretrained model, OpenAI GPT2-117 (Radford et al., 2019), to a state-of-the-art neural story generation model (Fan et al., 2018). By evaluating the generated text across a wide variety of automatic metrics, we characterize the ways in which pretrained models do, and do not, make better storytellers. We find that although GPT2-117 conditions more strongly on context, is more sensitive to ordering of events, and uses more unusual words, it is just as likely to produce repetitive and under-diverse text when using likelihood-maximizing decoding algorithms.

1 Introduction

In 2018, large-scale neural models such as ELMo (Peters et al., 2018), BERT (Devlin et al., 2019) and OpenAI GPT (Radford et al., 2018) emerged as a dominant approach in NLP. By pretraining on massive amounts of unlabeled text (often orders of magnitude larger than the the target task's labeled dataset), these models achieve state-of-the-art performance across a variety of Natural Language Understanding benchmarks. In particular, the OpenAI GPT2 language model (Radford et al., 2019) achieves state-of-the-art performance on several language modeling benchmarks, even in a zero-shot setting. While GPT2's performance as a language model is undeniable, its performance as a text generator is much less clear. Though the model has generated certain impressive samples of text – such as a widely-circulated passage about Ovid's Unicorn (Radford et al., 2019) – there has been no detailed study to formalize these observations.

In this work, we perform an in-depth study of the properties of text generated by GPT2-117 (the smallest version of GPT2) in the context of story generation. By comparing to a state-of-the-art, specialized-architecture neural story generation model (Fan et al., 2018), we ask the following questions. In what ways does a large amount of open-domain pretraining data change the characteristics of generated text? In what ways does it make no difference? And is a task-specific architecture necessary?

For any probabilistic language model, the generated text is strongly affected by the choice of decoding algorithm – this is especially true for *open-ended* text generation tasks such as storytelling and chitchat dialogue (Kulikov et al., 2018; Holtzman et al., 2019). Nevertheless, most natural language generation papers evaluate only *one* decoding algorithm – this is often due to the time and expense required for human evaluation. For example, Fan et al. use top-k sampling (a decoding algorithm in which k governs the quality-diversity tradeoff), but only evaluate one value of k. However, evaluating one k gives an incomplete view of the generation system – several researchers have emphasized the importance of evaluating generation systems over the entire quality-diversity spectrum, rather than a single point on it (Caccia et al., 2018; Hashimoto et al., 2019).

In this study, we prioritize evaluating text across the *whole* k spectrum, and measuring *many* different automatic metrics, rather than a few human metrics. Though the lack of human evaluation limits our ability to measure overall quality (Liu et al., 2016; Novikova et al., 2017; Hashimoto

*equal contribution

Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

et al., 2019), we are able to produce an objectively defined, richly detailed and reproducible evaluation of the generated text. To our knowledge, this work is the first comprehensive analysis of the characteristics of GPT2-generated text. Our study provides insight into the effect of large-scale pretraining on open-ended natural language generation, as well as the effect of k on text generated with top-k sampling. We hope our results will inform other researchers' choice of models, pretraining schemes, and decoding algorithms – decisions that can often feel like blind choices. To enable readers to browse the generated text, conduct their own evaluations, or run our evaluations on their own text, we publicly release our generated stories and evaluation code.[1]

2 Background

WritingPrompts dataset WritingPrompts (Fan et al., 2018) is a story generation dataset containing 303,358 human-written (*prompt*, *story*) pairs collected from the /r/WritingPrompts subreddit – a forum where Reddit users compose short stories inspired by other users' prompts. An example can be seen at the top of Table 2. The mean prompt length is 28.4 words and the mean story length is 734.5 words. The dataset is 887MB of text in total, contains 200 million story words, and is divided into 90% train, 5% validation and 5% test splits.

The Fusion Model The Fusion Model is a state-of-the-art neural story generation architecture trained on the WritingPrompts dataset (Fan et al., 2018). It is based on the Convolutional Seq2seq model of Gehring et al. (2017) and aims to improve two aspects of story generation: modeling long-range context and increasing relevance of the story to the prompt. To achieve the former, the model uses a multi-scale gated self-attention mechanism. For the latter, the model uses a fusion mechanism (Sriram et al., 2018) in which one seq2seq model is trained on the task, then frozen, and a second seq2seq model is trained on the task with access to the first model's hidden states. Compared to the Convolutional Seq2seq model and other baselines, the Fusion Model achieves improved perplexity, story-prompt relevance and human preference scores. The Fusion Model has a vocabulary of 104,960 words, a 3-layer encoder and 8-layer decoder in the first seq2seq model, and a 5-layer encoder and 5-layer decoder in the second model – in total, 255.4 million parameters.

GPT2-117 GPT2 (Radford et al., 2019) is a large Transformer language model trained on WebText, a diverse corpus of internet text (not publicly released) containing over 8 million documents equalling 40GB of text in total. The full-size GPT2 model, which has 1542 million parameters, obtains state-of-the-art results on a variety of language modeling and other Natural Language Understanding benchmarks. At the time of our experiments, Radford et al. had only released the smallest of the models, known as GPT2-117.[2] This model, which we use for our experiments, has 12 layers and 117 million parameters. Like the full-size GPT2 model, it has a vocabulary of 50,257 byte-pair-encoding (BPE) tokens. The BPE encoding allows the model to encode and generate any Unicode string, regardless of preprocessing, tokenization, or vocabulary size. The model has a context size of 1024, meaning it can process text up to 1024 BPE tokens in length.

Decoding algorithms Inspired by Neural Machine Translation, most early attempts at open-ended neural text generation (such as conversational response generation) used the *beam search* decoding algorithm (Shang et al., 2015; Serban et al., 2016). Like greedy decoding, beam search is a *likelihood-maximizing* decoding algorithm – given the input sequence x, the objective is to find an output sequence y which maximizes $P(y|x)$. However, researchers have shown that for open-ended generation tasks (including storytelling), beam search produces repetitive, generic and degenerate text (Holtzman et al., 2019).

More recently, *top-k sampling* has emerged as a primary decoding algorithm for open-ended text generation (Fan et al., 2018; Radford et al., 2019). In top-k sampling, on each step of the decoder the probability distribution over the vocabulary is truncated to the top k tokens, then re-normalized. The next token is sampled from the new distribution. Top-k sampling can be regarded as somewhere between a likelihood maximizing algorithm (when $k = 1$; greedy decoding) and an unbiased sampling algorithm (when $k =$ vocabulary size). Fan et al. use top-k sampling (with $k = 10$) to

[1] Code and generated stories available at https://github.com/abisee/story-generation-eval

[2] Since conducting our experiments, larger models have been publicly released. At the time of writing, the full-size GPT2 model has not been publicly released.

generate stories, and Radford et al. show impressive samples of generated text (primarily from the full-size GPT2 model) for $k = 40$.

3 Experimental Details

Preprocessing Fan et al. truncate WritingPrompts stories to 1000 words before training and testing. Due to the limited context size of GPT2-117, we additionally exclude (*prompt*, *story*) examples that are longer than 1024 BPE tokens when concatenated. The resulting dataset, which we call WritingPrompts-1024, has 192,364 training, 11,115 validation, and 10,686 test examples.

The Fusion Model We use the pretrained version of the Fusion Model, which is available in the Fairseq framework (Ott et al., 2019). For comparability with GPT2-117, we evaluate the Fusion Model on WritingPrompts-1024 (see Table 1), obtaining perplexities similar to those reported by Fan et al. on the full WritingPrompts dataset.

GPT2-117 In order for the model to condition on prompts and generate stylistically correct stories, we finetune GPT2-117 on WritingPrompts-1024.[3] We frame WritingPrompts as a language modeling task, representing the prompt and story as a single sequence separated by a delimiter token. We finetune the pretrained model until convergence using the default hyperparameters provided in the HuggingFace repository (though we reduce batch size to fit on a single GPU), and use the finetuned model for all further evaluations.

We compute the *word-level* perplexity of the finetuned GPT2-117 on the WritingPrompts-1024 dataset. That is, we normalize the total negative log probability of the target text by the number of *word*-level (i.e. Fusion Model) tokens, not the number of BPE tokens. This enables us to compare the perplexities of the two models, despite the tokenization difference (Radford et al., 2019). The finetuned GPT2-117 obtains a test set word-perplexity of 31.54[4] – six points lower than the Fusion Model.

Generation settings For both models, we generate stories using top-k sampling, obtaining 1000 stories (from 1000 different test set prompts) for several values of k ranging from 1 to vocabulary size. We use softmax temperature 1. Like Fan et al., we generate exactly 150-word stories and block the Fusion Model from generating <UNK>.

To obtain human-written stories for comparison, we truncate WritingPrompts-1024 test set stories to 150 words (discarding those shorter than 150 words). To reduce variance, measurements for human stories are computed over this entire set (rather than just 1000 stories).

Model	Valid ppl	Test ppl
Fusion Model	37.05	37.54
GPT2-117	31.13	31.54

Table 1: Word-level perplexities on WritingPrompts-1024 for the Fusion Model and finetuned GPT2-117.

4 Story-prompt relatedness

Prior research has observed that seq2seq systems frequently produce text that is unrelated to the provided context – particularly under likelihood-maximizing decoding algorithms such as beam search. The issue has inspired multiple explanations (Jiang and de Rijke, 2018) and multiple solutions – such as alternative training objectives (Li et al., 2016), decoding objectives (Baheti et al., 2018; See et al., 2019), and architectural changes (Fan et al., 2018). In this section, we measure how strongly the models condition on the prompt.

Prompt ranking accuracy For both models, we compute *prompt ranking accuracy* (Fan et al., 2018), which measures the language model's sensitivity to the provided prompt. Following the methodology of Fan et al., we randomly select 1000 human-written stories from the test set, and measure the probability (according to the model) of each story conditioned on 10 different prompts – the true prompt, plus nine randomly selected prompts. The prompt ranking accuracy of a model is the percentage of cases in which the model assigns a higher probability to the story under its true prompt than under all of the other nine. We find that GPT2-117 scores **80.16%** on this task, while the Fusion Model scores **39.8%**.[5] Random chance scores 10%. This striking result indicates

[3] We use the PyTorch re-implementation of GPT2-117 available at https://github.com/huggingface/pytorch-transformers

[4] This is similar to other GPT2-117 WritingPrompts finetuning experiments (Mao et al., 2019; Ziegler et al., 2019).

[5] Fan et al. (2018) report a prompt ranking accuracy of 16.3% for the Fusion Model. We provided the authors with our prompt ranking accuracy code (which was built on top of the authors' code). The authors indicated that the discrepancy may be due to some code version changes between the time of their original experiments and their code release.

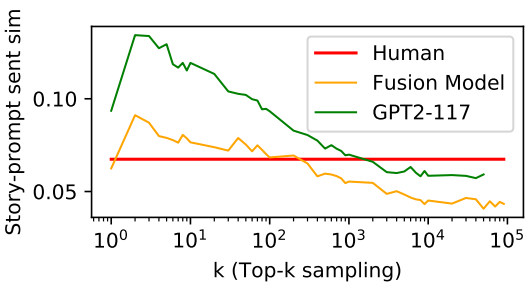

Figure 1: Compared to the Fusion Model, GPT2-117 produces stories that are more semantically similar to the prompt. Similarity decreases as k increases.

that GPT2-117 conditions on the prompt much more strongly than the Fusion Model. This is notable, especially because the fusion technique is intended to improve story-prompt relevance.

N-gram similarity For $n = 1, 2, 3$, we measure the percentage of generated n-grams that also appear in the prompt. For all n and k, we find that GPT2-117 has a higher overlap (i.e. copies more from the prompt) than the Fusion Model – see Figure 6 in the Appendix. Furthermore, for $k < 100$, the GPT2-117 overlap is generally much higher than human levels. Both these phenomena can be seen in Table 2, where, for $k = 10$, GPT2-117 copies words such as *queen* more often than both the Fusion Model and the human-written story.

Sentence embedding similarity To capture a higher-level notion of semantic similarity, we measure *story-prompt sentence similarity* – the cosine similarity of story-prompt sentence pairs, averaged by taking the mean over all pairs. Sentences are represented by the embedding method of Arora et al. (2017) – a weighted average of the GloVe embeddings (Pennington et al., 2014) of the words, with the first principal component removed. As shown in Figure 1, we find a similar pattern as for n-gram similarity: GPT2-117 generates sentences that are more similar to the prompt than the Fusion Model for all k, and both models' prompt similarity decreases as k increases.

Named entity usage Generally, most named entities mentioned in the prompt (such as *Queen* and *England* in Table 2), should also be mentioned in the story. Using the spaCy named entity recognizer,[6] we measure the *prompt entity usage rate*, which is the percentage of all prompt named entities that appear in the story.[7] As shown in Figure 7 in the Appendix, we find that GPT2-117 uses more of the prompt named entities than the Fusion Model (as well as more named entities overall), but both models use fewer named entities than humans when k is less than vocabulary size.

These patterns can be seen in Table 2: GPT2-117 uses the prompt entities *Queen* and *England* whereas the Fusion Model does not (for either k), and GPT2-117 uses specific time entities such as *Thursday* and *3:26 PM*. While the human story introduces highly-related entities such as *Charles Windsor* and *Prince of Wales* that were not in the prompt, neither model does this (for either k).

Conclusion In this section, we found that GPT2-117 conditions on the prompt much more strongly than the Fusion Model – a result which holds both in language modeling and generation settings. The latter result supports Radford et al.'s informal observation that GPT2 has a 'chameleon-like' ability to 'adapt to the style and content of the conditioning text'.[8] We speculate that GPT2-117's stronger conditioning ability may derive from its Transformer decoder architecture, whose powerful self-attention is used for story-prompt attention. Though the Fusion Model uses a similar self-attention mechanism in the decoder (i.e., story side), the prompt-story attention has a simpler formulation – for example, there are no separate key and value vectors (Gehring et al., 2017). Lastly, we note that very strong prompt-conditioning is not always a good thing – GPT2-117 often generates stories that copy too much or too literally from the prompt when k is small (this can be seen in Figure 6 in the Appendix).

5 Coherence

A good story generation model should produce coherent text with a logical ordering of events. Similarly, the underlying language model should be a good coherence scorer – assigning higher probability to coherent text than incoherent text. Barzilay and Lapata (2008) evaluate a coherence scorer by measuring its ability to rank shuffled human-written text as less coherent than the original unshuffled text. We use this method to evaluate our story generation models.

[6] https://spacy.io

[7] Given that we limit stories to 150 words, this percentage is lower than it would be if we generated longer stories.

[8] https://openai.com/blog/better-language-models/

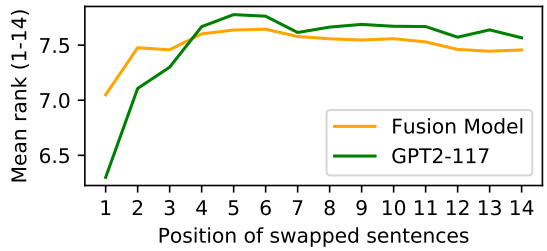

Figure 2: Sensitivity of the models to swapped sentences in different positions. A higher mean rank indicates higher sensitivity (i.e. the model assigns lower probability) relative to other positions. Both models are less sensitive to swapped sentences at the beginning of the text, compared to later. GPT2-117 shows this pattern more strongly, indicating greater use of context.

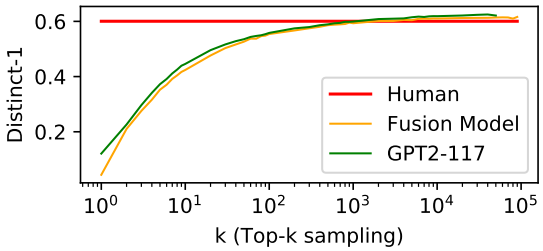

Figure 3: Repetition (low distinct-1) is primarily caused by choice of decoding algorithm (here low k), not insufficient training data. GPT2-117 is trained on $45\times$ more data than the Fusion Model, but is similarly repetitive for all k.

For each story in the test set, we select the first 15 sentences. We then produce 14 corrupted versions of the story by switching each pair of adjacent sentences. We use the language model to compute the probability of each of the 14 corrupted stories, as well as the original story. The model's error rate is the percentage of cases in which it rates any of the 14 corrupted candidates better than the original candidate. Random guessing yields 93.33% error. Both models perform well on this task – the Fusion Model has an error rate of **3.44%** and GPT2-117 an error rate of **2.17%**. This 36.92% error reduction indicates that GPT2-117 is more sensitive to ordering of events.

We also investigate how the position of the swap affects its plausibility (relative to other positions). Figure 2 shows, for each swap position, the mean rank assigned to that swap by the model (where rank 1 is the most probable of the 14 corrupted candidates, and rank 14 the least probable). GPT2-117 assigns a much lower rank to the first few swap positions (i.e., rates them more probable) than the later positions. The Fusion Model shows a similar but less pronounced pattern. This shows that both models are less sensitive to out-of-order sentences that occur at the beginning of the text, than those occurring later.[9] The stronger pattern for GPT2-117 may be due to its stronger context conditioning (as shown in Section 4) – thus becoming more sensitive as context increases. However, even for the first three swaps, GPT2-117 is more accurate than the Fusion Model at distinguishing the swapped text from the original.

[9]It's also possible that out-of-order sentences are inherently harder to detect at the beginning of text.

6 Repetition and rareness

Generic, under-diverse and repetitive text is a well-documented problem in neural text generation (Jiang and de Rijke, 2018). While there are many proposed solutions to the problem (Li and Jurafsky, 2016; Vijayakumar et al., 2018; Baheti et al., 2018; Zhang et al., 2018; See et al., 2019), it has been shown that a primary cause is likelihood-maximizing decoding algorithms such as greedy decoding and beam search (Holtzman et al., 2019). In this section we investigate the role of large-scale pretraining, and the role of k, in this problem.

N-gram repetition The *distinct-n* metric of a piece of text is the number of unique n-grams divided by the total number of generated n-grams (Li et al., 2016). We measure distinct-n of the generated stories for $n = 1, 2, 3$. A high ratio indicates a high level of within-story lexical diversity, while a low ratio indicates a large amount of within-story repetition. As shown in Figure 3, both models' unigram diversity is far below that of human text when k is small. For example, at $k = 10$ (the setting used by Fan et al.), the Fusion Model obtains a distinct-1 of 42.4%; much less than the human level of 60.0%. This results in a high level of repetition, as shown in Table 2: for $k = 10$, both models repeat many phrases (such as *always*, *so scared*, and *finally*).

For bigrams and trigrams, the pattern is similar to unigrams (see Figure 9 in the Appendix). For both models, distinct-n increases as k increases, converging to a value close to the human level as k approaches vocabulary size. Though GPT2-117 has a slightly higher distinct-n than the Fusion Model for most values of k, the difference is negligible compared to the influence of k. We

make three conclusions from these patterns: (1) Our findings support Holtzman et al.'s observation that repetition is strongly related to choice of decoding algorithm, and that likelihood maximizing algorithms (such as top-k sampling with low k) are a primary cause of repetition. (2) The models have in fact learned the correct rate of repetition in human text – they are able to match this rate when they sample from their full (untruncated) distribution. (3) Repetition is unlikely to be solved by more pretraining data alone – even though GPT2-117 is trained on 45 times as much data as the Fusion Model, it produces text that is almost equally repetitive (for equal k).

Rare word usage We compute the *mean log unigram probability* of the words in the generated story[10] – a high value indicates using fewer rare words while a low value indicates more rare words. As shown in Figure 12 in the Appendix, word rareness is primarily governed by k – however, GPT2-117 has a lower mean log unigram probability (i.e., uses more rare words) than the Fusion Model for all equal values of $k \geq 2$. This can be seen for example in Table 2, where GPT2-117 generates rarer words such as *idle* and *copious* for $k = 1000$. GPT2-117 also generates fewer stopwords than the Fusion Model, for all equal k.

GPT2-117's slightly higher rare word usage (compared to the Fusion Model) might be explained by: (1) its BPE encoding, which allows it to generate new words, not just those in a fixed vocabulary; (2) pretraining on a large amount of diverse text, allowing it to learn to produce a greater variety of words; (3) stronger conditioning on the prompt as described in Section 4 – which may inject more rareness into the generated text.

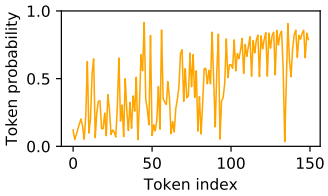
Conclusion Choice of decoding algorithm is a primary factor in diversity and repetition problems, with likelihood-maximizing algorithms the main culprit. Although GPT2-117 generates more rare words and is very slightly less repetitive than the Fusion Model, the difference is small compared to the effect of k, indicating that training data alone is unlikely to solve these problems.

7 Syntactic style and complexity

A well-trained story generation model should match both the syntactic style and complexity of its training data. Low complexity can be a sign of less sophisticated writing, while high complexity can be a sign of poor readability (Beers and Nagy, 2009; McNamara et al., 2010). In this section, we measure some features related to the syntactic style and complexity of the generated stories.

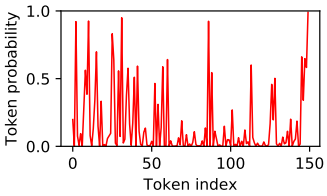
Sentence length Sentence length is a simple but effective feature to estimate readability and syntactic complexity of text (Kincaid et al., 1975; Roemmele et al., 2017). We find that both models generate sentences that are on average shorter than human sentences when k is small, but converge to approximately human length as k increases (see Figure 8 in the Appendix).

Part-of-speech usage It has been shown that the distribution of parts-of-speech (POS), and more generally the distribution of POS n-grams[11] is a useful feature to represent the style of a piece of text (Argamon et al., 1998; Ireland and Pennebaker, 2010; Roemmele et al., 2017).



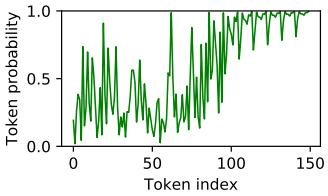
Firstly, we compare the part-of-speech distributions of the model-generated text and the human text (see Figure 11 in the Appendix). Both models (especially GPT2-117) closely fit the human POS distribution as k approaches vocabulary size.[12] This implies that, as with lexical diversity, the models have no difficulty fitting the statistical distribution of human syntax. However, under likelihood-maximizing decoding algorithms such as low k, a completely different distribution emerges, in which text contains more verbs and pronouns than human text, and fewer nouns, adjectives and proper nouns.

Secondly, we measure the syntactic diversity of the text using the distinct-n metric for POS n-grams ($n = 1, 2, 3$) – see Figure 10 in the Appendix. As with lexical diversity (see Section 6), we find that syntactic diversity is similar for the two models, is very low when k is small, and matches human level as k approaches vocabulary size. It's likely that for low k, the syntactic under-diversity of the text is largely caused by lexical under-diversity (i.e. repetition). However, we note that as k increases, lexical diversity reaches human level sooner than syntactic diversity – for example, GPT2-117's lexical distinct-3 reaches human level at $k = 600$ (Figure 9c), but its POS distinct-



[10] The unigram probability distribution was calculated with respect to the WritingPrompts training set.

[11] For example, the sentence *I like cats* has the POS bigrams PRONOUN VERB and VERB NOUN.



[12] One exception is Proper Noun: both models fail to produce enough of these even as k approaches vocabulary size.

(a) **Fusion Model** ($k = 2$): *I had never seen a man so young before. I had never seen him before, but he had always seemed to be a man of a man. He was young, and he was young. He was a man of a man, and a man who was young, and a man who was* [...]

(b) **Human Text**: *"Looks like the rain's stopped." I peered out the window. Art was right; time to get to work. "Alright, let's move out." I could hear the scraping of the stone armor as the men slowly stood. Despite the training,* [...]

(c) **GPT2-117** ($k = 2$): *I've always been a man of the people. I've always been a strong man. I've always been a strong man. I was born in the city, I was raised in the country. I was raised in a family that wasn't very good. I 'm not a good man.* [...]

Figure 4: Under top-k sampling with small k ($k = 2$), the two models (left and right) produce text that falls into increasingly confident repeating loops. By contrast, human text (center) maintains an irregular pattern of surprising (low probability) tokens. The human text probabilities are measured with respect to the Fusion Model, but similar patterns hold for GPT2-117. Inspired by Holtzman et al. 2019's figure showing probabilities under beam search.

3 reaches human level at $k = 6000$ (Figure 10c). This implies that, even when the text is no more repetitive than human text, it may still be syntactically repetitive (using the same part-of-speech patterns repeatedly).

Conclusion We find when k is small, syntactic complexity of generated text is low, consisting of shorter sentences and a narrower range of syntactic patterns. However, as k approaches vocabulary size, the syntactic style of generated text closely matches human syntactic patterns. As with n-gram diversity in Section 6, our results show that syntactic under-diversity is primarily caused by low k, not insufficient training data.

8 The element of surprise

Model confidence over time Several researchers have observed that *model over-confidence* (the model placing high probability on a small range of tokens) can cause poor quality generation (Jiang and de Rijke, 2018; Holtzman et al., 2019). In particular, they show that for likelihood-maximizing decoding algorithms such as beam search, model confidence can increase in a snowball-like effect, getting stuck in a loop of repetitive but increasingly self-confident text. We observe this problem in both our models when k is small. For example, in Figure 4, both models fall into self-reinforcing repetitive loops with rising confidence. The loop is difficult to break – the Fusion Model briefly escapes (shown as a sudden downwards spike), but quickly returns. By contrast, the human text does not show a strong rising trend in probability, and intermittently uses low probability words throughout.[13]

We formalize these anecdotal observations by measuring the average probability of each of the first 150 word-level tokens in the story (Figure 5). We find that even when teacher-forcing on human text, the token probabilities increase slightly as the story progresses. This is likely due to the usefulness of additional context, which increases the model's prediction accuracy. By comparison, we find that when generating with top-k sampling, the probabilities increase more rapidly, and the increase is even more rapid for smaller k. This confirms that likelihood-maximizing decoding algorithms (such as top-k sampling with small k) lead to more rapidly increasing model over-confidence. Furthermore, we find this pattern holds for both models, with probabilities increasing at a similar rate for equal k. This indicates that, like repetition, model over-confidence is unlikely to be solved by more training data, and is largely governed by choice of k.

Overall model confidence We also measure the models' overall confidence, as represented by the total log probability (according to the model) of the generated story. For both models, we find that story probability decreases as k increases – see Figure 13 in the Appendix. This makes sense, as higher k means sampling tokens with lower probability. As k approaches the vocabulary size, the Fusion Model's generated story

[13] Gehrmann et al. (2019) also identify presence of low probability words as an indicator of human-generated text.

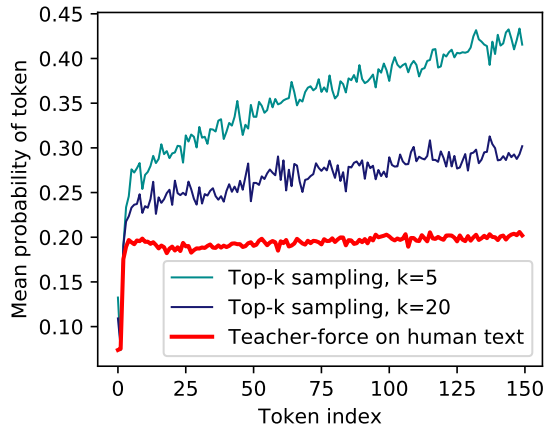


Figure 5: Mean probability for each of the first 150 word-level story tokens. When teacher-forcing the model on human text, probability increases slowly. When generating with top-k sampling, probability increases faster, especially for smaller k. This plot is for the Fusion Model; similar patterns hold for GPT2-117.

probability matches the probability it assigns to human-written WritingPrompts stories. Interestingly however, the same is not true for GPT2-117, which converges to a story probability that is *lower* than the probability it assigns the human stories. This means that under full (non-truncated) sampling, the Fusion Model produces text that is *equally surprising* (to itself) as the WritingPrompts stories, whereas GPT2-117 produces text that is *more surprising* to itself. Explaining this observation is an open question – we speculate that GPT2-117's WebText pretraining may cause it to generate (under high k) text in a style or genre that is less predictable than WritingPrompts stories.

9 Concreteness

Brysbaert et al. (2014) define the *concreteness* of a word as 'the degree to which the concept denoted by a word refers to a perceptible entity'. Concrete words are generally easier to remember than abstract words, and psycholinguists have theorized they may be learned differently (i.e., concrete words by direct experience and abstract words by text and discourse). Brysbaert et al. provide human concreteness ratings for 40,000 common English lemmas rated on a scale from 1 to 5.[14] We use these ratings to measure the mean concreteness of the nouns and verbs in the story text – see Figure 14 in the Appendix.

We find that, for the same k, GPT2-117 tends to generate more concrete words than the Fusion Model, and that for both models, concreteness converges to approximately human levels as k increases. Interestingly, however, when k is small, the noun concreteness is much *higher* than human levels, whereas the verb concreteness is much *lower*. This indicates that for small k, both models produce stories that, compared to human-written stories, have too many physical objects (as opposed to abstract nouns), and too few physical actions (as opposed to abstract verbs). This reflects the trend demonstrated in Table 2: when k is small, the models tend to generate descriptive sentences with mostly *is* verbs (e.g. *I was always so excited*), and physical nouns (e.g. *mother, father, queen*). Only when k increases do we see more tangible actions (e.g. *The bar patrons snickered*) and abstract nouns (e.g. *pain, glances*). A detailed example, with all nouns and verbs annotated with concreteness, is in the Appendix (Table 3).

10 Conclusions

The effect of massive pretraining In this study, we find that GPT2-117 is a better story generation model than the Fusion Model in several specific ways: it conditions much more strongly on the provided context, is more sensitive to correct ordering of events, and generates text that is more contentful (using more rare words, concrete words, and named entities). In particular, the stronger conditioning result is striking, as the Fusion Model is a complex task-specific architecture designed to increase story-prompt relevance. This demonstrates that sometimes, a general-purpose model architecture can outperform a complex task-specific architecture when provided with enough pretraining data.

However, we find that in other aspects, GPT2-117 performs *no better* than the Fusion Model: when k is small, the models generate text that is equally lexically under-diverse, syntactically under-complex, and repetitive – with a tendency to fall into a snowball effect of increasing overconfidence. However, these problems correct themselves (i.e., the metrics match human levels) when the models generate from their untruncated distribution. Our results show that these oft-cited neural generation problems are *not* the fault of the models themselves (which are in fact statisti-

[14] For example, the nouns *television*, *darkness*, and *idea* are rated 4.83, 3.85 and 1.61 respectively, and the verbs *talk*, *see*, and *hope* are rated 4.07, 3.21 and 1.25 respectively.

Prompt: You just discovered England's biggest secret: every time they say long live the queen it extends the queens life.	
Human-Written Story: I am immortal, I have inside me blood of kings. My name in Charles Windsor and I am heir to a throne. Prince of Wales, they've called me that my entire life and now I lay on my death bed and my mother - still going strong. I'm not sure how it's possible but she seems ageless, almost timeless. My whole life I've waited for that [...]	
Fusion Model ($k = 10$): *I have no idea when my father would come to visit this place, I was always so excited. I was always so scared. I had to go back to work. I was a little scared of him, but when I was younger, he had never come in for a visit. His mother told me, "I'm so scared", as he always did. She never talked to me about anything* [...]	**GPT2-117** ($k = 10$): ** " So what are we going to do? " * It was the first time she asked me this question that I ever had asked her. It has taken years but finally I am finally able to do it. It seems that this queen is the queen of England and she's finally the one to tell me that this queen is the reason why she's not being allowed to die.* [...]
Fusion Model ($k = 1000$): *"Where am I? What happened?" "Having been working on my job for over 6 hours now, I do not know how you worked!" "I have been working for the last three years. Surely I am an ancient god now." The bar patrons snickered. "Hello?" "Those last three years have been worse than a year ago." Pain.* [...]	**GPT2-117** ($k = 1000$): *It was an odd occasion for the Queen of England to meet with her. The plane sat idle at 3:26 PM on a Thursday night. Yesterday, the Queen had taken it upon herself to try and get a good look at the plane which had recently been found abandoned. A copious amount of curious glances from around the room until* [...]

Table 2: A prompt and human story from the dataset, plus the models' top-k generated stories, for two values of k.

cally well-trained to match human text for these metrics), nor caused by too little training data (as these problems are not improved by GPT2-117's extensive pretraining). Instead, they are primarily caused by likelihood-maximizing decoding algorithms – such as greedy decoding, beam search, and top-k sampling with low k.

The effect of k This study detailed the typical characteristics of long-form text generated by neural language models in open-ended settings, under both high entropy (large k) and low entropy (small k) decoding algorithms. The negative characteristics of low k output (genericness, repetition, oversimplicity) are by now familiar to researchers. However, we also uncovered some less obvious characteristics of low-k generated text: compared to human-written text, it tends to copy more from the provided context (particularly GPT2-117); it contains more verbs and pronouns but fewer nouns and adjectives; its nouns are more concrete but its verbs are less concrete; and it uses a smaller range of syntactic patterns (a phenomenon that can't be entirely attributed to n-gram repetition).

As k increases to vocabulary size, we find that the model-generated text closely fits the human text on most of the metrics we measured. However, it is clear by inspection that the high-k model-generated text lacks many crucial aspects such as commonsense reasoning, world knowledge and multi-sentence coherence – an example of this superficially fluent but nonsensical text can be seen in Table 4 in the Appendix. We believe that true progress in open-ended Natural Language Generation will come from attempting to address these high k problems – i.e., strategies to imbue the language model with better reasoning, knowledge and planning abilities – rather than continuing to seek ways to mitigate the diversity and repetition problems of the low k setting.

Limitations of this study This study uses only the smallest version of GPT2. It is likely that the larger versions of GPT2 may exhibit stronger statistical differences for the metrics we examine. Such a study would illustrate the effect of larger model capacity, and more fully reveal the possible benefits of massive pretraining. We release our annotation code so that other researchers may repeat our study on more models and datasets.

This study did not include human evaluation, which is currently the only reliable way to assess overall text quality, as well as quantify the deficiencies of high k output described above (coherence, reasoning, and world knowledge). As such, this study quantifies the *diversity* side more than the *quality* side of the quality-diversity tradeoff. Consequently, this study demonstrates the importance of developing better methods to computationally quantify notions such as text coherence, logicality and commonsense correctness – an effort that may ultimately hold the key to generating text with those desirable attributes.

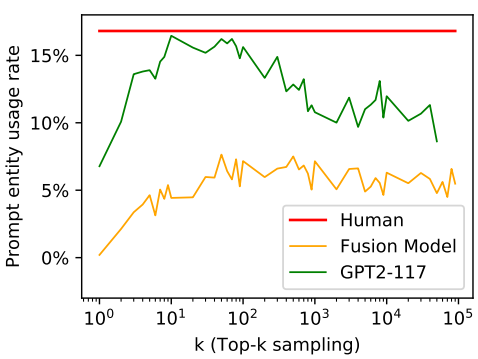
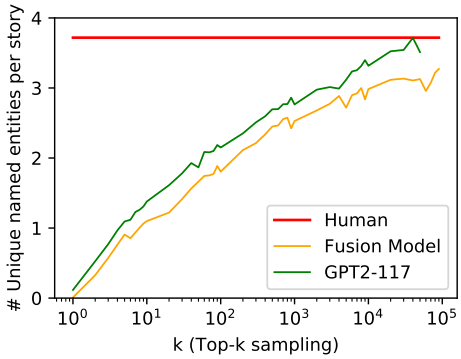
Appendix

(a) Percent of all story unigrams that are in the prompt.



(b) Percent of all story bigrams that are in the prompt.



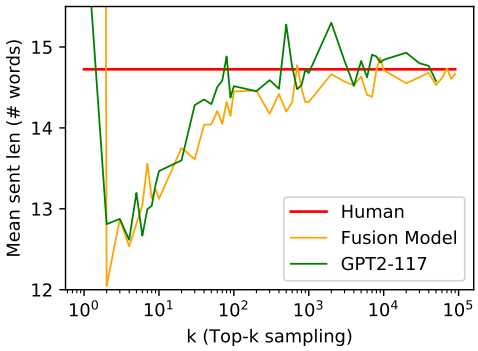
(c) Percent of all story trigrams that are in the prompt.

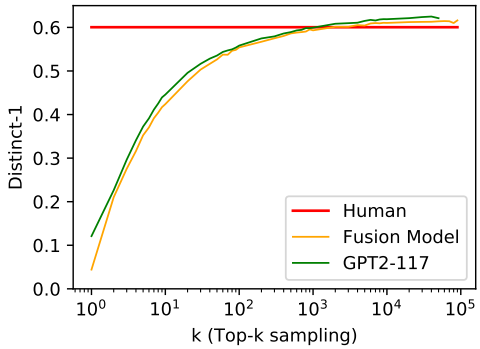
Figure 6: n-gram similarity between prompt and story, for $n = 1, 2, 3$, for both models and all k. GPT2-117 copies many more n-grams from the prompt than the Fusion Model. See Section 4 for discussion.

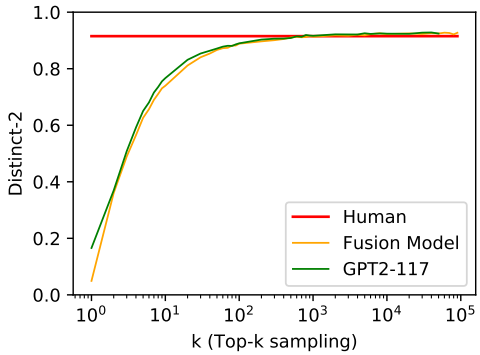
(a) The proportion of all prompt named entities that are used in the story.

(b) The number of unique named entities that appear in the story.

Figure 7: Prompt entity usage rate (left) and mean number of unique named entities in the story (right), for both models and all k. GPT2-117 generally uses a larger proportion of the prompt named entities, and more named entities overall, than the Fusion Model. Both models generally use fewer named entities than human text when k is less than vocabulary size. See Section 4 for discussion.







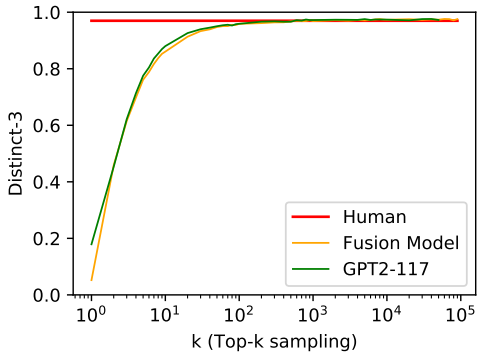


Figure 8: Mean sentence length for both models and all k. For both models, sentence length increases as k increases. The spike at $k = 1$ is due to long repeating sequences with no sentence-ending token. See Section 7 for discussion.

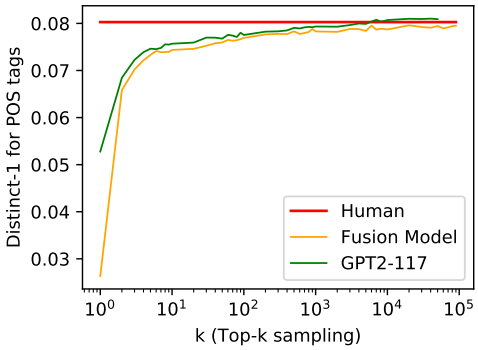
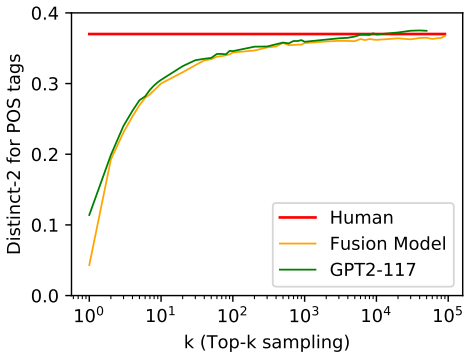
(a) Distinct-1 (ratio of unique unigrams in the story to total number of generated unigrams in the story).



(b) Distinct-2 (ratio of unique bigrams in the story to total number of generated bigrams in the story).



(c) Distinct-3 (ratio of unique trigrams in the story to total number of generated trigrams in the story).

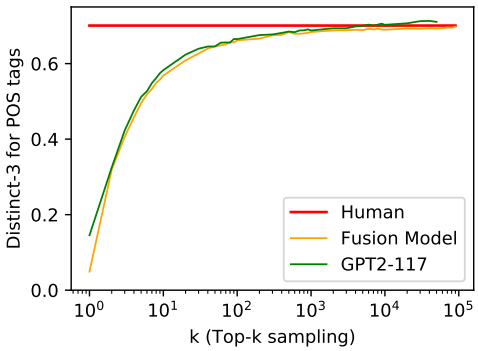


Figure 9: Distinct-n for $n = 1, 2, 3$, for both models and all k. The ratios, which represent lexical diversity, increase as k increases, with GPT2-117 reaching human levels at $k = 2000$ for unigrams, $k = 800$ for bigrams and $k = 600$ for trigrams. Lexical diversity is slightly higher for GPT2-117 than for the Fusion Model for equal k, but the primary determining factor is k. See Section 6 for discussion.

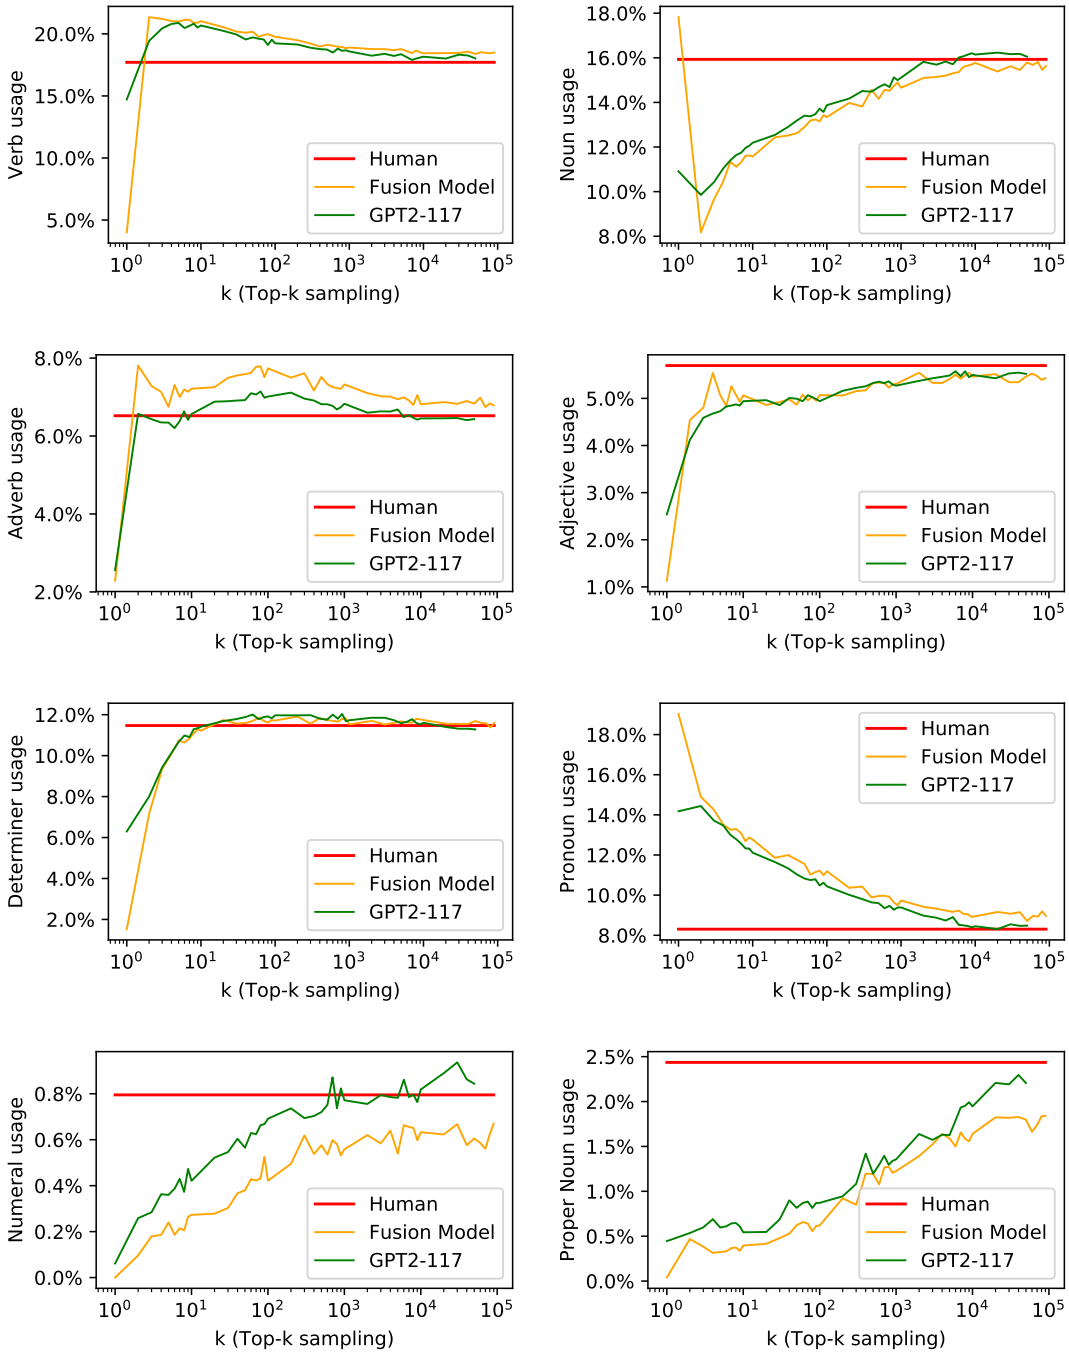
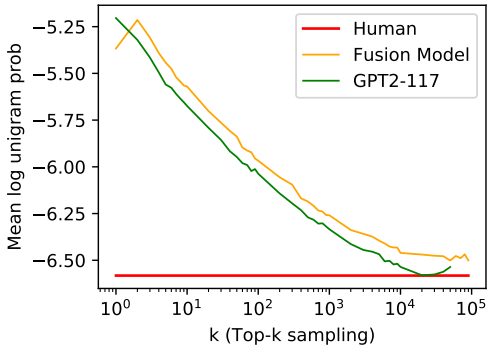
(a) POS tag distinct-1 (ratio of unique POS unigrams in the story to total number of generated POS unigrams in the story).

(b) POS tag distinct-2 (ratio of unique POS bigrams in the story to total number of generated POS bigrams in the story).

(c) POS tag distinct-3 (ratio of unique POS trigrams in the story to total number of generated POS trigrams in the story).

Figure 10: POS tag distinct-n metric for $n = 1, 2, 3$, for both models and all k. The ratios, which represent syntactic diversity, increase as k increases, with GPT2-117 reaching human levels at $k = 6000$ for unigrams, $k = 9000$ for bigrams, and $k = 6000$ for trigrams. Syntactic diversity is slightly higher for GPT2-117 than for the Fusion Model for equal k, but the primary determining factor is k. See Section 7 for discussion.





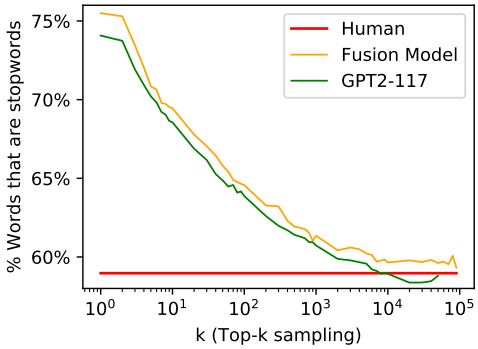


Figure 11: Usage of different POS tags in the generated stories. GPT2-117 tends to fit the human distribution more closely than the Fusion Model as k approaches vocabulary size, in particular producing more specific POS categories such as Numeral and Proper Noun. When k is small, generated text is characterized by more verbs and pronouns, and fewer nouns, adjectives, numerals and proper nouns, than human text. See Section 7 for discussion.

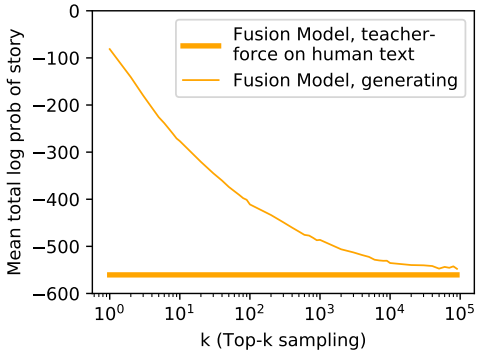

(a) The mean log unigram probability of generated words. Higher values indicate using fewer rare words while lower values indicate using more rare words.

(b) The percent of generated words that are stopwords, for both models, across different k. We use the NLTK English stopword list.

Figure 12: Rare word usage metrics for both models and all k. GPT2-117 produces slightly more rare words (left) and slightly fewer stopwords (right) than the Fusion Model, for equal values of k. These rareness metrics do not reach human levels until k is close to vocabulary size. See Section 6 for discussion.

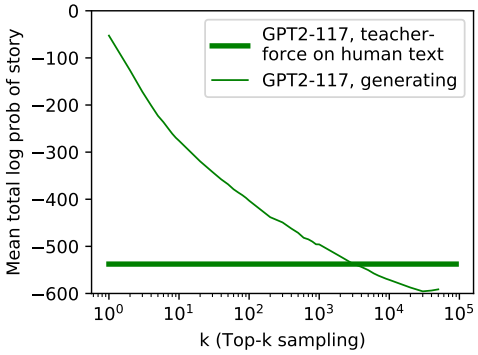

Figure 13: The mean total log probability of the story (150 words), as measured by the models on their own generated output and on human-written stories. Interestingly, the Fusion Model (left) converges to the same probability it assigns to human-written stories as k approaches vocabulary size, whereas GPT2-117 (right) converges to a lower probability. See Section 8 for discussion.

Prompt: A man finally discovers his superpower... well into his 80's.

Fusion Model ($k = 10$):

I be a child . bear into a world of darkness , and in the world , there be only a few people . My mother and I be always alone . She have never be like this . But , she have no idea what we be together to be . We be always alone . We be always together . And , of course , she have never exist . But , I never think about it , because she be always alone . In the world , it was n't like she have a power . I be always alone , and there be a time when the light would turn on . There be a time when I could see the light , and I could see it in her eyes , and I could see the light , and I could see it

Abstract

Residual has been widely applied to build deep neural networks with enhanced feature propagation and improved accuracy. In the literature, multiple variants of residual structure are proposed. However, most of them are manually designed for particular tasks and datasets and the combination of existing residual structures has not been well studied. In this work, we propose the Self-Adaptive Scaling (*SAS*) approach that automatically learns the design of residual structure from data. The proposed approach makes the best of various residual structures, resulting in a general architecture covering several existing ones. In this manner, we construct a learnable residual structure which can be easily integrated into a wide range of residual-based models. We evaluate our approach on various tasks concerning different modalities, including machine translation (IWSLT-2015 EN-VI and WMT-2014 EN-DE, EN-FR), image classification (CIFAR-10 and CIFAR-100), and image captioning (MSCOCO). Empirical results show that the proposed approach consistently improves the residual-based models and exhibits desirable generalization ability. In particular, by incorporating the proposed approach to the Transformer model, we establish new state-of-the-arts on the IWSLT-2015 EN-VI low-resource machine translation dataset.

1 Introduction

Recently, residual learning attracts considerable attention in training deep neural networks, and many efforts have been devoted to study the utilization of residual structure in tasks across a broad span of fields, including but not limited to computer vision (He et al., 2016a; Huang et al., 2017; He et al., 2016b; Szegedy et al., 2017) and natural language processing (Vaswani et al., 2017; Devlin et al., 2019). Residual structure, which alleviates the so-called gradient exploding or vanishing problem in optimization (He et al., 2016a), enables the training of neural networks with great depth by building skip connections between layers.

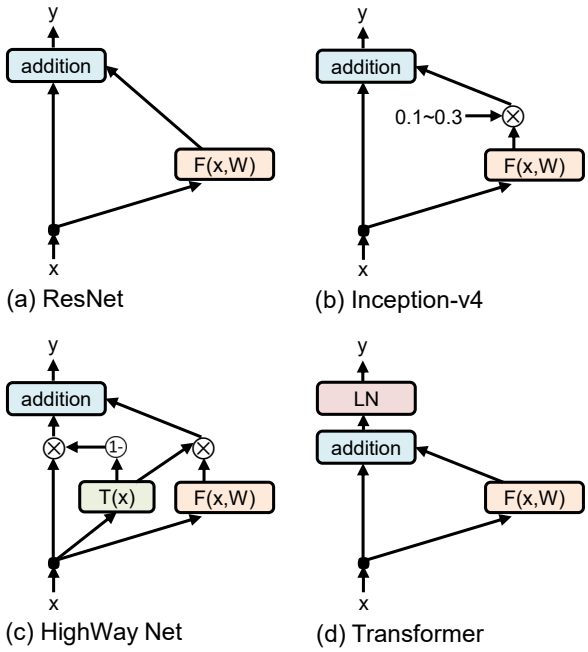

Figure 1: Various types of residual structures: (a) ResNet (He et al., 2016a); (b) Inception Net (Szegedy et al., 2017); (c) Highway Net (Srivastava et al., 2015); (d) Transformer (Vaswani et al., 2017), where LN represents layer normalization (Ba et al., 2016).

Generally, the residual structures (as illustrated in Figure 1) can be formulated as:

$$\boldsymbol{y} = \mathcal{G}(\alpha \cdot \boldsymbol{x} + \beta \cdot \mathcal{F}(\boldsymbol{x}, \mathcal{W})) \quad (1)$$

where $\boldsymbol{x}$ denotes the input (i.e., the skip connection), $\mathcal{F}$ denotes the residual function (i.e., residual branch) parameterized by W, and $\boldsymbol{y}$ is the output of the residual block. The balance between $\boldsymbol{x}$ and $\mathcal{F}$ is governed by the weights α and β, followed by $\mathcal{G}$, which could be either identity mapping or

normalization.

Previous works on residual structure designing, which differ in the way that the information flows are regulated, mainly concern two elements, namely the mapping formulation (weight assignment) and the normalization mechanism. As shown in Figure 1, ResNet (He et al., 2016a), Inception-v4 (Szegedy et al., 2017) and Highway Net (Srivastava et al., 2015) explored the question on how should the residual connection be incorporated into the existing neural network structures so that the best improvements can be achieved. Recently, Transformer (Vaswani et al., 2017) applied the layer normalization (Ba et al., 2016) to help the optimization of the non-linear transformation (i.e., the $\mathcal{F}$) to some extent. At the same time, He et al. (2016b) observed considerably worse results when they utilized batch normalization (Ioffe and Szegedy, 2015) after the residual connection, the reason for which batch normalization is less employed in the residual structure.

Despite their respective advantages and success in certain fields, we argue that the structures are only particular cases of a more general one, which necessitates further insights into possible combinations. However, the determination of an effective combination may require prior knowledge of the data distribution, which is not always available, or extensive hyper-parameter exploration, which is inefficient.

In this paper, we aim at constructing a comprehensive and flexible residual structure. To this end, we propose the Self-Adaptive Scaling approach. In the residual structure, the proposed approach automatically computes scaling factors to adjust the mapping formulation and the normalization mechanism, respectively. By assigning different importance to the skip connection, the residual branch and a normalized result, the scaling factors adaptively controls the topology of the residual building blocks.

As a result, the structure learned by our proposed approach can be easily generalized to various kinds of tasks and data, dispensing with the time-consuming architecture search, to some extent. The proposed learnable residual structure can be easily integrated into existing residual-based models. We evaluate the proposed approach on representative residual models for various tasks. The experiment results and analyses attest to our argument and the effectiveness of the proposal.

Overall, the contributions are summarized as followed:

- We proposed a novel self-adaptive scaling (*SAS*) approach to acquire a learnable residual structure, which allows deep neural models to automatically learn the residual structure and can cover different types of existing ones.
- The proposed approach is simple and can be easily applied to a wide range of existing residual-based models. According to our empirical studies, the *SAS* can enable existing models to achieve consistent performance gains, demonstrating its generalization ability to a wide range of existing systems.
- The experimental results on the IWSLT-2015 EN-VI show that *SAS* helps the Transformer-Base model to perform even better than the Transformer-Big model and, encouragingly, we establish a new state-of-the-art on this low-resource machine translation dataset.

2 Related Work

In recent years, the application of residual structure to deep neural networks has become an active research topic (He et al., 2016a; Srivastava et al., 2015; He et al., 2016b; Vaswani et al., 2017; Szegedy et al., 2017). In the studies on residual architectures, there are two problems of interest. The first is how should the information from the skip connection and the residual branch be well balanced so that the best improvements can be achieved. The second is how should the neural network with residual connections be optimized so that its representation capability could be fully mined. These two types of problems are mainly addressed by designing appropriate mapping formulation and normalization mechanism, respectively, and we refer to them as *On the Connection Problem* and *On the Optimization Problem*.

On the connection problem. There are roughly three lines of methods to control the balance in residual connections: identity mapping, constant scaling ratio and adjusted scaling ratio. He et al. (2016b) designed five types of shortcut connections and discussed the possible residual connections in detail. Based on their theory and experiments, they argued that "keeping a 'clean' information path is helpful for easing optimization". The reason is that with scaling, the gradient of the residual suffers

from the gradient exploding or vanishing problem, which hinders the deep neural network from efficient optimization. Szegedy et al. (2017) adopted constant scaling to govern the residual balance in deep inception networks, which, despite its decent performance, is relatively inflexible. Highway network (Srivastava et al., 2015) is among the very first endeavors to implant residual structures into deep neural networks. It built a highway connection from the input to the output, where a transform gate was proposed to control the balance of the skip connection $\boldsymbol{x}$ and the residual branch $\mathcal{F}(\boldsymbol{x}, \mathcal{W})$, as opposed to the identity mapping.

On the optimization problem. In the realm of computer vision, PreAct-ResNet (He et al., 2016b) demonstrated that it is helpful to apply batch normalization to $\boldsymbol{x}$, instead of $\mathcal{F}(\boldsymbol{x}, \mathcal{W})$. In other words, the batch normalization acts on the output of the previous block. For natural language processing, the popular Transformer (Vaswani et al., 2017) makes use of residual connection in conjunction with layer normalization to build the model architecture and achieves record-setting performance. Layer normalization is widely believed to be helpful for stabilizing training and facilitating convergence. According to our experiments and analyses, the layer normalization can indeed facilitate optimization and therefore improve the overall performance of the model.

Different from existing work, we summarize the combination of normalization and residual connection in existing works with a general form $\boldsymbol{y} = \alpha * \boldsymbol{x} + \beta * \mathcal{F} + \gamma * \mathrm{LN}(\boldsymbol{x} + \mathcal{F})$, where the mapping formulation and the normalization mechanism are both taken into account. By changing the scaling factors α, β and γ, the topology of the residual block can be adaptively adjusted, resulting in a learnable residual structure. The learned architecture distinguishes itself from the previous ones with generality and flexibility.

Our work is also related to the line of research on neural architecture search (Zoph and Le, 2017), where the network structure is also automatically learned by algorithm. However, neural architecture search requires sampling architecture descriptions based on predicted probability from a controller network that is optimized via reinforcement learning, which is time-consuming. But our proposed approach can be trained directly with the loss functions of different tasks.

No.	α	β	γ	Architecture
1	0	0	1	$\mathrm{LN}(\boldsymbol{x} + \mathcal{F})$ (Vaswani et al., 2017)
2	1	1	0	$\boldsymbol{x} + \mathcal{F}$ (He et al., 2016a)
3	1	β	0	$\boldsymbol{x} + \beta * \mathcal{F}$ (Szegedy et al., 2017)
4	α	1	0	$\alpha * \boldsymbol{x} + \mathcal{F}$ (He et al., 2016b)

Table 1: Four particular cases in formula (3), which cover four representative residual structures, i.e., Transformer (Vaswani et al., 2017), ResNet (He et al., 2016a), Inception-v4 (Szegedy et al., 2017) and shortcut-only gating proposed in He et al. (2016b).

3 Architecture

In this section, we first briefly introduce the Scaling Gate in Section 3.1, which is used to predict the scaling factors for the mapping formulation and the normalization mechanism. Then, based on the scaling factors, in Section 3.2, we describe how to adaptively make the best of different types of residual structure to build a learnable residual structure.

3.1 Scaling Gate

The Scaling Gate should be able to predict reasonable scaling factors. Our motivation stems from the superior performance of Feed-Forward Network used in Vaswani et al. (2017). When selecting the activation function, since we expect the final predicted value of the scaling factors to cover the range of 0∼1, we applied the Sigmoid activation function to the original outputs of the scaling gate. As a result, the scaling gate takes the $\boldsymbol{x} \in \mathbb{R}^h$ and the $\mathcal{F}(\boldsymbol{x}, \mathcal{W}) \in \mathbb{R}^h$ as input and computes the output through two linear transformations with a Tanh activation in between:

$$\mathcal{S}(\boldsymbol{x}, \mathcal{F}) = \mathrm{Tanh}([\boldsymbol{x}; \mathcal{F}]W_f + b_f)W_{ff} + b_{ff} \quad (2)$$

where [;] denotes concatenation operation, $W_f \in \mathbb{R}^{2h \times h}$ and $W_{ff} \in \mathbb{R}^{h \times 1}$ are the parameters to be learned, and $\mathcal{S}(\boldsymbol{x}, \mathcal{F})$ is followed by a Sigmoid activation function.

In HighWay Net (Srivastava et al., 2015), the inputs of the Transform Gate only involve the information of $\boldsymbol{x}$ and the structure only contains one layer of linear transformation, i.e., $\boldsymbol{x}W + b$. In contrary, we integrate the information from $\boldsymbol{x}$ and $\mathcal{F}$ and build the structure with two layers of linear transformation, which strengthens the scaling gate's expressive power. The difference is illustrated in Figure 2, and as illustrated in Table 6, our scaling gate is experimentally found to perform better.

No.	α	β	Architecture	Remarks
1	0	0	$\mathrm{LN}(\boldsymbol{x}+\mathcal{F})$	The residual structure of Transformer (Vaswani et al., 2017).
2	0	1	$\mathcal{F}$	The well-trained $\mathcal{F}$ is sufficient in representation ability.
3	1	0	$\boldsymbol{x}$	$\mathcal{F}$ is poor-trained or $\boldsymbol{x}$ is sufficient in representation ability.
4	1	1	$\boldsymbol{x}+\mathcal{F}$	The residual structure of ResNet (He et al., 2016a).
5	1	β	$\boldsymbol{x}+\beta*\mathcal{F}$	The residual structure of Inception-v4 (Szegedy et al., 2017).
6	α	1	$\alpha*\boldsymbol{x}+\mathcal{F}$	The residual structure of shortcut-only gating (He et al., 2016b).
7	1-β	β	$(1-\beta)*\boldsymbol{x}+\beta*\mathcal{F}+$ $\beta(1-\beta)*\mathrm{LN}(\boldsymbol{x}+\mathcal{F})$	The combination of Highway Net (He et al., 2016b) and Transformer.

Table 2: Seven special cases in formula (4), which include four representative structures, i.e., Transformer (Vaswani et al., 2017), ResNet (He et al., 2016a), Inception-v4 (Szegedy et al., 2017) and Highway Net (Srivastava et al., 2015).

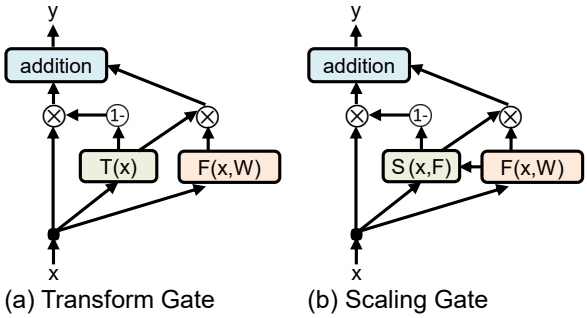

Figure 2: The difference between the Transform Gate in Highway Net (Srivastava et al., 2015) and the proposed Scaling Gate.

3.2 Self-Adaptive Scaling Approach

It is intuitive to combine different types of residual structure through adjustable scaling factors. Therefore, we reformulate the residual block as follows:

$$\boldsymbol{y} = \alpha * \boldsymbol{x} + \beta * \mathcal{F} + \gamma * \mathrm{LN}(\boldsymbol{x}+\mathcal{F}) \quad (3)$$

where α, β and γ can be predicted by scaling gates with different parameters, and LN stands for layer normalization (Ba et al., 2016).

By choosing certain values for α, β and γ, we can get several special cases, as shown in Table 1. However, from the summarized cases, we can easily find that if we set $\gamma = (1-\alpha)(1-\beta)$, the approach can also cover these four baselines. Especially, it is essential to decrease the parameters to achieve the same purpose[1]. Thus, the final self-adaptive scaling approach can be defined by the following formula:

$$\boldsymbol{y} = \alpha * \boldsymbol{x} + \beta * \mathcal{F} + (1-\alpha)(1-\beta) * \mathrm{LN}(\boldsymbol{x}+\mathcal{F}) \quad (4)$$

where α and β act as the scaling factors predicted as aforementioned. From the above formula, we can obtain seven special cases in Table 2. In all, our proposed self-adaptive scaling approach is not only the general form of several existing structures, which is able to encourage the model to take full advantage of different types of residual structures, but also gives rise to a learnable residual structure, which can be automatically learned by deep neural models from the data.

[1]The empirical results also show that $(1-\alpha)(1-\beta)$ performs better than γ (94.05 accuracy vs. 93.95 accuracy in CIFAR-10).

4 Experiment

In this section, we evaluate the proposed approach on three representative tasks in the natural language processing field, computer vision field, and cross-modal scenario, that is, image classification, machine translation and image captioning. We first briefly introduce the baseline models for comparison, the datasets, the metrics and implementation details, followed by the discussions about the experimental results. Since our major concern is the combination of different components in residual units, we keep the internal structure (i.e., the residual function $\mathcal{F}(\boldsymbol{x}, \mathcal{W})$) of each component unaffected. The training and inference strategies also remain the same as the original models. For more details, please refer to the cited publications.

4.1 Machine Translation

Baselines, Datasets, Metrics and Settings. For the task of machine translation, we adopt the popular Transformer (Vaswani et al., 2017), which is a strong baseline. The model is implemented with the code from tensor2tensor (Vaswani et al., 2018). Transformer follows the encoder-decoder paradigm, but it replaces the self-recursive operation in RNNs with the self-attention that summarizes all context. In each Transformer block, the self-attended results are post-processed by residual connection and layer normalization.

There are 133K, 4.5M, and 36M training

Method	EN-VI	EN-DE	EN-FR
Transformer-Base (Vaswani et al., 2017)			
Baseline	30.9	27.5	38.2
+ Proposal	**32.0**	**27.6**	**38.4**
Transformer-Big (Vaswani et al., 2017)			
Baseline	31.6	28.5	41.0
+ Proposal	**32.2**	**28.7**	**41.3**

Table 3: Results (BLEU) on the machine translation task. Higher means better. The proposal brings consistent and substantial improvements.

Dataset	Baseline	+ Proposal	Improvements
PreAct-ResNet (Vaswani et al., 2017)			
CIFAR-10	93.66	**94.05**	+0.39
CIFAR-100	71.29	**72.91**	+1.62

Table 4: Results (Accuracy (%)) on the image classification task, averaging over 5 runs. Higher is better. The proposal consistently outperforms the baselines as in machine translation. Especially, better improvements are achieved for models on CIFAR-100.

pairs in the IWSLT-2015 English-Vietnamese (EN-VI) (Cettolo et al., 2015), WMT-2014 English-German (EN-DE) and English-French (EN-FR), respectively. `tst2012` and `tst2013` are selected as the development and test sets, respectively, for EN-VI. For EN-DE, we use `newstest2013` and `newstest2014`; and for EN-FR, `newstest2012+2013` and `newstest2014` are selected. For experiments on the two WMT datasets, we follow the implementation settings in Vaswani et al. (2017). For experiments on the IWSLT EN-VI dataset, we set the batch size equal to 4096 and train on single GPU, as it is relatively small. For all datasets, we use a single model by averaging the last 10 checkpoints to produce the results with beam search of 4 and length penalty of 0.6.

Results. The results of machine translation are presented in Table 3. Under both the Base and the Big configuration, our proposal consistently boosts the performance of the Transformer baseline. When equipped with our proposed approach, the Transformer-Base model even transcends the big version, which is three times as large in size, on the EN-VI translation task. It shows that the scaling factors indeed help adjust the residual structure to the data distribution, which is very efficient in exploiting the expressive power of deep residual networks. Encouragingly, an union of the proposal and the Transformer-Big model achieves substantial improvement, and it outperforms the state-of-the-art method (Huang et al., 2018) in the EN-VI low resource dataset.

4.2 Image Classification

Baselines, Datasets, Metrics and Settings. In the computer vision field, we benchmark our proposed learnable residual structure with residual-based image classification systems, i.e., Pre-Activated ResNet (PreAct-ResNet) (He et al., 2016b). ResNet-110 consists of 54 double-layer residual blocks, which makes it non-trivial to optimize. To demonstrate that our *SAS* is applicable to such deep framework, we select ResNet-110 in the experiments. We retain most of the hyper-parameters in He et al. (2016b), with the exception of the weight decay rate, which is set to 0.0002, so as to guarantee more stable training. Both CIFAR-10 and CIFAR-100 (Krizhevsky, 2009) are comprised of colored images for classification. CIFAR-100, which contains 100 classes, appears to be more difficult as compared to CIFAR-10, where there are only 10 classes. Following common practice (He et al., 2016b; Srivastava et al., 2015), accuracy rate of classification over 5 runs are reported as the evaluation results. In Srivastava et al. (2015) and He et al. (2016b), they found that it may be beneficial to attach more importance to the skip connection $\boldsymbol{x}$ for initialization, i.e., the bias term in the transform gate should be initialized with a negative value. Following this practice, in image classification task, we set the bias b_{ff} for α and β to 3 and -3, respectively, at the start of training.

Model	BLEU-1	BLEU-2	BLEU-3	BLEU-4	METEOR	ROUGE-L	CIDEr	SPICE
GLIED (Liu et al., 2019c)	80.4	-	-	**39.6**	**28.9**	58.8	129.3	**22.6**
Transformer (Vaswani et al., 2017)								
Baseline	80.2	64.9	50.7	39.0	28.4	58.6	126.3	21.7
+ Proposal	**81.2**	**65.4**	**51.2**	39.3	28.7	**59.0**	**129.8**	**22.6**
Improvements	+1.0	+0.5	+0.5	+0.3	+0.3	+0.4	+3.5	+0.9

Table 5: Performance on the MSCOCO Karpathy test split. Higher is better in all columns. The baseline enjoys a comfortable improvement with the proposed approach. Additionally, we report the performance of the recently published state-of-the-art GLIED, as we can see, our approach helps the Transformer captioning model outperforms GLIED substantially in terms of CIDEr, which further demonstrates the effectiveness of our approach.

The remaining weights are initialized in the same way as in (He et al., 2016b).

Results. As can be seen in Table 4, consistent improvements are also obtained over the baseline model, which is much deeper than the six-layer Transformer model. The increase in accuracy is 0.39 and 1.62 on the CIFAR-10 and CIFAR-100 dataset, respectively. This demonstrates that our proposal also works in deeper cases. It comes to our notice that the proposal induces better improvements on the more challenging CIFAR-100 dataset. This is presumably that the learnable structure can make the best of each component in the residual building block, which allows more flexible fitting into the multi-class image distribution, resulting in a larger space for improvement in the 100 classes scenario.

4.3 Image Captioning

Baselines, Datasets, Metrics and Settings. To further demonstrate the generalization ability of our proposed approach, we conduct experiments on the task of image captioning. The experiments are based on the multi-head attention mechanism (Vaswani et al., 2017), which has recently shown great potential and is competitive with the most advanced models (Liu et al., 2019c,b), for the reason of which we choose it as our baseline to examine the performance of our approach on the multidisciplinary task.

There are several datasets that consist of image-sentence pairs. Our reported results are evaluated on the popular Microsoft COCO (MSCOCO) (Chen et al., 2015) dataset, which contains 123,287 images. Each image in the dataset is paired with 5 sentences. The results are reported using the widely-used publicly-available splits in the work of Karpathy and Li (2015). The MSCOCO validation and test set contain 5,000 images each. Following common practice (Liu et al., 2018, 2019a), we replace caption words that occur less than 5 times in the training set with the generic unknown word token UNK, resulting in 9,567 words.

We adopt SPICE, CIDEr, BLEU, METEOR and ROUGE for testing. They are previously used as evaluation methods for image captioning, we report the results using the MSCOCO captioning evaluation toolkit (Chen et al., 2015). Among the metrics, BLEU (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005) are originally designed to evaluate the performance of machine translation systems. ROUGE is widely used to examine the quality of machine-produced summaries. SPICE and CIDEr are bespoke metrics for image captioning, which measures scene graph and n-gram matching, respectively, and we refer to them as primary indicators of model performance.

Results. The results on Karpathy test split (Karpathy and Li, 2015) are reported in Table 5. By using our proposed learnable residual structure, improvements of 3.5 points and 0.9 points in terms of CIDEr and SPICE respectively can be achieved, further demonstrating the effectiveness and generalization capabilities of our approach to a wide range of tasks. More encouragingly, the proposed approach helps the baseline model achieves 129.8 CIDEr score, an improvement over GLIED (Liu et al., 2019c) by 0.5.

5 Analysis

In this section, we conduct several analyses to give further insights into our proposed approach, which are based on the image classification task and we adopt PreAct-ResNet-110 (He et al., 2016b) as the baseline model.

Analysis on Scaling Gate. Table 6 summarizes the obtained results when applying the Transform

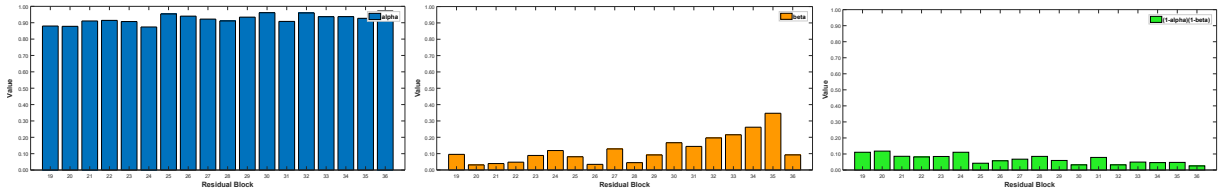

Figure 3: Illustrations of the averaged value of α (left) and β (middle), together with the corresponding $(1-\alpha)(1-\beta)$ (right), which are predicted by the proposed approach for each residual block in pretrained PreAct-ResNet-110 on CIFAR-10.

Methods	CIFAR-10
Baseline (PreAct-ResNet-110)	93.66
+ Transform Gate	92.15
+ Scaling Gate (Single Layer)	92.73
+ Scaling Gate (Full Model)	**93.82**

Table 6: The effects of applying the Transform Gate from Highway Net (Srivastava et al., 2015) and the proposed Scaling Gate to the PreAct-ResNet-110 (He et al., 2016b), where the performance is evaluated by Accuracy(%). The single layer Scaling Gate takes the form $\mathcal{S}(\boldsymbol{x}, \mathcal{F}) = [\boldsymbol{x}; \mathcal{F}]W_f + b_f$.

Architecture	Acc.(%)
$\boldsymbol{x} + \mathcal{F}$ (Baseline) (He et al., 2016b)	93.66
$\alpha * \boldsymbol{x} + \beta * \mathcal{F} + (1-\alpha)(1-\beta) * \text{BN}(\boldsymbol{x} + \mathcal{F})$	93.23
$\alpha * \boldsymbol{x} + \beta * \mathcal{F} + (1-\alpha)(1-\beta) * \text{LN}(\boldsymbol{x} + \mathcal{F})$	**94.05**

Table 7: Results on CIFAR-10 using the PreAct-ResNet-110 with the batch/layer normalization. The batch normalization is less effective than the layer normalization in residual structure.

Gate in Highway Net and our Scaling Gate to PreAct-ResNet-110, as well as the results of the vanilla model. As we can see, when equipped with Transform Gate, the effect is counter-productive on CIFAR-10 dataset. This indicates that the information from $\boldsymbol{x}$ along is not robust and effective enough to predict the scaling factors in the residual structure. The single layer version of our Scaling Gate takes into account the residual branch $\mathcal{F}$, thereby improving over the Transform Gate. It is worth mentioning that compared with the Transform Gate ($\mathcal{T}(\boldsymbol{x}) = \boldsymbol{x}W_f^T + b_f^T$), which has $(h \times h) + h$ learnable parameters, Scaling Gate (Single Layer) only introduces $(2h \times 1) + 1$ learnable parameters, which is much more efficient. By modeling the scaling factor with Scaling Gate (Full Model), a 0.16 points promotion is achieved over the baseline on CIFAR-10, which further demonstrates the advantages and effectiveness of the proposed Scaling Gate.

Analysis on Self-Adaptive Scaling. Averaging over 10,000 experimental examples, we display in Figure 3 the value of α, β and $(1-\alpha)(1-\beta)$ in each residual block of the pretrained PreAct-ResNet-110 on CIFAR-10. The filter sizes for the blocks at the bottom, middle and top of the model are different. We only show the representative blocks at the middle of the model due to space limitation. The first column shows that in almost all cases, α is greater than 0.9, which indicates that identity mapping is very helpful to information transfer and eases the optimization of deep neural networks. This can be attributed to the facilitated backward propagation of error signals by identity mappings. It is shown in the second column that as the number of network layers increases, the value of β grows simultaneously, which indicates that the representation ability of the residual branch $\mathcal{F}$ is stronger when it comes closer to the output of the model. The main reason is that the error signal passed to $\mathcal{F}$ is more adequate in the upper blocks, which is beneficial to optimization. As can be seen from the third column, more importance is assigned to the normalized result when it comes to the lower parts of the entire architecture, which means that the value of $(1-\alpha)(1-\beta)$ is larger. This is because that in the underlying static blocks of deep neural networks, the guidance from error signal is weak and the optimization is unstable, thus making the introduction of layer normalization necessary.

In all, the proposed approach regulates the information from individual components with scaling factors to build the learnable residual structure, which helps make the best of different type of residual structure, resulting in an effective combination for better performance.

Analysis on Using Batch Normalization. The batch normalization is used commonly in the field of computer vision. Therefore, we replace the layer normalization with the batch normalization in the proposed approach to see the difference. As shown

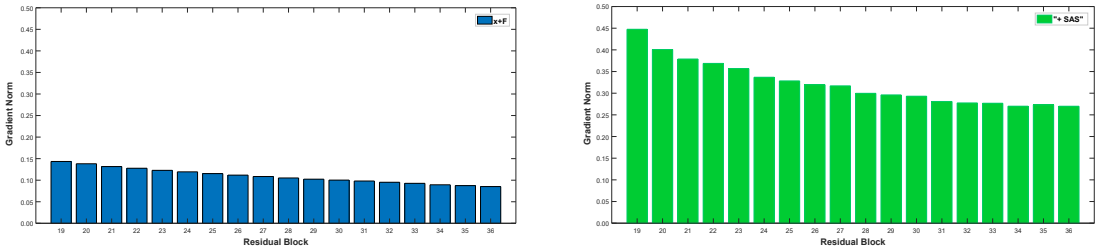

Figure 4: Gradient norm of the output of residual blocks of two different structures that are based on PreAct-ResNet-110. The values are calculated as an average of over 10,000 random examples in the training set of CIFAR-10. We conduct analyses on the blocks from the model's middle part. The *SAS* denotes the self-adaptive scaling approach.

in Table 7, applying batch normalization has a negative effect on the performance. Most importantly, it lags behind the baseline by a noticeable margin, which shows that batch normalization is less effective than layer normalization in the residual structure. We speculate that layer normalization is able to mitigate the training issue in the form of exploding gradient induced by the adjusted ratio provided by the layer normalization's own parameters, while batch normalization could not, which could be intuitively derived by the framework in Hanin and Rolnick (2018). It is probably the reason why He et al. (2016b) observed considerably worse results when they applied batch normalization on the residual structure.

Analysis on Better Optimization Capability. To understand how the proposed approach helps the optimization of deep neural models, we inspect into the gradient norm of the output of each residual block in the pre-trained PreAct-ResNet-110 on CIFAR-10. The gradients are averaged over 10,000 randomly selected training examples. As shown in the left plot of Figure 4, the gradients of the "$x + \mathcal{F}$" structure are basically the same, indicating that all the residual blocks have similar speed for gradient descent and optimization. In contrast, the right plot of Figure 4 reflects that more gradients are allocated to the lower blocks with the help of *SAS*, and the overall gradient values are greater. This phenomenon is interesting and finally gives rise to better results, as shown in Table 4. We conjecture that the layers distant from the model output cannot receive adequate guidance from the error signal, thus requiring more gradient for optimization. Moreover, since the layer normalization is able to stabilize the information flow and accelerate convergence, adaptively incorporating the residual structure with layer normalization can also facilitate optimization. By allocating more importance to layer normalization in the residual blocks via scaling factors, the layers at the bottom of the network can be better optimized, which is in line with the foregoing analysis on Self-Adaptive Scaling approach.

6 Conclusion

In this work, we focus on building a learnable residual structure, which automatically learns the design of residual structure from data, instead of the handy-crafted designs in previous work. We propose the Self-Adaptive Scaling approach to achieve this goal, which combines various residual structures via the predicted scaling factors, resulting in a general residual structure covering several existing models. The proposed approach is simple and can be easily integrated into existing residual-based models. Experiments on the machine translation, image classification and image captioning tasks validate the effectiveness of the proposed method, which successfully promotes the performance of all the strong baselines. This also demonstrates the generalization ability of our method. In particular, when being applied to the recently proposed Transformer model, our approach establishes new state-of-the-arts on the IWSLT EN-VI low resource machine translation task, which further substantiates its efficiency. Detailed analyses prove that the proposed approach can also promote the optimization ability of deep neural networks, and is conducive to exerting the expressive power of existing models.

Abstract

The *Specialized Information Service Biodiversity Research* (*BIOfid*) has been launched to mobilize valuable biological data from printed literature hidden in German libraries for over the past 250 years. In this project, we annotate German texts converted by OCR from historical scientific literature on the biodiversity of plants, birds, moths and butterflies. Our work enables the automatic extraction of biological information previously buried in the mass of papers and volumes. For this purpose, we generated training data for the tasks of *Named Entity Recognition* (NER) and *Taxa Recognition* (TR) in biological documents. We use this data to train a number of leading machine learning tools and create a gold standard for TR in biodiversity literature. More specifically, we perform a practical analysis of our newly generated *BIOfid dataset* through various downstream-task evaluations and establish a new state of the art for TR with 80.23% F-score. In this sense, our paper lays the foundations for future work in the field of information extraction in biology texts.

1 Introduction

Data is the gold to any machine learning (ML). Most ML approaches to *Natural Language Processing* (NLP) address modern, high-resource languages (such as English or Chinese) rather than historical, low-resource languages. As a consequence, feasible ML-tools for processing historical documents are still rare. In this paper we consider corpora of historical German texts in order to extract useful information about biological systems in the past (e.g. species, biotopes etc.).

As a contribution to closing the gap between NLP of modern and of historical languages, we present the newly annotated *BIOfid dataset* for *Named Entity Recognition* (NER) and for *Taxa Recognition* (TR) in the domain of biology, the first of its kind concerning the German language. Our approach is especially designed to address the exploration of biodiversity data[1] from historical documents. We perform a large-scale annotation of scanned texts converted by OCR from historical scientific books on the biodiversity of plants, birds, moths and butterflies, thereby creating the necessary training data to accomplish the task of biological NER and TR using various ML algorithms. Our work facilitates an automatic extraction of biological information so far buried in the bulk of papers and volumes (see Table 1). Over-

Input sentence:

TR output:
Ahmed observes that [Iris]TAXON grows in Mai in Frankfurt.
Biological NER output:
[Ahmed]PER observes that [Iris]TAXON grows in [Mai]TIME in [Frankfurt]LOC.

Table 1: Example for our selected tasks.

all, our newly generated dataset provides a gold standard and hereby lays the foundations for future work, such as relation extraction and classification based on extracted biological named entities and taxa.

We perform a practical analysis of our dataset via various downstream-task evaluations. First, we generate a baseline for recognizing taxonomic entities by constructing a sequence tagger based on skip-n-grams and external knowledge resources (i.e. WikiData). Secondly, we apply the best publicly available word embeddings for German and use them alongside our BIOfid dataset as an input for training high-performing neural mod-

[1]Biodiversity is the science which measures the variability and diversity of animals and plants.

els for NER, namely BiLSTM, ELMo, Flair and BERT (Ahmed and Mehler, 2018; Peters et al., 2018; Akbik et al., 2018; Devlin et al., 2018). By using the optimized BiLSTM model we achieve a new best F-score of 80.23% regarding the recognition of taxonomic entities.

The remainder of the paper is organized as follows: Section 2 reviews related work. Section 3 describes the source texts and the preprocessing pipeline. Section 4 describes the annotation guidelines, process and environment for producing the BIOfid dataset, and methods (n-gram-based sequence tagger, neural models) for evaluating the practical quality of our annotated dataset. Section 5 presents the experimental results. Finally, Section 6 draws a conclusion.

2 Related Work

2018 was a vital year for the task of German NER, following a saturation period from when the last major progress was made by Lample et al. (2016). With the grammar-specific morphological processing and resource-optimization presented by Ahmed and Mehler (2018), the gap between English and German NER was closed. In the same year, with the emergence of multilingual language models such as *ELMo*, *Flair* and *BERT* (Peters et al., 2018; Akbik et al., 2018; Devlin et al., 2018), the performance of various NLP tasks, including NER, was notably improved. Hence, the task of German NER has benefited from these developments.

However, with respect to the availability of a variety of resources, there has not been much progress made until now. Regarding the standard task of NER based on four categories (`PERSON`, `LOCATION`, `ORGANIZATION`, `OTHER`), the first choice of resources for German is still the *GermEval* dataset (Benikova et al., 2014), followed by the datasets of *CoNLL* and *TüBa-D/Z* (Tjong Kim Sang and De Meulder, 2003; Telljohann et al., 2012). However, their potential for purposes outside of theoretical ML is limited. These datasets do not contain any annotations for taxonomic and temporal entities which are of key interest for biodiversity researchers.

For biological NER in the German language, there are no predecessor resources available to the knowledge of the authors; only an English counterpart exists, namely the *Copious* dataset (T.H. Nguyen et al., 2019), which has been recently published during our ongoing work. This confirms our research endeavors and shows the necessity of more data in this field. We take the English counterpart as the baseline and compare its dataset and results with our own. Overall, our work constitutes the first effort on enabling a state-of-the-art performance for neural representation learning to biological NER.

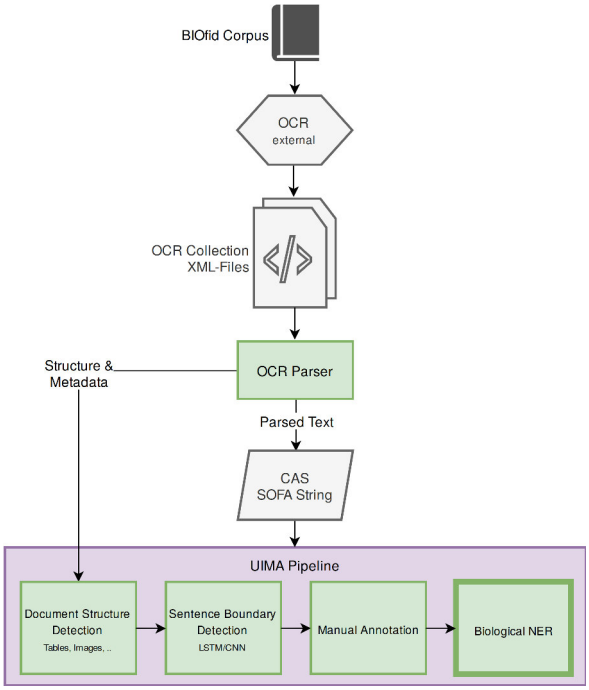

Figure 1: Flowchart showing the data cleaning steps within our preprocessing pipeline.

3 Source Texts & Preprocessing Pipeline

BIOfid Corpus The *BIOfid Corpus* is a collection of historical scientific books on central European biodiversity. It was assembled by a group of German domain experts, denoting a potential pool of relevant print-only journals and publications for historical biodiversity science. However, mainly due to license issues, not all publications could be considered for the corpus.

The available publications were scanned by an external service and subsequently paginated with the software *Visual Library*. Subsequently, every high-resolution page (400 dpi) was digitized with *ABBYY FineReader 8.0 (2005)* to ABBYY-XML, which includes structural information like paragraphs, bold/italic text, images, and table blocks.

OCR Parser The raw OCR data contained various errors, e.g. delivering typical OCR errors such as confusing letters (**ß** → **b**), or delivering

gibberish due to the wrong recognition of non-textual elements in scans such as images, figures, or tables. Furthermore, species names or their appended author citation were frequently recognized incorrectly, e.g. "Lepidium ruderale L." → "Lepidium rüderale I.".

We built the following preprocessing pipeline (see Figure 1) to clean the source data and increase its overall quality. First, the raw OCR data was passed to a parser (labeled "OCR Parser" in Figure 1). This parser read a given ABBYY-XML into a UIMA CAS, while retaining all structural information in a custom UIMA type system, which was tailored to the ABBYY-XML output.

Using a set of heuristics, the structural information was used to detect erroneous parts in the parsed text, such as page numbers, image and figure blocks mislabeled as text, text margins and table lines parsed as the characters "I" or "-", and tables containing merely non-word characters such as counts of observations[2].

The parser performed further fundamental text segmentation using the information given by the ABBYY-XML, such as tokenization and paragraph splitting. The ABBYY-XML contains tokenization information on the character basis, denoting whether a character is marking the beginning of a word. This information was used alongside plain whitespaces to tokenize the raw text, while further splitting words from non-word characters. All this information was stored in a UIMA CAS using the aforementioned type system and passed down the UIMA pipeline.

Document Structure The BIOfid corpus comprises about 15 journal titles including approximately 410 books. 201 of these books containing 969 articles were selected by domain experts as a representative sample from the entire corpus to generate training data for biological NER.

Sentence Boundary Detection In biological literature, author citations are commonly abbreviated (e.g. Carl von Linné in "Fagus sylvatica L.") as well as species names (e.g. "F. sylvatica" after the first definition). Therefore, standard rule-based tools often fail to detect the correct sentence boundaries in such unstructured raw text documents. Hence, for this task we included the LSTM-based sentence boundary detector *DeepEOS* (Schweter and Ahmed, 2019) in our preprocessing pipeline and trained it with 1,361 sentences, which were manually extracted from the BIOfid corpus. The total amount of training sentences was increased from a preliminary size of 300, since the first experimental results revealed that the SBD is crucial for the performance of our downstream-task.

[2] An example of such pages is given in Appendix C.

4 BIOfid Dataset & Methods

4.1 Annotation Guidelines

Named Entities NEs are real-world objects in a given natural language text which denote a unique individual with a *proper name* (e.g. Frankfurt, Africa, Linnaeus, BHL). This stands in contrast to the class of *common names* which refer to some kind of entities (e.g. city, continent, person, corporation) and *not* a uniquely identifiable object.

The standard task of NER focuses on the former class of proper names. However, it is often not easy to differentiate between both classes. Hence, to support the annotators in making the right decision, we created guidelines which demonstrated the rules for annotations. We gradually developed this document in collaboration with the annotators, until finalizing it as the guidelines for annotating the BIOfid corpus. The appendix shows the material which was provided to the team of annotators. First, in Appendix A some introductory examples from the BIOfid corpus are given. Next, in Appendix B the general guidelines used for producing the NER dataset are shown.

As we essentially extend the standard task of NER to our scope of biodiversity, our guidelines are built upon those used for producing the GermEval dataset (Benikova et al., 2014). For this, we take the original German text and extend it with the important adjustments described in the next paragraphs for the context of biodiversity. In contrast to Benikova et al. (2014), we do not consider derivative or partial NEs as a separate category. As the recent work of Ahmed an Mehler (2018) has shown, discarding subtle details is even beneficial, whereas fine-graded feature engineering for deep neural networks usually deteriorates the final performance.

Time In the standard task of NER, temporal information is not captured by the four base entities. However, the aspect of time is important for the research on biodiversity which is constantly evolving. Therefore, we annotated every text unit

Dataset	Sentence	PERSON	LOCATION	ORGANIZATION	OTHER	TIME	TAXON
CoNLL	18,933	*5,369*	6,579	4,441	3,968	N/A	N/A
GermEval	31,300	10,807	17,275	8,303	4,557	N/A	N/A
TüBa-D/Z	104,787	55,746	28,582	32,224	12,865	N/A	N/A
Copious	*26,277*	*2,889*	*9,921*	*N/A*	*N/A*	*2,210*	*12,227*
BIOfid	**15,833**	**5,393**	**6,785**	**1,085**	**7,849**	**5,197**	**15,085**

Table 2: Statistics for German NER datasets together with the English biological NER dataset *Copious* (T.H. Nguyen et al., 2019).

which denotes a specific temporal entity with the tag TIME (e.g. *[13.02.1835]*TIME, see more in Appendix B: Table 9). For text units which describe a time interval, we marked the starting and ending points as two distinct temporal entities.

Taxonomy Taxonomy is a field in biology that deals with the systematic classification of organisms by morphological, phenotypic, behavioral and phylogenetic characteristics. Based on a variety of common traits, a group of organisms forms a so-called taxon. A well-known example of this are the Darwin's finches, endemic birds in the Galápagos Islands. The different species (each species represents a taxon) are distinguished primarily by the size and shape of their beaks and the associated specialized diets.

Taxa are classified according to international nomenclature codes[3,4,5,6] and are delineated at different hierarchical levels, also known as taxonomic ranks. Most of us are well acquainted with the distinction between the animal and plant kingdoms, although there are other kingdoms e.g. fungi or bacteria. Subordinate to a kingdom are many more ranks such as phylum, class, order, family, genus and species. According to this, the hierarchical classification of the bird species *Struthio camelus*, the common ostrich, from the lowest to the highest taxonomic rank is as follows: *Struthio camelus* (species), *Struthio* (genus), *Struthionidae* (family), *Struthioniformes* (order), *Aves* (class), *Chordata* (phylum), *Animalia* (kingdom). Each scientific name mentioned here along with its taxonomic rank (in parentheses) represents a taxon, meaning a group of organisms with a set of common characteristics being indicative for a common ancestry.

Due to differing and evolving methods of classification, taxonomies are subject to constant change. This also applies to taxonomic nomenclature. Therefore, among others, synonymy and homonymy also play an important role in biology (e.g. there is a plant genus with the name "Paris"). The relevance of taxonomy for biodiversity research and conservation is fundamental (Thomson et al., 2018), consequently, we considered it justified to introduce the NE-category of TAXON into the process of NER.

For organisms of all taxonomic ranks, we considered scientific names (both accepted and synonyms) and vernacular names, if referring to a certain taxon, as NEs (e.g. *[Struthio camelus]*TAXON or [common ostrich]TAXON, *[Mirza zaza]*TAXON or [northern giant mouse lemur]TAXON, see more in Appendix B: Table 7). Author citation and year, usually appended to the scientific name of a taxon, were tagged as NEs of the categories PERSON and TIME, respectively (e.g. *[Falco]TAXON [Linnaeus]PER [1758]TIME*). Both author and temporal information embedded within the scientific name, were included in the NE TAXON (e.g. *[Carex praecox [Jacq.]PER var. distans]TAXON [Appel]PER*).

4.2 Annotation Process

We performed a single major series of annotations. Instead of just focusing on some inter-agreement value, we performed double checks on existing annotations on given articles through biological experts. This strategy removed the time overload associated to multi-annotations while ensuring a high quality of data.

For this scheme, a group of annotators consisting of two researchers from the project team were employed. Both researchers were native speakers of German, and, additionally had a profound background in biology. Besides, two further student assistants with similar profiles were employed to provide further assistance.

[5] http://www.the-icsp.org/
[6] http://talk.ictvonline.org/taxonomy/

Figure 2: Working environment for annotating the BIOfid corpus (figure taken from (Abrami et al., 2019)).

4.3 Annotation Environment

We used the *TextAnnotator* (Abrami et al., 2019), a browser-based annotation tool specifically adjusted for this project. Figure 2 shows the working environment which was provided to the annotators. On the left-hand side of the *QuickAnnotator* view, the raw OCR text from the BIOfid corpus is displayed, separated from the choice of annotation tags on the right-hand side. As sentence splitting was part of the annotation task, we did not provide a sentence view. Instead, we provided the whole article, further allowing the annotators to use contextual information while making their decisions.

4.4 Quality of Data

4.4.1 Quantitative Characteristics

Table 2 shows the total amount of annotated sentences along their six NE-categories and compares this with the three major public datasets for German NER. For our BIOfid dataset, we can see the high value of `TIME` and `TAXON` entities which, so far, do not exist for any publicly available dataset.

4.4.2 Data Format

We use the 4-column CoNLL-format which writes each word of a sentence horizontally along its lemma, POS tag and gold label, separating each sentence by an empty new line. For the tagging scheme, we opt for BIO (IOB2). Listing 1 shows an excerpt of the train file in which the entities `TIME`, `PERSON`, `LOCATION`, `TAXON` are marked by our team of annotators for a given sentence from the BIOfid corpus.

We split the BIOfid dataset into train, dev, test files by the common ratio of 80:10:10 percentages after randomizing its order of sentences. These final data files are utilized for training and evaluating our models, which are described in the next section.

4.5 Methods

For the evaluation of the BIOfid dataset, we use six different approaches and compare each others results: one classic *rule-based* model and five high-performing *embedding-based* models.

4.5.1 N-Gram Tagger for TR

We develop a naive sequence tagger as a baseline for the recognition of taxonomic entities in the BIOfid dataset. The baseline is only for a subtask of the full task of biological NER, described in the previous Section 4.1. Our sequence tagger is built on the k-skip-n-grams (with $k = 1$) which are constructed from the tokens of taxonomic entries in the comprehensive *Latin* and *German* gazetteers of biology. Both gazetteers consist of 83,348 taxonomic entries from various biological systematics such as of *aves*, *lepidoptera* and *vascular plant*. In addition, we consider *WikiData*[7] and construct an additional gazetteer by extracting 2,663,995 German and Latin taxonomic entries from the online resource by selecting all entries from a XML-dump that are subjects (`?s`) in the following two SPARQL triple patterns[8]:

- `?s instance-of taxon.`
- `?o subclass-of taxon.`
  `?s instance-of ?o.`

For each gazetteer entry consisting of at least three tokens ($n \geq 3$), we take all tokens as an input and create a list of 1-skip-n-grams. For example, for the taxonomic entry *iris kashmiriana b.*, we create four n-grams *(iris kashmiriana), (iris b.), (kashmiriana b.)* and *(iris kashmiriana b.)*. In this way, we construct 3,023,270 unique n-grams in total from 2,682,959 merged taxonomic entries, while dropping 140,432 duplicate n-grams entirely. Next, we map all these n-grams to the BIOfid test file by standard string matching and thus find the taxonomic occurrences in the target set of text data.

4.5.2 Neural Models for NER

Our neural models consist of two separately trained components: a) foundational word embeddings, modeling the general knowledge from large unlabeled text corpora, and b) various task-specific neural architectures, modeling the domain knowledge from the labeled training data. In this section, both components are presented briefly.

Word Embeddings The language model of continuous space word representations (*word2vec*) (Mikolov et al., 2013) and its variations by (Levy and Goldberg, 2014; Komninos and Manandhar, 2016) are the foundations of most ongoing research in NLP with neural networks. Based on the context, the model embeds words, phrases or sentences into high dimensional vector spaces. We use the model of *Wang2vec* (Ling et al., 2015) and its morphological extension (Ahmed and Mehler, 2018) which explores syntactic data specific for German and, thus, better suites the task of NER. We use the recently published German language word embeddings from the TTLab[9] which are pre-trained with the morphological extension of the Wang2vec algorithm on the COW corpus (Schäfer, 2015), the largest collection of German texts extracted from web documents with over 617 Mio. sentences. Out of the six published variants of embeddings, we opt for token-based embeddings (*COW.lower.wang2vec*), as they delivered the best results for German NER according to the publishers.

BiLSTM We provide a brief overview of the configurations for the five neural models which we use throughout this paper. The model *BiLSTM-CRF* is similar to the one used in (Ahmed and Mehler, 2018), which goes back to the work of (Lample et al., 2016). The neural network consists of stacked LSTM and CRF layers. The *base layer* combines for a given word its (pre-trained) word embedding with its character-based embedding. These features are forwarded to the *prediction layer* which produces the final NE tag.

Model	Emb.	Language Model	Train Data
BiLSTM-a	COW	N/A	BIOfid
Flair Wang2v.	COW	PCE	BIOfid
Flair ELMo	COW	PCE+Leipzig	BIOfid
Flair BERT	COW	PCE+BERT-Base	BIOfid
BiLSTM-b	COW	N/A	All

Table 3: Overview of the model inputs. For BiLSTM-b we consider all merged training data (i.e. BIOfid + GermEval + CoNLL)

Flair Wang2vec We further train a sequence labeling model using Flair[10]. We build the model in

[7] http://www.wikidata.org/

[8] All results can be acquired with the following WikiData queries: http://w.wiki/3u3 and http://w.wiki/3ud

[9] http://www.texttechnologylab.org/resources2018/

[10] http://github.com/zalandoresearch/flair

the same fashion as used by (Akbik et al., 2018) following the guide given by the authors for the task "CoNLL-03 Named Entity Recognition (German)", while keeping the pooled contextualized embeddings (PCE) and exchanging the GloVe embeddings employed by the authors with Wang2vec embeddings trained on the COW corpus.

Flair ELMo In addition to the previous model, we train a Flair Sequence Tagging model by stacking an ELMo embedding layer on top of the Flair Wang2vec model. The ELMo embeddings were trained on a section of the *Leipzig Corpora Collection* (Goldhahn et al., 2012) containing 100,000 sentences from Wikipedia using default parameters.

Flair BERT Similarly, we added BERT (Devlin et al., 2018) to the Flair Wang2vec model. We used the recently published *BERT-Base, Multilingual Cased*[11] pre-trained model for this purpose.

Hyperparameters We take the original neural models and keep the hyperparameters as described in their references. The only adjustments we make to the models are on the input level, i.e. we perform variations for the pre-trained word embeddings, the pre-trained language models, and the training data (see Table 3).

5 Results

We evaluate the performance of all models with the official script from the shared task of CoNLL 2003 (Tjong Kim Sang and De Meulder, 2003). All our experiments were run on Nvidia's *GTX 1080 Ti* GPUs.

5.1 Baseline for TR

N-Gram Tagger Applying the gazetteer to the BIOfid test file gives us the respective baseline for the recognition of taxonomic entities. For evaluation, we use the CoNLL-script and contrast it with easing the conditions by evaluating only the NE predictions and ignoring the prefixed BIO-tagging scheme to every NE. The evaluation does not take into account the other words and is based only on the actual words annotated as `TAXON`.

Table 4 displays the results for the n-gram tagger. We can nicely see that the increase in size of gazetteers leads to an increase in the final performance. More specifically, for the eased condition, every incremental step from *Latin* to *Latin+German*, and the next step to *All* (i.e. *Latin+German+WikiData*) leads to an increase of $+6.64\%$ and $+6.56\%$ F-scores, respectively. This matter of fact demonstrates that for the n-gram tagger the resource-size matters.

Gazetteer	CoNLL-Eval	Pr. [%]	Re. [%]	F1 [%]
Lat.	standard	61.50	34.71	44.37
Lat.+Ger.	standard	65.83	45.42	53.75
WikiData	standard	69.05	53.91	60.55
Lat.	eased	92.48	46.04	61.06
Lat.+Ger.	eased	92.94	54.55	67.70
WikiData	eased	95.55	58.87	72.85
All	standard	69.20	55.75	61.75
All	eased	95.57	60.72	74.26

Table 4: Baseline for TR on the BIOfid test file with the N-Gram sequence tagger.

Furthermore, for the eased condition, we see very high scores for precision, however, the recall values are relatively low. This result demonstrates a classic problem of rule-based approaches; as there is no learning process involved, we assume that the performance of the n-gram tagger is highly limited on the features extracted from the source of knowledge (i.e. the amount of information contained in the gazetteer). Besides, no transfer learning is possible from related resources, demonstrating the downsides of non-learning methods.

5.2 Biological NER

We report here the results of our comprehensive survey of five current embedding-based high-performers for biological NER in historical biodiversity literature[12].

The Gold Standard Table 5 contains a detailed summary of all results. In that table, we the report the results which are given by T.H. Nguyen et al. (2019). For the optimized *BiLSTM Tagger*, we achieve excellent results and establish a new state-of-the-art for the first task of TR with 80.23% F-score (see Table 5: BiLSTM-a). For biological NER, we outperform the English counterpart *Co-*

[11] http://github.com/google-research/bert

[12] Our manual inspection of the training data showed that the annotations are content-wise homogeneous, except for the category `OTHER`. The annotators reported its usage as a residual NE-category for everything which is biologically interesting (e.g. morphology, animal behavior, reproduction, development) but does not fall under the definition of the five major categories. Initial experimental results confirmed its heterogeneous quality. Therefore we omitted `OTHER` (3,143 sentences) from our further experiments which in turn increased the final performance of NER.

Model	Scores [%]	TAXON	PERSON	LOCATION	ORGANIZATION	TIME	*Overall*
Copious Nguyen (2019)	Precision	77.42	58.92	85.05	N/A	70.67	77.49
	Recall	69.67	48.44	85.63	N/A	54.36	71.89
	F1	73.34	53.17	85.34	N/A	61.45	74.58
BiLSTM-a	Precision	81.33	63.19	66.20	60.24	91.16	75.62
	Recall	79.16	77.45	57.35	67.57	88.16	74.98
	F1	**80.23**	69.60	61.46	63.69	89.63	75.30
Flair Wang2vec	Precision	75.94	61.25	67.58	61.64	90.59	73.58
	Recall	81.37	76.09	62.89	58.11	85.24	75.89
	F1	78.08	71.89	62.63	56.95	87.89	74.30
Flair ELMo	Precision	75.64	67.16	58.31	56.82	90.49	73.05
	Recall	79.92	79.89	65.06	60.81	86.02	76.50
	F1	77.88	69.34	66.30	61.22	88.25	75.01

	Recall	77.38	81.02	61.89	58.00	90.33	76.22
	F1	77.01	72.31	64.32	58.00	**91.26**	75.59
BiLSTM-b	Precision	80.45	88.61	72.72	81.21	87.63	79.35
	Recall	76.65	89.40	84.02	70.74	81.17	75.38
	F1	78.50	**89.00**	**77.96**	**75.61**	84.27	**77.31**

Table 5: Results for the task of German biological NER with various neural networks models along the English baseline on the Copious dataset (T.H. Nguyen et al., 2019). All models are trained on the BIOfid dataset and evaluated with the official CoNLL-2003 eval script.

pious for all categories except for LOCATION. For the latter category, the *Copious* dataset contains *9,921* training samples whereas ours has 3,136 fewer samples. We assume that this lower amount results into the lower performance.

With the popular deep language models *Flair*, *ELMo* and *BERT*, we interestingly stay below the performance of the BiLSTM model (except for TIME). Although we utilize the same pre-trained COW word embeddings for all models, we assume that the lower performance arises due to the language models themselves being trained on only a relatively small corpus (ELMo: 100,000 sentences). However, for training ELMo on larger corpora, such as the COW corpus, we would require many months of training time. For the pre-trained Flair and BERT, we can only fine-tune the last tagging layer, not the whole language model itself. This stands in contrast to the BiLSTM model which can be wholly targeted to our domain-specific training data. Hence, this demonstrates the downside of such heavy language models; although they might deliver the top performances, it is difficult to adjust them for lightweight processes, making them impractical for the context of low-resources scenarios.

Data Merging for BiLSTM Tagger For BiLSTM-a, it can be noted that the performance of the standard categories PERSON, ORGANIZATION, and, especially LOCATION is inferior. Therefore, we performed resource-optimization by merging high quality data with our BIOfid dataset in order to increase the training samples for the low performing categories. We merge the datasets of GermEval and CoNLL with our annotated sentences, resulting in train, dev, and test sizes of *46,857*, *6,629*, and *9,437* sentences, respectively. Table 5: BiLSTM-b shows the improvements in performance with the increased dataset. Our results demonstrate the effectiveness of our approach; we do not need to modify the model, rather it is sufficient to perform data-driven optimization. Considering the overall performance, we outperform the English counterpart by $+2,73\%$ F-Score and thus establish a new state-of-the-art for the task of biological NER.

Error Analysis We manually analyze the errors made by the ensemble of neural models. We observe three major issues that compose the absolute majority of errors: a number of *missing annotations* from our experts, *OCR erros* in the raw text and *rare words* that occur frequently in our test dataset. An example of an OCR error is the annotated text span *[1, Juni 1967]* TIME which is misclassified by all models as *1, [Juni 1967]* TIME due to the comma in the date format. Another example is *[KLeebend]* LOC which is not tagged due to the capital "L". Further, the word *[Venn-*

fußfläche] LOC occurs 17 times in the test dataset, but only twice in the training set. It is a three word compound of the words *Venn*, *Fuß* and *Fläche*, that describes a part of the landscape *Vennvorland* in Germany. We conclude that the preprocessing pipeline has to be further refined to remove the OCR errors, while a re-annotation of the data could solve the missing annotations and a more thorough shuffle may solve the rare word issue.

6 Conclusion

In this study, we presented a newly annotated *BIOfid* dataset for German NER in historical biodiversity literature and performed a comprehensive evaluation of the quality of our dataset with five competing neural models. We come to the conclusion that the value of our dataset does not rely solely on the two new entities of TIME and TAXON. By generating domain-related annotation data typical for historical biodiversity literature, we increase the potential performance for biological NER, even for the four standard NE categories. This was demonstrated by the limited scope of the rule-based approach which could not come close to the performance delivered by the neural models and which, in turn, established a new state-of-the-art for both of our selected tasks of TR and NER.

In the course of the annotation process, we discovered that there are further information entities in the BIOfid corpus which do not fall into the definition of standard NE-categories, albeit they are useful from the perspective of biodiversity researchers. For future work, we plan to increase the semantic granularity of the BIOfid dataset by mapping and re-annotating the existing six NE-categories to the top-level hierarchy of *WordNet* (Miller, 1995). This includes 26 categories that can be either *abstract entities* or *concrete entities* (i.e. NE) and can be assigned to specific biological entities, such as morphology, habitat, reproduction, behavioral traits, or species community. By re-annotating the dataset we additionally plan to deliver an inter-agreement value for both the current NER-dataset and the much smaller WordNet-dataset (which is planned to contain an up to 9 times higher amount of annotated information per sentence). Furthermore, we plan to extract all biological entities with the trained neural models from the BIOfid corpus and perform on them the task of *relation extraction* based on current embedding methods.

Overall, our work mobilizes data from undigitized literature leading to huge potentials for biodiversity researchers. It enables cartographic research on the distribution of Central European biodiversity ranging from the pre-modern time up to our current ever increasingly digitizing age.

Acknowledgments

This work was funded by the German Research Foundations (DFG) as part of the *BIOfid* project[13] (DFG-326061700). The BIOfid dataset, the taxonomic gazetteers, the source code, and the supporting appendix (which includes the full annotation guidelines) are uploaded on GitHub[14] for the research community. Special thanks go to W. A. Hemati and G. Abrami for setting up the annotation environment, and to R. Roller, S. Löbbert, Dr. G. Kasperek, Dr. A. Hausinger, Dr. T. Hörnschemeyer and further project members for supporting the annotation process.

Abstract

The prevalence of informal language such as slang presents challenges for natural language systems, particularly in the automatic discovery of flexible word usages. Previous work has explored slang in terms of dictionary construction, sentiment analysis, word formation, and interpretation, but scarce research has attempted the basic problem of slang detection and identification. We examine the extent to which deep learning methods support automatic detection and identification of slang from natural sentences using a combination of bidirectional recurrent neural networks, conditional random field, and multilayer perceptron. We test these models based on a comprehensive set of linguistic features in sentence-level detection and token-level identification of slang. We found that a prominent feature of slang is the surprising use of words across syntactic categories or syntactic shift (e.g., verb→noun). Our best models detect the presence of slang at the sentence level with an F1-score of 0.80 and identify its exact position at the token level with an F1-Score of 0.50.

1 Introduction

Slang, or 'the language of streets' (Green, 2015), is a type of informal language consisting of words and expressions shared within specific groups. A hallmark of slang is its expressivity, instantiated in the flexible use of words. For example, the word *sick* with the conventional sense of "ill" can also denote a positive slang sense of "awesome", such as "the band's album is sick". The expressive nature of slang exemplifies its social function, because it provides an effective way of communicating and knowledge-sharing within groups of distinct social identities, such as in the cases of vulgar tongue (Green, 2015) and online language. On the other hand, the flexible nature of slang use can be intriguing for language users, learners, and natural language systems. Here, we ask whether slang can be automatically detected in natural sentences, and what linguistic features might distinguish slang usage from conventional language use.

Our problem statement is simple: Given a natural sentence such as "the band's album is sick", can machines learn to 1) detect whether slang usage is present or not (i.e., sentence-level detection), and 2) identify the exact position of the slang term in the sentence (i.e., token-level identification). For each of these tasks, our systems should be able to learn to cope with two main categories of slang usage (Dhuliawala et al., 2016):

- **Newly extended senses**: existing words in the lexicon that develop novel slang senses distinct from their conventional senses, e.g., *clutch* refers to "an act of grasping" in its conventional usage, but is later extended to the slang sense of "tense critical situation".

- **Newly created words**: words that do not exist in the standard lexicon, e.g., blending of *friend* and *enemy* forms the slang word *frenemy* that describes a person who is simultaneously friend of and in conflict with someone.

Research on slang in the natural language processing community falls under several categories, but to our knowledge the current work is the first to tackle the basic problem of automatic slang detection and identification.

2 Related computational work

2.1 Slang dictionary construction and sentiment analysis

Existing approaches such as SlangNet (Dhuliawala et al., 2016), SlangSD (Wu et al., 2018), and SLANGZY (Gupta et al., 2019) have focused on efficiently maintaining and extending the construction of slang dictionaries to aid computational

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 881–889
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

sentiment analysis of slang content. Some popular systems from this line of research are based on modular representation (Pal and Saha, 2013) that treats slang in terms of various linguistic stages, each of which deals with slang word from different aspects, e.g., sound, concept, formation, etc. These dictionary-based methods rely on static lexical information and structure, which are typically not sufficient to capture the flexible semantics and lexical coinage in natural slang usages.

2.2 Slang word formation and interpretation

An independent line of work has explored generative models (Kulkarni and Wang, 2018) for slang word formation that captures processes such as blending, clipping, and reduplication. This work uses long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) models to generate slang words in terms of string components according to type-sensitive characteristics. Related work has also explored automatic interpretation of non-standard English words and phrases using sequence-to-sequence architecture with dual encoders (Ni and Wang, 2017). This method generates literal interpretations for queried non-standard expressions from source sentences, but the primary focus is on explanation as opposed to detection or identification, both of which are prerequisite tasks for slang interpretation.

Differing from these existing research, we present a methodological framework based on standard techniques in deep learning for automatic slang detection and identification that does not rely heavily on dictionary construction. We examine a comprehensive set of linguistic features that might be diagnostic of slang usage in natural settings, and we explore existing methods that leverage bidirectional LSTM with multilayer perceptron (MLP) (Rauber and Berns, 2011) and conditional random field (CRF) (Lafferty et al., 2001). Our framework is related to existing work that applies sequence-to-sequence models with attention mechanism (Luong et al., 2015) for the identification of dialectal varieties (Jurgens et al., 2017) and feature-based emotion detection from online media (Ileri and Karagoz, 2016). However, our emphasis here is on learning features that are relevant to the automatic discovery of slang usage.

To preview the framework, our models formulate slang detection and identification as a sequence-labelling task. In addition to typical word embedding inputs, we incorporate relevant linguistic features in the input via an efficient feature boosting procedure. Throughout our experiments, we found that the flexibility of Part-of-Speech (POS) feature is most diagnostic of slang usage: Slang often entails structured POS transformation of existing syntactic uses of words. We show how features related to POS confidence and POS shift in the input provide the improvement on model performance. We also demonstrate how novel tokens of slang can be discovered using a character level convolutional neural network (Zhang et al., 2015).

3 Computational methodology

We present the models and features we use for machine detection and identification of slang.

3.1 Specification of predictive tasks

In the *slang detection* task, our models determine whether a given sentence contains at least one slang usage, which can be an existing word with a novel slang meaning or a newly created word. We formulate this as a binary classification task.

In the *slang identification* task, our models identify each token within the input sentence as 'non-slang' or 'slang' by sequence labeling, which determines the exact positions of slang usage. Note that the models in the identification task encapsulate the detection task; an empty prediction that labels all tokens as 'non-slang' is equivalent to classifying the sentence as a non-slang sentence in the detection task, and vice versa.

3.2 Model architectures

We present a BiLSTM-MLP model that is capable of identifying slang words in a given sentence. The basic architecture is shown in Figure 1. Fully connected MLP layers are placed on top of both the forward and backward hidden states H_f and H_b of a biLSTM network encoding the input sentence. The output of the two MLP layers f_L and b_L are then concatenated as an input to the final MLP layer. In total, there are three components $W^{(f)}_{MLP}$, $W^{(b)}_{MLP}$, $W^{(con)}_{MLP}$ within the MLP block that are shared across all hidden states:

$$f_L = \sigma(W^{(f)}_{MLP} H_f + b^{(f)}) \quad (1)$$

$$b_L = \sigma(W^{(b)}_{MLP} H_b + b^{(b)}) \quad (2)$$

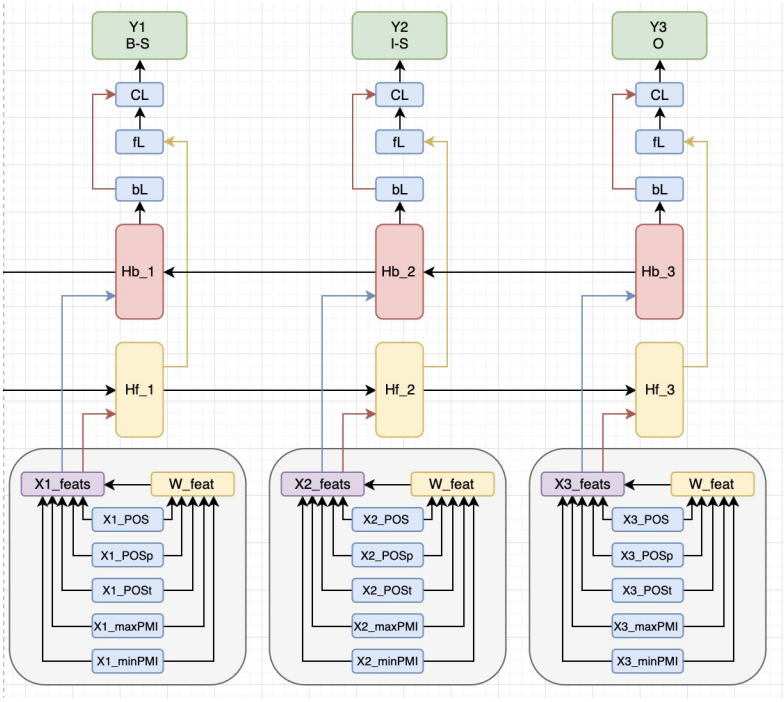

Figure 1: **BiLSTM-MLP model architecture with feature boosting.** The architecture for bidirectional LSTM with Multilayer Perceptron (MLP) as the output layer. The shared bL layer is the MLP unit for the current backward hidden state; the shared fL layer is the MLP unit for forward hidden state; the shared CL layer takes as input the concatenation of the outputs from fL and bL, and output the predictive tagging distribution.

$$C_L = \sigma(W_{MLP}^{(con)}[f_L; b_L] + b^{(con)}) \quad (3)$$

$$Y = softmax(W^{(Y)}C_L + b^{(Y)}) \quad (4)$$

The resulting output vectors are subsequently used to compute the predictive tag for input tokens. There are seven tags here: 'START', 'END', 'O', 'B-U', 'I-U', 'B-N', 'I-N'. These tags apply 'BIO' convention (Ramshaw and Marcus, 1999) that labels non-target token as 'O', initial token of the interested region (e.g., phrase) as 'B-', and the subsequent intermediate tokens of interest as 'I-', etc.

The MLP block in BiLSTM-MLP model can be swapped with an alternative conditional random field (CRF) (Lafferty et al., 2001) that better considers explicit sequential restrictions, e.g., the tag 'I-U' has to be placed after a 'B-U' tag. This sequential restriction can be captured via combination of an LSTM network and a CRF network. The CRF layer has a state transition matrix $A_{(i,j)}$ that models the transition score between the i-th tag and the j-th tag, and an emission matrix $f_{(i,k)}$ that models the output score for the i-th tag at the k-th word (Huang et al., 2015). The source sentence $X_{(i)}$ along with a sequence of tags $Y_{(i)}$ is evaluated via a CRF score:

$$S(X, Y) = \sum_{t=1}^{T}(A_{Y_{t-1},Y_t} + f_{Y_t,X_t}) \quad (5)$$

The CRF layer uses output states from BiLSTM layer to find tags in sequence with optimal CRF score to make prediction. (i.e. $X = [H_f; H_b]$) The CRF probability is easily computed in favor of the logarithmic predictive score as follows:

$$log(P(Y|X)) = S(X, Y) - log(\sum_{Y' \in Y_x} exp(S(X, Y'))) \quad (6)$$

Analogous to Huang et al. (2015), we apply dynamic programming during training to handle the intractable summation term. This BiLSTM-CRF model aims to identify the exact position of each slang word, in terms of sequential restrictions.

3.3 Linguistic features

We use a comprehensive set of linguistic features to facilitate interpretable learning from the models described. Carefully curated linguistic features can improve the training efficiency because linguistic knowledge helps to rectify the learning

process. Feature-based inputs support mapping between contextual concepts and domain-specific clues via distributed representations. The following linguistic features are stored with unique entries in the lookup tables, and they are encoded into embeddings via distributed representation. Figure 2 illustrates these features for the example token *fire*.

Unigram. We take each individual word as an input to the models. The words are represented by standard multi-dimensional word vectors obtained via embedding models such as word2vec (Mikolov et al., 2013).

Bigram. Similar to unigram embedding, a bigram embedding represents the word vector for a bigram. For instance, given an arbitrary word W_t at time-step t in its source sentence, the bigrams for W_t are $W_{t-1}W_t$ and W_tW_{t+1}, which correspond to forward bigram and backward bigram respectively. Whereas the unigram embedding X_t is identified as the word vector representation for W_t, the bigram embeddings are defined as their concatenations. The forward bigram embedding fB_t represents the vector $[W_{t-1};W_t]$, and the backward bigram embedding bB_t represents the vector $[W_t;W_{t+1}]$. Note that both forward and backward bigrams are implemented using the identical lookup table.

Pointwise Mutual Information. We consider measurement of discrepancy between two linguistic variables via PMI (Aji and Kaimal, 2012). Given two source words W_i and W_j, the PMI between them is computed as follows:

$$PMI(W_i, W_j) = log\frac{Pr(W_i, W_j)}{Pr(W_i)Pr(W_j)} \quad (7)$$

We estimate the probabilistic distributions from the Penn Treebank (Marcus et al., 1993), where the probabilities of the PMI can be computed based on co-occurrence statistics. In our models, we compute PMI of the current word with each of its neighboring words, and encode the resulting maximum and minimum PMIs as the features. For example, given $PMI(W_i, W_{i-1}) = 0$ and $PMI(W_i, W_{i+1}) = 2$, we would have the PMI features related to the current word W_i as $maxPMI = 2$ and $minPMI = 0$.

Part-of-Speech. We consider Part-of-Speech (POS) that represents a word's syntactic category. Common POSs include noun, verb, adjective, adverb, pronoun, preposition, conjunction, interjection, and numeral. Multiple POSs can be assigned to an identical word due to the possibility of a word having distinct grammatical properties in different sentences, e.g., *work* is a verb in "these models work", but it is a noun in "I don't like this work". We use Natural Language Toolkit (NLTK) (Loper and Bird, 2002) for POS tagging.

POSp. This linguistic feature is an accessory feature to the POS feature that only represents the grammatical property for the token in its current semantic context. Since each word token might have multiple POS tags, it is possible to count a word's POS distribution that represents the probabilities of a word attached with this specific POS tags as an additional linguistic feature. For example, given a well-formed text corpus C:

$$Pr(POS(like) \leftarrow verb|C) = 0.8$$
$$Pr(POS(like) \leftarrow noun|C) = 0.1$$
$$Pr(POS(like) \leftarrow numeral|C) = 0.0$$

POSt. Word class transfer is a common mechanism (e.g., in English) for extending word senses. We consider a novel feature that represents the transformation from the root-POS (the most commonly used POS for the current token) to the current-POS for the token, e.g., "IN-VB" is a POSt feature, where "IN" is the root-POS, "VB" is the current-POS of the token.

Bigram-Count. The Bigram-Count is similar to the $POSp$, except that the Bigram-Count represents the probability that the current word is collocated with its neighboring words. Given an arbitrary word token W_i in a sequence ϕ, the forward and backward Bigram-Counts are evaluated as

$$fBC = log(\frac{Pr(W_{i-1}W_i)}{Pr(W_i)}) \quad (8)$$

$$bBC = log(\frac{Pr(W_iW_{i+1})}{Pr(W_i)}) \quad (9)$$

The Bigram-Counts are also similar to PMI except that the Bigram-Counts focus more on the current word. In some cases, the Bigram-Count will leverage the zero PMI of low-frequent collocations.

3.4 Feature boosting: Feature-level learning

We present feature boosting for the models with limited features to learn feature-level knowledge. The linguistic features are assumed to be related in terms of the concatenated form of input vectors. For an input token, the related features can

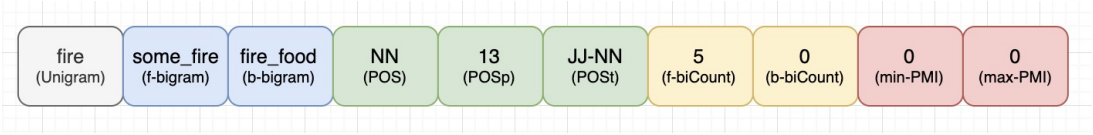

Figure 2: **Concatenation of linguistic features for a given token.** For a specific token *fire* in the source sentence "she can cook some fire food", the related linguistic features are represented as token vectors to concatenate the feature-based input for this token. Each randomly initialized vector is updated during training. The unigram features are represented as 32-dimensional word vectors, the bigram vectors are 20-dimensional, and all else are 16-dimensional.

be assigned with distinct weights that selectively focus on specific features. Suppose we have a token x represented by k distinct linguistic features $[f_1^{(x)}...f_k^{(x)}]$, where $f_i^{(x)} \in \mathbb{R}^{|V_i|\times 1}$, and a shared multi-layer perceptron W_{feat} across all the states. The local feature weights are defined as:

$$\alpha_{feat}{}^{(x)} = W_{feat}[f_1^{(x)}...f_k^{(x)}] + b_f \qquad (10)$$

Where b_f is the MLP bias, and $\alpha_{feat}{}^{(x)}$ is k-dimensional vector that assigns distinct weights to each feature. To provide feature-level information for the vectors fed as inputs to the BiLSTM layer, the feature vectors are weighted in terms of the computed $\alpha_{feat}{}^{(x)}$ for concatenation:

$$V_x = [f_1^{(x)} \cdot \alpha_{feat_1}{}^{(x)}...f_k^{(x)} \cdot \alpha_{feat_k}{}^{(x)}] \qquad (11)$$

The concatenation of weighted feature embeddings contains global feature-level information, allowing the inputs to selectively feed into the model in terms of the feature distribution. As an alternative, the last propagated hidden states from both forward and backward layers of the BiLSTM can be concatenated with the raw features $f_i^{(x)}$ to compute the local feature weights.

We demonstrate later the relative importance of different features in a feature ablation analysis where we remove less relevant input features and keep only the light-weighted but informative linguistic features such as Part-of-Speech and POSp.

3.5 Treatment of novel slang word forms

Our models are able to handle novel tokens by learning the contextual structure within a sentence. Although all the out-of-vocabulary tokens are consistently labelled as 'UKT' such that they are truly unseen by the models, the sequential relations can be captured by the hidden layers of LSTMs. In order to improve model predictability on unknown tokens, we apply character-based convolutional neural network to encode the spelling of words.

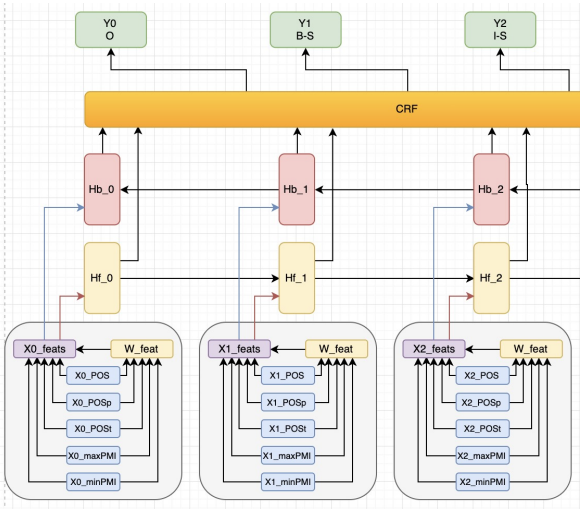

Figure 3: **BiLSTM-CRF model architecture with feature boosting.** The architecture for bidirectional LSTM with Conditional Random Field as the output layer. The shared CRF layer takes as input the BiLSTM's outputs from hidden states, then finds the optimal path in terms of sum of emission scores and transition scores. The optimal path results in the prediction.

Each character is represented by a fixed dimensional embedding (Zhang et al., 2015), similar to word embeddings, and forwarded into a convolutional neural network to obtain a character-level encoding of the word. The resulting Char-CNN embeddings are concatenated with the original input embeddings that feed into the models.

4 Experiments and results

4.1 Experimental setup

We consider datasets that are composed of sentences in two distinct categories, standard (slang-less) and slang-specific:

- **Slang-less sentence dataset**: 15-thousand non-slang sentences from Wall Street News (2011-2016) in Penn Treebank (Marcus et al., 1993) as the negative examples.

- **Slang-specific sentence dataset**: 15-thousand sentences that contain slang words from Online Slang Dictionary (http://onlineslangdictionary.com/) as the positive examples.

The sentences from Wall Street News are taken to be non-slang sentences since the news-based sentences were typically standard English conformed and reviewed before publication. In order to construct an even more trustworthy negative set for standard English, we filtered the sentences from Wall Street News based on the proportion of unknown tokens within the sentences. A News sentence will be considered as an eligible non-slang sentence if it has at most 20% words that have not been covered by the provided frequency-based vocabulary. The vocabulary (or lexicon) consists of top 25,000 most frequent English words from an authoritative text corpus, e.g., Penn Treebank. On average, each negative example sentence contains 12.11 (mean) tokens with standard deviation of 2.52.

We collect positive examples from lexical entries in the Online Slang Dictionary (OSD) where example usage sentences are available. We obtain the ground-truth slang usage positions from OSD and apply the BIO tagging scheme, which labels interested tokens with "B-" at the beginning token, and with "I-" at the subsequent tokens. All the tokens out of interest are labelled as "O". There are two kinds of slang types: UKT-slang and Normal word slang, labelled with "U" and "N", respectively. The UKT-slang refers to slang usages with novel word forms, while normal word slang refers to slang usages with existing words. Out of the 15,000 positive examples, 10,000 of which contain UKT slang words that are not covered by the lexicon. On average, each positive example sentence contains 13.79 (mean) tokens with standard deviation of 3.42.

All models are trained using the Adam optimizer (Kingma and Ba, 2015) with a learning rate 0.001 with $\beta_1 = 0.9$ and $\beta_2 = 0.999$.

4.2 Evaluation and results

We evaluate our models in terms of slang detection and identification. We also perform feature ablation to locate salient features of slang usage and show example cases of model success and failure.

4.2.1 Detection task

We evaluated our models to determine whether a given sentence contains at least one slang usage. The evaluation metrics are precision, recall, and F1-score. Table 1 summarizes the results from the models. Overall, all our proposed models performed substantially better than the baseline, with the CRF-based models yielding better performance than the MLP-based models. For instance, although all models tend to have high precision and relatively lower recall, the CRF-based models generally achieve better recall than the MLP-based models given the same level of precision. Importantly, the best overall model makes use of all linguistic features and yields an F1-score close to 0.80. This result suggests that the features we proposed contribute critically to both the precision and recall of slang detection. It is worth noting that models with only the POS related features achieve reasonable performance (although not as well as the full model), and we will return to this observation in the ablation analysis.

4.2.2 Identification task

We evaluated our models to identify each word in a given sentence at the word level. The evaluation metrics are precision, recall, and F1-score. Table 2 summarizes the results. Similar to the case of detection, our models performed substantially above the baseline in this task. In particular, both the MLP and CRF-based models yielded higher F1 scores (close to 0.50) when multiple features are taken into account. Tables 3 and 4 further summarize the results (i.e., number of correctly predicted cases) of these models in identifying the two main different types of slang: novel slang word and novel slang sense (of an existing word), and how the models fair with and without the incorporation of CNN character-based embeddings.

4.2.3 Feature ablation

We evaluated the contributions of the linguistic features on the test set via model performance degradation through ablation. We would like to evaluate the extent that the model performance would be degraded with respect to a single feature (e.g., POS), given a trained model with the complete featured set. In this case we would force all the POS embeddings to be zero-vectors, and we then compare the ablated model against the full model. Figure 4 summarizes the degradation of

Model (features)	Precision	Recall	F1-score

Table 4: Comparisons of model performance with and without character-based embedding.

model performance based on ablation of each individual feature in question.

Salience of Part-of-Speech transformation. Based on the feature ablation analysis, Part-of-Speech features are the most crucial to overall model performance. Bigram counts come next which suggests that syntacmatic relations also play a role in slang usage. We probed the most prominent features by dividing the POS transformations observed in the data into two kinds: homogeneous and heterogeneous transformations. POSt features such as "VV-VV" (i.e. the identified

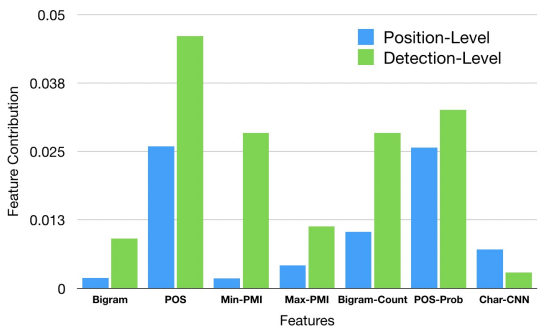

Figure 4: **Summary of feature ablation analysis.** The contributions of the individual linguistic features are shown. The degradation in performance is considered to be equivalent to a feature's contribution.

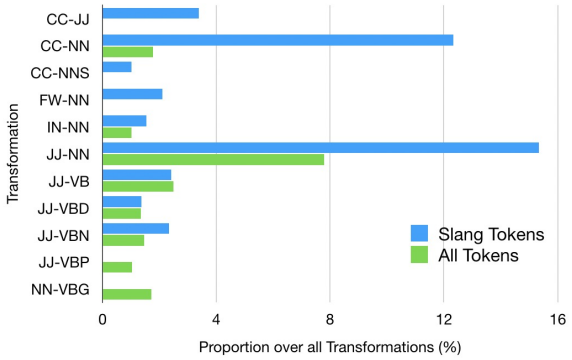

Figure 5: **Transformation of Part-of-Speech in slang usage.** Heterogeneous POS transformations (POSt) that have proportions higher than 1% are shown. There are 11 distinct POSt, 9 of which correspond to cases where the POSt proportion of slang word usage is higher than that of common word usage (i.e., control set). Both the slang tokens and normal tokens with JJ (adjective) tend to transfer to NN (noun); the slang words with CC (coordinating conjunction) are more likely to tranfer to NN (noun).

POS given the source sentence is identical to the root POS) are considered homogeneous transformations; the heterogeneous POSt refer to the case when the target POS differs from the root POS. The proportion of heterogeneous POSt over all the transformations is 25.74% among all the tokens, while the heterogeneous proportion surprisingly increases to 53.94% in slang-specific tokens. This indicates that a slang word is twice as likely to experience (heterogeneous) POS transformation in comparison to an arbitrary word, providing evidence that syntactic shift is a salient feature of slang usage. A comparison between POSt distributions of slang-specific and ordinary use cases is shown in Figure 5.

4.2.4 Examples of model success and failure

We provide examples of both successful and failed predictions to demonstrate the model capability in slang detection and identification:

- **Probe sentence**: "That money you sent me was clutch."
- **Model prediction**: ["clutch"]
- **Ground truth**: ["clutch"]

In the probe sentence, the token *clutch* refers to tense critical situation (noun) rather than its common sense "grasping" (verb). Our model successfully detected this slang component in the query.

- **Probe sentence**: "That's a real blower."
- **Model prediction**: ["–"] (no slang detected)
- **Ground truth**: ["blower"]

The token *blower* normally refers to a device that produces a current of air in common usage, while it refers to "surprise" in this probe sentence. Our model failed to detect this slang-component possibly due to insufficiency of contextual information.

5 Discussion

We take an initial step at automatic detection and identification of slang from natural sentences using established deep learning methods. We show how linguistic features combined with deep learning algorithms offer interpretability. We find that the bidirectional LSTM with feature-based inputs and character-based convolutional embeddings using multilayer perceptron yield the best performance in position identification, and the model with similar mechanisms except with conditional random field has better performance in detecting whether a source sentence contains a slang term. For unknown tokens, character-based convolutional embeddings improve the model in handling novel slang terms. We demonstrate that features combined with distributed word embeddings help machine detection of slang in general, and that Part-of-Speech among others is a prominent feature of slang usage. Our work provides a basis for locating slang from its flexible and unconventional syntactic word uses and offers opportunities for slang processing in downstream tasks in natural language processing.

Abstract

In sequence modeling tasks the token order matters, but this information can be partially lost due to the discretization of the sequence into data points. In this paper, we study the imbalance between the way certain token pairs are included in data points and others are not. We denote this a token order imbalance (TOI) and we link the partial sequence information loss to a diminished performance of the system as a whole, both in text and speech processing tasks. We then provide a mechanism to leverage the full token order information—Alleviated TOI—by iteratively overlapping the token composition of data points. For recurrent networks, we use prime numbers for the batch size to avoid redundancies when building batches from overlapped data points. The proposed method achieved state of the art performance in both text and speech related tasks.

1 Introduction

Modeling sequences is a necessity. From time series (Connor et al., 1994; Lane and Brodley, 1999) to text (Sutskever et al., 2011) and voice (Robinson, 1994; Vinyals et al., 2012), ordered sequences account for a large part of the data we process and learn from. The data are discretized and become, in this paradigm, a list of *tokens*.

The key to processing these token sequences is to model the interactions between them. Traditionally (Rosenfeld, 2000) this has been achieved with statistical methods, like N-grams.

With the advances in computing power and the rebirth of neural networks, the dominant paradigm has become the use of recurrent neural networks (RNNs) (Mikolov et al., 2010).

The dominance of RNNs has been recently challenged with great success by self-attention based models (Vaswani et al., 2017). Instead of modeling the sequence linearly, Transformer-based models use learned correlations within the input to weight each element of the input sequence based on their relevance for the given task.

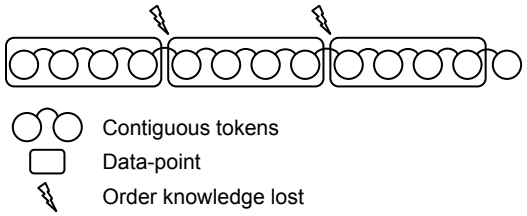

Figure 1: The common way of building data points given a dataset of contiguous tokens. Here we illustrate a dataset with a contiguous list of 13 tokens, from which we build 3 data points of 4 tokens each. This process keeps the order of the tokens inside the data points, but loses the order information from token pairs that happen to fall between adjacent data points.

Series discretization. Both RNNs and self-attention models take as input *data points*—token sequences of a maximum predefined length—and then create outputs for each of them. These tend to be much shorter in size, compared to the size of the full dataset. While for humans time seems to pass continuously, this discretization step is important for the machine understanding of the sequence.

A side effect of this step is a partial loss of the token order information. As portrayed in Figure 1, we notice that the token order information within a data point are kept. On the other hand, the knowledge about the token order at the boundaries of data points is lost. We name the situation *Token Order Imbalance (TOI)*.

As the discretization in Figure 1 is the current standard of sequence processing, we denote this as standard Token Order Imbalance (TOI). We hypothesize that this loss of information unnecessarily affects the output of the neural network models.

Alleviated Token Order Imbalance. A first contribution in this work is a mechanism to en-

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 890–899
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

sure that all token sequences are taken into account, i.e. every token pair is included in a data point and does not always fall between two data point boundaries. Thus, all sequence information is available for subsequent processing. The proposed method, denoted Alleviated TOI, employs a token offset in the data point creation to create overlapped data point sequences in order to achieve this effect.

Batch Creation with Alleviated TOI. A second contribution is a strategy for batch creation when using the proposed Alleviated TOI method. We have observed an unintended data redundancy within batches introduced by the overlapped data point sequences. A strategy for avoiding this data redundancy is surprisingly simple but effective: Always use a prime number for the batch size. The intuition behind the prime batch size is that it ensures a good distribution of the batches over the entire dataset. If used naively, the Alleviated TOI policy leads to very similar data points being selected in a batch, which hinders learning. By decoupling the batch size and the token offset used in the token creation, this negative effect is effectively removed.

We then compare the Alleviated TOI with the Standard TOI and show that, on the same dataset and with the same computation allocated, the Alleviated TOI yields better results. The novel TOI reduction method is applicable to a multitude of sequence modeling tasks. We show its benefits in both text and voice processing. We employ several basic and state of the art RNNs as well as Transformers and the results are consistent—the additional information provided by the Alleviated TOI improves the final results in the studied tasks.

For text processing we focus on a well-studied task—language modeling—where capturing the sequence information is crucial. Using Alleviated TOI (P) with the Maximum Over Softmax (MoS) technique on top of a recurrent cell (Yang et al., 2017) we get the new state of the art on the Penn-Tree-Bank dataset without fine-tuning with 54.58 perplexity on the test set. We also obtain results comparable to the state of the art on speech emotion recognition on the IEMOCAP (Busso et al., 2008) dataset[1].

The paper continues with an overview of the related work in Section 2, a description of the alleviated TOI mechanism in Section 3 and a detailed description of the batch generation in Section 4. The experimental design follows in Section 5 and the results are detailed and interpreted in Section 6.

2 Related work

At the core of our work is the idea that the way that data samples are provided for training a model can affect speed or capabilities of the model. This field is broad and there are several distinct approaches to achieve it. Notable examples include curriculum learning (Bengio et al., 2009) and self-paced learning (Kumar et al., 2010), where data points for training are selected based on a metric of *easiness* or *hardness*. In Bayesian approaches (Klein et al., 2016), the goal is to create sub-samples of data points, whose traits can be extrapolated as the full dataset.

Our work thus differs from the aforementioned methods in the fact that we focus on exploiting valuable but overlooked information from sequences of tokens. We change the way data points are generated from token sequences and extend the expressivity of a model by providing an augmented, and well sorted, sequence of data points. This method has a related effect of a randomized-length backpropagation through time (BPTT) (Merity et al., 2017), which yields different data points between epochs. It also resembles classical text data-augmentation methods, such as data-augmentation using thesaurus (Zhang and LeCun, 2015).

Our method takes a step forward and proposes a systematic and deterministic approach on building data points that provides the needed variety of data points without the need of randomized-length backpropagation through time (BPTT). This has the effect of producing a text-augmentation without the need of using external resources such as a thesaurus, but only requires the dataset itself. Our method uses a concept of overlapped data points, which can be found in many areas such as data-mining (Dong and Pei, 2007), DNA sequencing (Ng, 2017), spectral analysis (Ding et al., 2000), or temporal data (Lane and Brodley, 1999). In language modeling however, this approach of overlapped data points has not yet been fully exploited. On the other hand, extracting frame-based acoustic features such as mel-fequency cepstral coefficients (MFCCs) using overlapping windows

[1]To make our results reproducible, all relevant source codes are publicly available at https://github.com/nkcr/overlap-ml

is a common technique in speech processing and more specifically in automatic speech recognition (ASR) (Chiu et al., 2018; Xiong et al., 2016; Kim and Stern, 2016). We hypothesize that extending the current overlapping technique to a higher level, that is using a sliding overlapping window over the already extracted features, will be proven beneficial. We believe this to have a positive impact on speech processing tasks such as speech emotion recognition (SER). This is because the emotional load in an spoken utterance expands over larger windows than frame-, phoneme- or syllable-based ones (Frijda, 1986).

We investigate the proposed method using a simple LSTM model and a small-size Transformer model on the IEMOCAP dataset (Busso et al., 2008), composed of five acted sessions, for a four-class emotions classification and we compare to the state of the art (Mirsamadi et al., 2017) model, a local attention based BiLSTM. Ramet et al. (2018) showed in their work a new model that is competitive to the one previously cited, following a cross-valiadation evaluation schema. For a fair comparison, in this paper we focus on a non-cross-valiation schema and thus compare our results to the work of Mirsamadi et al. (2017), where a similar schema is followed using as evaluation set the fifth session of IEMOCAP database. It is noteworthy that with a much simpler method than presented in Ramet et al. (2018), we achieve comparable results, underscoring the importance of the proposed method for this task as well.

3 Alleviated Token Order Imbalance

Let a token pair denote an ordered pair of tokens—for instance token A followed by token B, as in the sequence "$ABCDEFG...$". When splitting a token sequence into data points "$D1, D2, ..$", if the split is fixed, as in $D1$ always being equal to "ABC", $D2$ always being equal to "DEF", etc., then the information contained in the order of tokens C and D for instance is partially lost. This occurs as there is no data point that contains this token pair explicitly. We call the "CD" token pair a *split token pair* and its tokens, C and D, are denoted as *split tokens*.

In its most extreme form, split token pair order information is lost completely. In other cases, it is partially taken into account implicitly. In recurrent cells, for instance, the internal state of the cell allows for the order information of split tokens pairs to be used. This is due to the serial processing of the data points containing the split tokens.

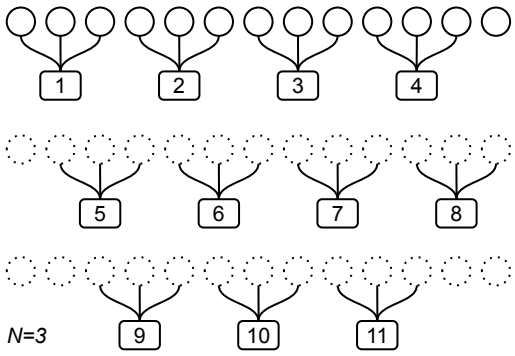

Figure 2: Illustration of an Alleviated TOI (3) made from a single contiguous list of 13 tokens. With a Standard TOI and N=3 (ie. 3 tokens per data point), a contiguous list of 13 tokens would produce 4 data points, which is illustrated by the first overlapped sequence. Here, an Alleviated TOI (3) splits the contiguous list of tokens 3 times with each time a different offset ($0, 1, 2$ respectively). This finally leads to a list of 11 data points coming from the 3 appended overlapped sequences.

As some token pairs are taken into account fully, others partially and others not at all, we denote this situation as *token order imbalance* (TOI).

In this paper, we propose to alleviate the TOI by means of overlapping sequences of data points. The aim is to avoid the loss of information between the last token of a data point and the first token of its subsequent data point. Instead of splitting the sequence of tokens only once, we repeat this process multiple times using different offsets. Each time we subdivide the sequence of tokens with a new offset, we include the links that were missing in the previous step. Finally, the overlapping sequences of data points are concatenated into a single sequence, forming the final dataset.

Figure 2 illustrates an Alleviated TOI (3), which means the sequence of data points is split three times instead of only once, producing 3 overlapped sequences that will then be concatenated.

Our Alleviated TOI (P) method is detailed in the pseudo-code below, where `olp_sequence` holds an overlapped sequence and P is the number of times we subdivide the sequence of tokens with a different offset:

```
Let N = Number of tokens per data point
    P = Number of overlapped sequences
    Step = N / P
DataPoints = empty list
FOR i = 0..P-1
```

```
  olp_sequence = create data points
                 from Dataset with
                 offset (i * Step)
  Add olp_sequence to DataPoints
RETURN DataPoints
```

When we apply an Alleviated TOI (P), this means that we are going to create P times a sequence of data points with different offsets. Therefore, the final dataset will be the concatenation of P repetitions of the original dataset, with data points shifted by a specific and increasing offset at token level for each repetition.

For example, given a sequence S_1 with $N = 70$ tokens per data point and an Alleviated TOI (P) with $P = 10$, the step size will be $\frac{N}{P} = 7$ tokens. Therefore, starting from the sequence S_1, nine additional sequences of data points will be created: S_2 starting from token 7, S_3 starting from token 14, S_4 starting from token 21 and so on until S_{10}.

When using Alleviated TOI (P), with P smaller than the data point size, within an epoch, a split token pair—that is a token pair that is split in the original data point splitting—becomes part of a data point $P - 1$ times. A token pair that is never split will be part of the data point P times.

We can thus define a *token order imbalance ratio* that describes the imbalance between the number of times we include split token pairs and the number of times we include pairs that are not split:

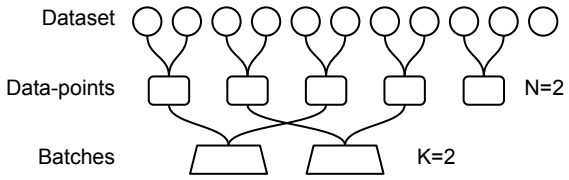
$$(P - 1)/P$$

We notice that the higher P, the closer the ratio becomes to 1. We hypothesize that the closer the ratio becomes to 1, the better we leverage the information in the dataset. We thus expect that for higher values of P the Alleviated TOI (P) method will outperform versions with lower values, with Alleviated TOI (1) being the Standard TOI, which is now prevalent.

We quantify the additional computational cost of Alleviated TOI (P). Since our method only results in P (shifted) repetitions of the dataset, each epoch using the augmented dataset would take $\sim P$ times longer than an epoch over the original dataset. Therefore, we ensure fair comparison by allowing baseline models to train for P times more epochs than a model using Alleviated TOI (P).

4 Batch Creation with Alleviated TOI

Series discretization may also occur at higher levels than data points, in particular when building batches for mini-batch training of neural networks. We can distinguish two types of batches, i.e. *sequential* and *distributed* batches. The former keep the data point sequences intact, thus creating split token pairs only between two consecutive batches. The latter distribute data points from different parts of the dataset to approximate the global distribution, thus creating split token pairs between all data points in batches.



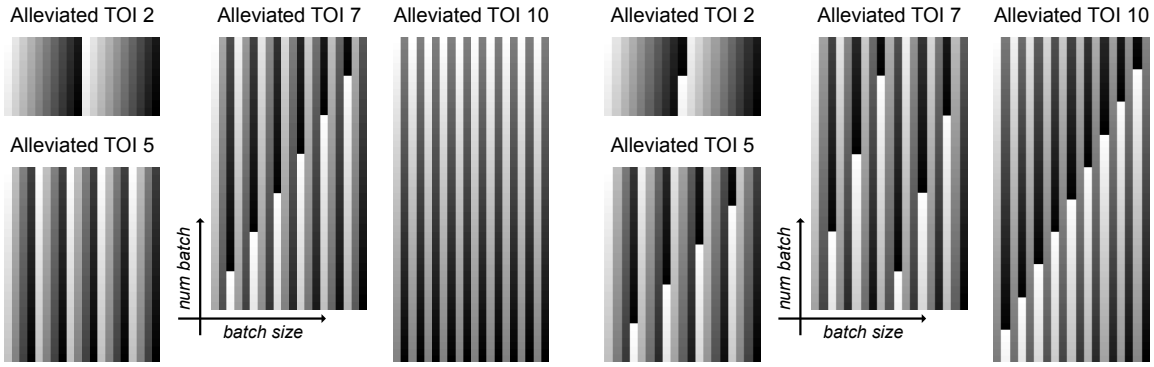


Figure 3: Three levels of data representation used to create distributed batches. The dataset is a sequence of tokens on which data points are built by splitting the sequence into subsequences of N tokens. Batches of K data points are then built by subdividing the sequence of data points into K equal parts. Here, the first part contains the first two data points, the second part the following two, and the last data point is dropped. Each batch then uses one element of each part.

In principle, our proposed method alleviates the TOI in both cases, since multiple overlapping sequences of data points are generated. However, we have observed an unintended interference with the batch creation in the case of distributed batches. In this section we explain the problem in detail and propose a simple but effective solution—choosing a prime batch size.

Figure 3 illustrates the three levels of data representation in the case of distributed batches. Data points are built from N consecutive tokens to capture the sequential information. Batches are then built from K parts of the data point sequence to capture the global distribution. An example of this approach is the batching procedure used in Zoph and Le (2016); Merity et al. (2017); Yang et al. (2017); Zołna et al. (2017) for word language modeling, where the basic token is a word.

The batching mechanism can be seen as building a 2-dimensional matrix, where each row contains a batch. Consider a sequence of M data points and a batch size of K. In order to build batches, the data points are split into K parts, represented as $\frac{M}{K} \times 1$ column vectors. They are concatenated to form a $\frac{M}{K} \times K$ matrix, such that the rows correspond to batches.

When applying the proposed Alleviated TOI (P) method (see Section 3), we augment the original

(a) Matrix of batches with batch size of 20

(b) Matrix of batches with batch size of 19

Figure 4: Illustrations of the 2D matrix of batches with different P-values of Alleviated TOI (P). On the left we used a batch size of 20 and on the right we used a prime batch size of 19. Each data point is a pixel and each row is a batch. The grayscale value models the proximity of the data points with respect to the dataset. Therefore, two pixels with similar color represents two data points that are close in the dataset. The illustrations demonstrate how different values of P affect the content of the batches, which can lack a good distribution over the dataset. Ideally, each row should contain a gradient of different grayscale values. We can observe how using a prime batch size affects the distribution of data points within the batches, where the matrices on the right offer a better distribution. This effect is especially well visible for the Alleviated TOI 10.

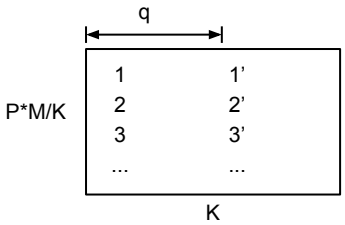

Figure 5: Data point repetition with period q for M data points, K batches, and Alleviated TOI (P). Data point 1' is the same as data point 1 with a token offset.

P	**Period** q	**Repetitions**
2	10	2
5	4	5
7	20	1
10	2	10

Table 1: Data point repetition with period q for batch size $K = 20$ and Alleviated TOI (P).

dataset to a total of $P \cdot M$ data points, adding additional data points with token offsets. Therefore, the $\frac{P \cdot M}{K} \times K$ matrix used for batch creation may contain repeated data points within the same batch as illustrated in Figure 5. A *repeated data point* differs from the previous data point only marginally due to the token offset. This redundancy can be problematic, as the batches are not well-distributed over the entire dataset anymore.

With respect to the batch matrix, a repeated data point occurs iff $\frac{P \cdot M}{K} \cdot q = n \cdot M$ with *period* $q < K$ and $q, n \in \mathbb{N}$. This is equivalent to

$$\frac{P}{K} \cdot q = n, \quad q < K, q, n \in \mathbb{N}$$

independent of the number of data points M. A repetition thus occurs iff the greatest common divisor (GCD) of P and K is larger than 1. Otherwise, for $\text{GCD}(P, K) = 1$ a data point repeats only after period $q = K$, i.e. there is no repetition within the same batch.

Table 1 lists exemplary periods for a batch size of $K = 20$ and different values of P for the Alleviated TOI (P). The worst case is $P = 10$ with 10 repetitions of the same data point within the same batch and the best case is $P = 7$, which avoids any redundancy because the GCD of P and K is 1. Figure 4 illustrates the repetition with grayscale values, where similar grayscale values indicate that two data points are close within the original data points sequence.

In general, while we aim for large values of P for reducing the TOI, a simple solution for avoiding redundancy within batches is to choose a prime number for the batch size K.

5 Experimental Setup

To validate the generalization capability of the proposed technique, we apply it on both text and

speech related tasks. We thus run the Alleviated TOI (P) with language modeling (text) and emotion recognition (speech). The text datasets used are Penn-Tree-Bank (PTB) (Marcus et al., 1993) as preprocessed in Mikolov et al. (2011), Wikitext-2 (WT2), and Wikitext-103 (WT103) (Merity et al., 2016). The speech dataset is the IEMOCAP database (Busso et al., 2008), a collection of more than 12 hours of recorded emotional speech of 10 native-English speakers, men and women. The audio data is filtered down to 5.5 hours containing only *angry*, *happy*, *neutral* and *sad* utterances.

5.1 TOI in Language Modelling

For language modeling, we use three different methods:

- A simple LSTM that does not benefit from extensive hyper-parameter optimization.
- An Average Stochastic Gradient Descent Weight-Dropped LSTM (AWD-LSTM) as described in Merity et al. (2017), with the same hyper-parameters.
- The latest State-of-the-Art model: Mixture of Softmaxes (MoS) (Yang et al., 2017).

We compare our results against the original process of building data points, i.e. Standard TOI, and use the same computation load allocated for each experiment. We use the same set of hyper-parameters as described in the base papers, except for the batch size with Alleviated TOI (P), where we use a prime batch size in order to prevent any repetitions in batches, as described in Section 4. That is, on the PTB dataset, we use a sequence length of 70 for all the models. For the Simple LSTM and AWD-LSTM, we use a batch size of 20 and a hidden size of 400. AWD-LSTM and MoS are trained on 1000 epochs, and the Simple LSTM on 100 epochs. For the MoS model, embedding size used is 280, batch size 12, and hidden size 980. All the models use SGD as the optimizer.

We set up experiments to compare 4 different token order imbalance setups: Extreme TOI, Inter-batch TOI, Standard TOI, and Alleviated TOI (P).

Extreme TOI The Extreme TOI setup builds batches using a random sequence of data points. This removes any order inside the batches (i.e. among data points within a batch), and among batches.

Inter-batch TOI In the Inter-batch TOI setup, batches are built using an ordered sequence of data points, but the sequence of batches is shuffled. This keeps the order inside batches, but removes it among batches. Looking at the 2D matrix of batches, in Figure 4, this results in shuffling the rows of the matrix.

Standard TOI In the Standard TOI setup, the process of building batches is untouched, as described in section 3. This keeps the order inside, and among batches.

Alleviated TOI (P) In the Alleviated TOI (P) setup, we apply our proposed TOI reduction by creating P overlapped data point sequences (see Sections 3 and 4). This strategy not only keeps the order inside and among batches, but it also restores the full token order information in the dataset.

5.2 TOI in Speech Emotion Recognition

For Speech Emotion Recognition (SER) we use two different models: the encoder of the Transformer (Vaswani et al., 2017) followed by convolutional layers, and the simple LSTM used in text domain case. Since the Transformer is stateless and uses self-attention instead, we are able to investigate the effect of Alleviated TOI (P) independently of LSTM cells.

As with language modeling, we set up experiments to compare the 4 different token order imbalance strategies: Extreme TOI, Inter-batch TOI, Standard TOI, and Alleviated TOI (P).

We apply the methodology used in text on the SER task, using the simple LSTM and a window size of 300 frames. In this case, a data point, instead of being a sequence of words, is a sequence of frames coming from the same utterance. Each frame is described by a 384-dimensional features vector. OpenSMILE (Eyben et al., 2013) is used for extracting the features. We opt for the IS09 features set (Schuller et al., 2009) as proposed by Ramet et al. (2018) and commonly used for SER.

Finally, to investigate the effect of the Alleviated TOI (P) strategy independently of LSTM cells, we design a final experiment in the SER task. We investigate whether or not we have improved results as we increase P, the number of overlapped data point sequences in a stateless scenario. For this reason, we use the Transformer model described above.

Experiment	PTB	WT2	WT103
Extreme TOI	63.49	73.52	36.19
Inter-batch TOI	64.20	72.61	36.39
Standard TOI	**58.94**	**65.86**	**32.94**
Alleviated TOI 2	57.97	65.14	32.98
Alleviated TOI 5	57.14	65.11	33.07
Alleviated TOI 7	57.16	64.79	32.89
Alleviated TOI 10	**56.46**	**64.73**	**32.85**

Table 2: Perplexity score (PPL) comparison of the AWD model, on the three datasets, with batch sizes $K = 20$ (PTB), $K = 80$ (WT2) and $K = 60$ (WT103), with different levels of Token Order Imbalance (TOI). With Alleviated TOI (P), we use a prime batch size of $K = 19$ (PTB), $K = 79$ (WT2) and $K = 59$ (WT103).

Model	test ppl
AWD-LSTM (Merity et al., 2017)	58.8
AWD-LSTM + Alleviated TOI	56.46
AWD-LSTM-MoS (Yang et al., 2017)	55.97
AWD-LSTM-MoS + Alleviated TOI	54.58
Simple-LSTM	75.36
Simple-LSTM + Alleviated TOI	74.44

Table 3: Comparison between state-of-the-art models (Merity et al., 2017; Yang et al., 2017) and a Simple LSTM, and the same models with Alleviated TOI. The comparison highlights how the addition of Alleviated TOI is able to improve state-of-the-art models, as well as a simple model that does not benefit from extensive hyper-parameter optimization.

6 Experimental Results

6.1 Language Modelling

Table 2 compares the 4 token order imbalance strategies using the AWD model and three text datasets. We use the test perplexity after the same equivalent number of epochs. The different Alleviated TOI (P) experiments use a different number of overlapped sequence: An Alleviated TOI (P) means building and concatenating P overlapped sequences. Our results indicate that an Alleviated TOI (P) is better than the Standard TOI, which is better than an Extreme or Inter-batch TOI. We note a tendency that higher values of P lead to better results, which is in accordance with our hypothesis that a higher TOI ratio $(P-1)/P$ improves the results.

Comparison with State of the Art and Simple LSTM. With the MoS model and an Alleviated TOI, we improve the current state of the art without fine tuning for the PTB dataset with 54.58 perplexity on the test set. Table 3 demonstrates how models can be improved by applying our Alleviated TOI method on 2 latest state-of-the-art models: AWD-LSTM (Merity et al., 2017) and AWD-LSTM-MoS (Yang et al., 2017), and the Simple LSTM model. We compare the results with the same hyper-parameters used on the original papers with the only exception of the batch size, that must be prime. To ensure fairness, we allocate the same computational resources for the base model as well the model with Alleviated TOI, i.e. we train with the equivalent number of epochs.

Experiment	K=20	K=19
Alleviated TOI 2	59.37	57.97
Alleviated TOI 5	60.50	57.14
Alleviated TOI 7	**56.70**	57.16
Alleviated TOI 10	65.88	**56.46**

Table 4: Perplexity score (PPL) comparison on the PTB dataset and the AWD model. We use two different values for the batch size K — the original one with $K = 20$, and a prime one with $K = 19$. The results directly corroborate the observation portrayed in Figure 4, where the obtained score is related to the diversity of grayscale values in each row.

Comparison without prime batch size. In Table 4 we demonstrate how using a prime batch size with Alleviated TOI (P) actually impacts the scores. We compare the scores of a prime batch size $K = 19$ with the scores of the original batch size $K = 20$ for the AWD model with Alleviated TOI (P). When using a prime batch size, we observe consistent and increasing results as P increases. This is due to the good distribution of data points in the batches regardless of the value of P, which is visible in Figure 4(b) where each row contains a high diversity of grayscale values. With the original batch size $K = 20$, we observe a strong performance for $P = 7$, but a low performance for $P = 10$. Again, this effect is related to the distribution of data points in the batches, which is visible in Figure 4(a). The matrix with $P = 7$ shows a good distribution—corresponding to the strong performance—and the matrix with $P = 10$ shows that each row contains a low diversity of data points.

Experiment	WA	UA
Extreme TOI (15k steps)	0.475	0.377
Inter-batch TOI (15k steps)	0.478	0.386
Standard TOI (15k steps)	0.486	0.404
Alleviated TOI (15k steps)	**0.553**	**0.489**
Alleviated TOI (60 epochs)	**0.591**	**0.523**

Table 5: Token order imbalance (TOI) comparison for the IEMOCAP dataset on a SER task using *angry, happy, neutral* and *sad* classes with a simple LSTM model.

Experiment	WA (60 epochs)	UA (60 epochs)
Alleviated TOI 1	0.591±0.012	0.543±0.021
Alleviated TOI 2	0.594±0.007	0.549±0.016
Alleviated TOI 3	0.605±0.018	0.563±0.024
Alleviated TOI 5	0.608±0.015	0.562±0.028
Alleviated TOI 10	**0.617±0.015**	**0.571±0.024**
Local attention	**0.635**	**0.588**

Table 6: Token order imbalance (TOI) comparison for the IEMOCAP dataset on a SER task using *angry, happy, neutral and sad* classes for 60 epochs using the Transformer model.

6.2 Speech Emotion Recognition Results

The results on the IEMOCAP database are evaluated in terms of weighted (WA) and unweighted accuracy (UA). The first metric is the accuracy on the entire evaluation dataset, while the second is the average of the accuracies of each class of the evaluation set. UA is often used when the database is unbalanced, which is true in our case, since the *happy* class has a total duration that is half of the second smallest class in speech duration.

Table 5 shows that our proposed method brings value in the speech related task as well. When choosing the Extreme TOI instead of the Standard TOI approach we observe a smaller effect than in text related task: this is due to the different nature of the text datasets (large "continuous" corpuses) and the IEMOCAP one (composed of shorter utterances). The fact that we can still observe improvements on a dataset with short utterances is a proof of the robustness of the method.

A greater effect is obtained when we increase the size of the dataset with the proposed Alleviated TOI (P) approach: Due to the increasing offset at each overlapped sequence, the data fed into the model contains utterances where the emotions are expressed in slightly different ways. For this reason, the performance notably increases.

Table 6 reports the result of a final experiment that aims to investigate the effect of Alleviated TOI (P) independently of LSTM cells. For each Alleviated TOI (P) setup and Standard TOI described in Table 6, we repeat the training and evaluation for each of the following window sizes: 100, 200, 300, 400 and 500 frames. The previously described Transformer model is used in these experiments. The results reported in Table 6 are the mean $\pm$ the standard deviation computed for different P-values of Alleviated TOI (P).

The last line of Table 6 refers to Mirsamadi et al. (2017) results. We want to highlight the fact that the goal of these experiments is to show the direct contribution of the Alleviated TOI technique for a different model. For this reason we use a smaller version of the Transformer in order to reduce the computational cost. We believe that with a more expressive model and more repetitions, the proposed method may further improve the results.

The results from Table 6 demonstrate that, as we increase the value of P, more significant improvements are achieved. This is in accordance with our hypothesis that a higher TOI ratio $(P-1)/P$ improves the results.

7 Conclusions

In this work, the importance of overlapping and token order in sequence modelling tasks were investigated. Series discretization is an essential step in machine learning processes which nonetheless can be responsible for the loss of the continuation of the tokens, through the token order imbalance (TOI) phenomenon. The proposed method, Alleviated TOI, has managed to overcome this drawback and ensures that all token sequences are taken into account. The proposed method was validated in sequence modelling tasks both in the text and speech domain outperforming the state of the art techniques.

Abstract

Standard autoregressive seq2seq models are easily trained by max-likelihood, but tend to show poor results under small-data conditions. We introduce a class of seq2seq models, GAMs (Global Autoregressive Models), which combine an autoregressive component with a log-linear component, allowing the use of global *a priori* features to compensate for lack of data. We train these models in two steps. In the first step, we obtain an *unnormalized* GAM that maximizes the likelihood of the data, but is improper for fast inference or evaluation. In the second step, we use this GAM to train (by distillation) a second autoregressive model that approximates the *normalized* distribution associated with the GAM, and can be used for fast inference and evaluation. Our experiments focus on language modelling under synthetic conditions and show a strong perplexity reduction of using the second autoregressive model over the standard one.

1 Introduction

Neural sequential text generation models have become the standard in NLP applications such as language modelling, NLG, machine translation. When enough data is available, these models can be trained end-to-end with impressive results. Generally, inference and training proceed in an auto-regressive manner, namely, the next decoded symbol is predicted by a *locally normalized* conditional distribution (the "softmax"). This has several advantages: (i) the probability of the sequence is already normalized, by the chain-rule over local decisions, (ii) max-likelihood (ML) training is easy, because the log-likelihood of the full sequence is simply the sum of local CE (cross-entropy) losses, (iii) exact sampling of full sequences from the model distribution is directly obtained through a sequence of local sampling decisions.

However, these autoregressive models (AMs) tend to suffer from a form of myopia. They have difficulty accounting for global properties of the predicted sequences, from overlooking certain aspects of the semantic input in NLG to duplicating linguistic material or producing "hallucinations" in MT, and generally through being unable to account for long-distance consistency requirements that would be obvious for a human reader.[1]

The main contributions of this paper are as follows.

First, we propose a hybrid seq2seq formalization, the *Global Autoregressive Model* (GAM), that combines a local autoregressive component with a global log-linear component, allowing the use of *a priori* features to compensate for the lack of training data. GAMs are related both to the class of Energy-Based Models (EBM) and to that of Exponential Families (EF), and inherit some important properties from those: an intimate relationship between training and sampling (EBM); the identity of empirical and model expectations at maximum-likelihood; convexity of log-likelihood (EF).

Second, we propose a training procedure in two steps. In the first step, we train through max-likelihood a GAM, which however is *unnormalized* and improper for fast inference or evaluation. In the second step, we use this GAM to train (by distillation) a second autoregressive model that approximates the *normalized* distribution associated with the GAM, and can be used for fast inference

* Work conducted during an internship at NAVER Labs Europe.

[1] To borrow terminology from Reinforcement Learning (RL) (Sutton and Barto, 2018), such NLP models work by "imitation learning", without any representation of "objectives" to be realized. While this defect can be mitigated in the presence of large training sets, it can become serious when this condition is not met.

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 900–909

and evaluation.

Third, we demonstrate the ability of GAMs to be data-efficient, namely, to exploit the original data better than a standard autoregressive model. In order to clarify the core techniques and issues, we design a simple class of synthetic data, consisting of random binary strings containing "motifs" (specific substrings) that we can manipulate in different ways. We show that, in limited data conditions, GAMs are able to exploit the features to obtain final autoregressive models that perform better than the original ones.

The remainder of the paper is structured as follows. In Section 2, we provide some background about autoregressive models, energy-based models, and log-linear models. In Section 3, we introduce GAMs. In section 4, we describe our focus on synthetic data. In Section 5, we explain our training procedure. In Section 6, we comment on related work. In Section 7, we describe our experiments. In Section 8, we provide an analysis of our results. We conclude with a discussion in Section 9. *Note that some additional explanations and experiments are provided in the Supplementary Material, indicated by [SM].*

2 Background

2.1 Autoregressive models (AM)

These are currently the standard for neural seq2seq processing, with such representatives as RNN/LSTMs (Hochreiter and Schmidhuber, 1997; Sutskever et al., 2014), ConvS2S (Gehring et al., 2017), Transformer (Vaswani et al., 2017)). Formally, they are defined though a distribution $r_\eta(x|C)$, where C is an input (aka Context, e.g. a source sentence in Machine Translation (MT)), and x is a target sequence (e.g. a target sentence in MT). We have:

$$r_\eta(x|C) \doteq \prod_i s_\eta(x_i|x_1, \ldots, x_{i-1}, C),$$

where each $s_\eta(x_i|x_1, \ldots, x_{i-1}, C)$ is a normalized conditional probability over the next symbol of the sequence, computed by a neural network (NN) with parameters η. The local normalization of the incremental probabilities implies the overall normalization of the distribution $r_\eta(x|C)$, and consequently, the possibility of directly sampling from it and evaluating the likelihood of training sequences.

2.2 Energy-Based Models (EBM)

EBMs are a generic class of models, characterized by an energy function $U_\eta(x|C)$ computed by a NN parametrized by η (LeCun et al., 2006). Equivalently, they can be seen as directly defining a potential (an unnormalized probability distribution) $P_\eta(x|C) = e^{-U_\eta(x|C)}$, and indirectly the normalized distribution $p_\eta(x|C) = 1/Z_\eta(C)\ P_\eta(x|C)$, with $Z_\eta(C) = \sum_x P_\eta(x|C)$. A fundamental property of these models is that, for max-likelihood training, the SGD updates can be computed through the formula:[2]

$$\nabla_\eta \log p_\eta(x|C) = \nabla_\eta \log P_\eta(x|C) - E_{x\sim p_\eta(\cdot|C)} \nabla_\eta \log P_\eta(x|C), \quad (1)$$

which, in principle, reduces the problem of *training* with unnormalized potentials to the problem of *sampling* from them.

2.3 Log-Linear Models / Exponential Families

Log-Linear models (Jebara, 2013) are the conditional version of Exponential Families (Jordan, 2010). The general form of a log-linear model (for the discrete case) is as follows:

$$p_\lambda(x|C) = 1/Z_\lambda(C)\ \mu(x;C)\ e^{\langle \lambda(C),\ \phi(x;C)\rangle},$$

with $Z_\lambda(C) = \sum_x \mu(x;C)\ e^{\langle \lambda(C),\ \phi(x;C)\rangle}$. Here $\phi(x;C)$ is a vector of predefined real features of the pair (x, C), which is combined by scalar product with a real vector of weights $\lambda(C)$ of the same dimension; $\mu(x;C)$ is an arbitrary "base measure", which is fixed. These models, which allow to introduce prior knowledge through features and have nice formal properties (see below), were mainstream in NLP before the revival of neural approaches.

3 Proposal: GAMs

We now define *Global Autoregressive Models* (GAMs). These are hybrid seq2seq models that exploit both local autoregressive properties as well as global properties of the full target sequence. A GAM is an unnormalized distribution $P_\eta(x|C)$ over sequences x, parametrized by a vector $\eta = \eta_1 \oplus \eta_2$:

$$P_\eta(x|C) = r_{\eta_1}(x|C) \cdot e^{\langle \lambda_{\eta_2}(C),\ \phi(x;C)\rangle}. \quad (2)$$

[2] See (LeCun et al., 2006, p. 15), and [SM] for a derivation.

Here $r_{\eta_1}(x|C)$ is an autoregressive seq2seq model for generating x from input C, parametrized by η_2; $\phi(x;C)$ is a vector of predefined real features of the pair (x, C), which is combined by a scalar product with a real vector $\lambda_{\eta_2}(C)$ of the same dimension, computed over the input C by a network parametrized by η_2. The normalized distribution associated with the GAM is $p_\eta(x|C) = \frac{P_\eta(x|C)}{Z_\eta(C)}$, where $Z_\eta(C) = \sum_x P_\eta(x|C)$.

GAMs appear promising for the following reasons:

- Features $\phi(x;C)$ provide a simple way to draw attention of the model to potentially useful aspects that may be difficult for the AM component to discover on its own from limited data.

- GAMs are an instance of EBMs, where the potential $P_\eta(x|C)$ is the product of the an AM potential $r_{\eta_1}(x|C)$ with a "log-linear" potential $e^{\langle \lambda_{\eta_2}(C), \phi(x;C) \rangle}$. Here the gradient relative to the log-linear part takes the especially simple form:

$$\nabla_{\eta_2} \log p_\eta(x|C) = \phi(x;C) - E_{x \sim p_\eta(\cdot|C)}\, \phi(x;C). \quad (3)$$

- Log-linear models, on their own, while great at expressing prior knowledge, are not as good as AM models at discovering unforeseen regularities in the data. Also, they are typically problematic to train from a log-likelihood perspective, because sampling from them is often unfeasible. GAMs address the first issue through the r component, and alleviate the second issue by permitting the use of r as a powerful "proposal" (aka "surrogate") distribution in importance sampling and related approaches, as we will see.

4 Experimental focus

While the motivation for GAMs ultimately lies in practical NLP applications such as those evoked earlier, in this paper we aim to understand some of their capabilities and training techniques in simple and controllable conditions. We focus on the unconditional (i.e. language modelling) case, and on synthetic data. Our setup is as follows:

- We consider an underlying process p_{true} that generates *binary sequences* according to a well-defined and flexible process. In this paper we use PFSAs (Probabilistic Finite State Automata) to impose the presence or absence of sub-strings ("motifs") anywhere in the generated data, exploiting the intersection properties of automata.

- Due to the dynamic programming properties of PFSAs, it is possible to compute the true entropy $H(p_{true}) = -\sum_x p_{true}(x) \log p_{true}(x)$ of the process (see [SM]), as well as other quantities (Partition Functions, Mean sequence length); it is also possible to generate training (D), validation (V), and test data (T) in arbitrary quantities.

- We employ an unconditional GAM of the simple form:

$$p_\lambda(x) \doteq \frac{P_\lambda(x)}{Z_\lambda}, \text{with } Z_\lambda \doteq \sum_x P_\lambda(x) \text{ and } P_\lambda(x) \doteq r(x) \cdot e^{\langle \lambda,\, \phi(x) \rangle}, \quad (4)$$

where r is trained on D and then kept fixed, and where λ is then trained on top of r, also on D.

It should be noted that with r fixed in this way, this formulation exactly corresponds to the definition of an exponential family (Jordan, 2010), with r as *base measure*. In such models, we have two important properties: (i) the log-likelihood of the data is *convex* relative to the parameters λ, and thus a local maximum is also global; (ii) the max-likelihood value λ^* has the property that the model expectation $E_{x \sim p_{\lambda^*}(\cdot)}\, \phi(x)$ is equal to the empirical expectation $|D|^{-1} \sum_{x \in D} \phi(x)$ ("Moment Matching" property of exponential families).

- We are specially interested in the relative *data-efficiency* of the GAM compared to the AM r: namely the ability of the GAM to recover a lower perplexity approximation of p_{true} than r, especially in small training-set conditions.

5 Training procedure

5.1 Two-stage training

We consider a two-stage training procedure (see Fig. 1).

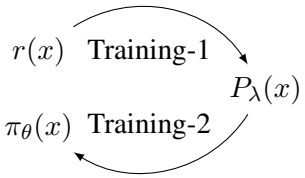

Figure 1: Two-stage training. At the end of the process, we compare the perplexities of r and π_θ on test data: $CE(T, r)$ vs. $CE(T, \pi_\theta)$.

Training-1 This consists in training the model P_λ on D. This is done by first training r on D in the standard way (by cross-entropy) and then by training λ by SGD with the formula (adapted from (3)):

$$\nabla_\lambda \log p_\lambda(x) = \phi(x) - E_{x \sim p_\lambda(\cdot)}\, \phi(x). \quad (5)$$

The main difficulty then consists in computing an estimate of the model moments $E_{x \sim p_\lambda(\cdot)}\, \phi(x)$. In our experiments, we compare two Monte-Carlo approaches (Robert and Casella, 2005) for addressing this problem: (i) *Rejection Sampling* (rs), using r as the proposal distribution and (ii) *Self-Normalized Importance Sampling* (snis) (Owen, 2017; Y. Bengio and J. S. Senecal, 2008), also using r as the proposal.

Rejection sampling is performed as follows. We use $r(x)$ as the proposal, and $P_\lambda(x) = r(x)\ e^{\lambda \cdot \phi(x)}$ as the unnormalized target distribution; for any specific λ, because our features are bounded between 0 and 1, we can easily upper-bound the ratio $\frac{P_\lambda(x)}{r(x)} = e^{\lambda \cdot \phi(x)}$ by a number β; we then sample x from r, compute the ratio $\rho(x) = \frac{P_\lambda(x)}{\beta\ r(x)} \leq 1$, and accept x with probability $\rho(x)$. The accepted samples are unbiased samples from $p_\lambda(x)$ and can be used to estimate model moments.

Snis also uses the proposal distribution r, but does not require an upper-bound, and is directly oriented towards the computation of expectations. In this case, we sample a number of points $x_1, \ldots, x_N$ from r, compute "importance ratios" $w(x_i) = \frac{P_\lambda(x_i)}{r(x_i)}$, and estimate $E_{x \sim p_\lambda(\cdot)}\, \phi(x)$ through $\hat{E} = \frac{\sum_i w(x_i)\phi(x_i)}{\sum_i w(x_i)}$. The estimate is biased for a given N, but consistent (that is, it converges to the true E for $N \to \infty$).

Training-2 While Training-1 results in a well-defined model $P_\lambda(x)$, which may fit the data closely in principle, we should not conclude that $P_\lambda(x)$ is convenient to use for inference — namely, in language modeling, efficiently sampling from its normalized version $p_\lambda(x)$; as seriously, because of the partition factor Z_λ, it is also not obvious to *evaluate* the perplexity of $P_\lambda(x)$ on test data. In order to do both, one approach consists in using a *distillation* technique (Hinton et al., 2015), where, during training, one expends generous time towards producing a set of samples from P_λ, for instance by Monte-Carlo (e.g. Rejection Sampling) techniques, and where this set (which may be arbitrarily larger than the original D) is in turn used to train a new autoregressive model $\pi_\theta(x)$, which can then be used directly for sampling or for computing data likelihood. This is the approach that we use in our current experiments, again using the original $r(x)$ as a proposal distribution.

5.2 Cyclical training

In the case of small $|D|$, the proposal distribution r is weak and as a result the distillation process, based on rejection sampling, can be slow. To address this issue, we also consider a cyclical training regime that updates the proposal distribution after distilling each batch of samples, with the intention of reducing the rejection rate. Once the process of distillation is finished, we use the aggregated samples to train the final π_θ. The two-stage training procedure is a variant of the cyclical one, with a fixed proposal (see Algorithm 1 for more details).

6 Related Work

(Hoang et al., 2018), working in a NMT context, have a similar motivation to ours. They first train an autoregressive seq2seq model (Transformer in their case) on bilingual data, then attempt to control global properties of the generated sequences through the introduction of a priori features. They interpolate the training of the autoregressive model with training of a Moment Matching component which tries to equate the features expectations of the model with those of the data. Contrarily to our approach, they do not directly try to maximize likelihood in an integrated model.

(Andor et al., 2016) consider transition-based neural networks, and contrast local to global normalization of decision sequences, showing how the global approach avoids the *label bias* problem in such tasks as tagging or parsing. They

focus on inference as maximization, e.g. finding the best sequence of tags for a sequence of words, and consistent with that objective, their training procedure exploits a beam-search approximation. By contrast, our focus is on inference as sampling in a language modelling perspective, on the complementarity between auto-regressive models and log-linear models, and on the relations between training and sampling in energy-based models.

7 Experiments

We conduct a series of experiments on synthetic data to illustrate our approach.

7.1 Synthetic data

To assess the impact of GAMs, we focus on distributions $p_{true}(x)$ that are likely to be well approximated by the AM $r(x)$ in the presence of large data. The first class of distributions is obtained through a PFSA that filters binary strings of fixed length $n = 30$, 0's and 1's being equally probable (white-noise strings), through the condition that they contain a specific substring ("motif") anywhere; here the relative frequency of sequences containing the motif among all sequences varies from ~ 0.01 (shorter motifs $|m| = 10$) to ~ 0.001 (longer motifs $|m| = 14$).

We also consider mixtures of two PFSAs (motif/anti-motif): the first (with mixture prob. 0.9) produces white-noise strings containing the motif and the second (with mixture prob. 0.1) strings excluding the motif.

From these processes we produce a training set D, of size $|D|$ varying between $5 \cdot 10^2$ and $2 \cdot 10^4$, a validation set V of size $0.25 \cdot |D|$ (but never smaller than $5 \cdot 10^2$ or bigger than $2 \cdot 10^3$) and a test set T of fixed size $5 \cdot 10^3$.

7.2 Features

In a real world scenario, prior knowledge about the true process will involve, along with predictive features, a number of noisy and useless features. By training the λ parameters to match the empirical moments, the GAM will learn to distinguish between these types. In order to simulate this situation we consider feature vectors over our artificial data that involve both types.

With x the full string and m the fixed motif used in constructing the training data, we consider variations among the 7 binary features in the set F:

$$F = \{m,\ m_{+0},\ m_{/2},\ d_0,\ d_1,\ d_2,\ d_3\},$$

where $m = 0$ iff the motif m appears in x, $m_{+0} = 0$ iff the motif followed by a zero ("super-motif") appears in x, $m_{/2} = 0$ iff an initial section of the motif ("sub-motif", roughly half the size of m) appears in x. These three features are chosen because they have some correlation with

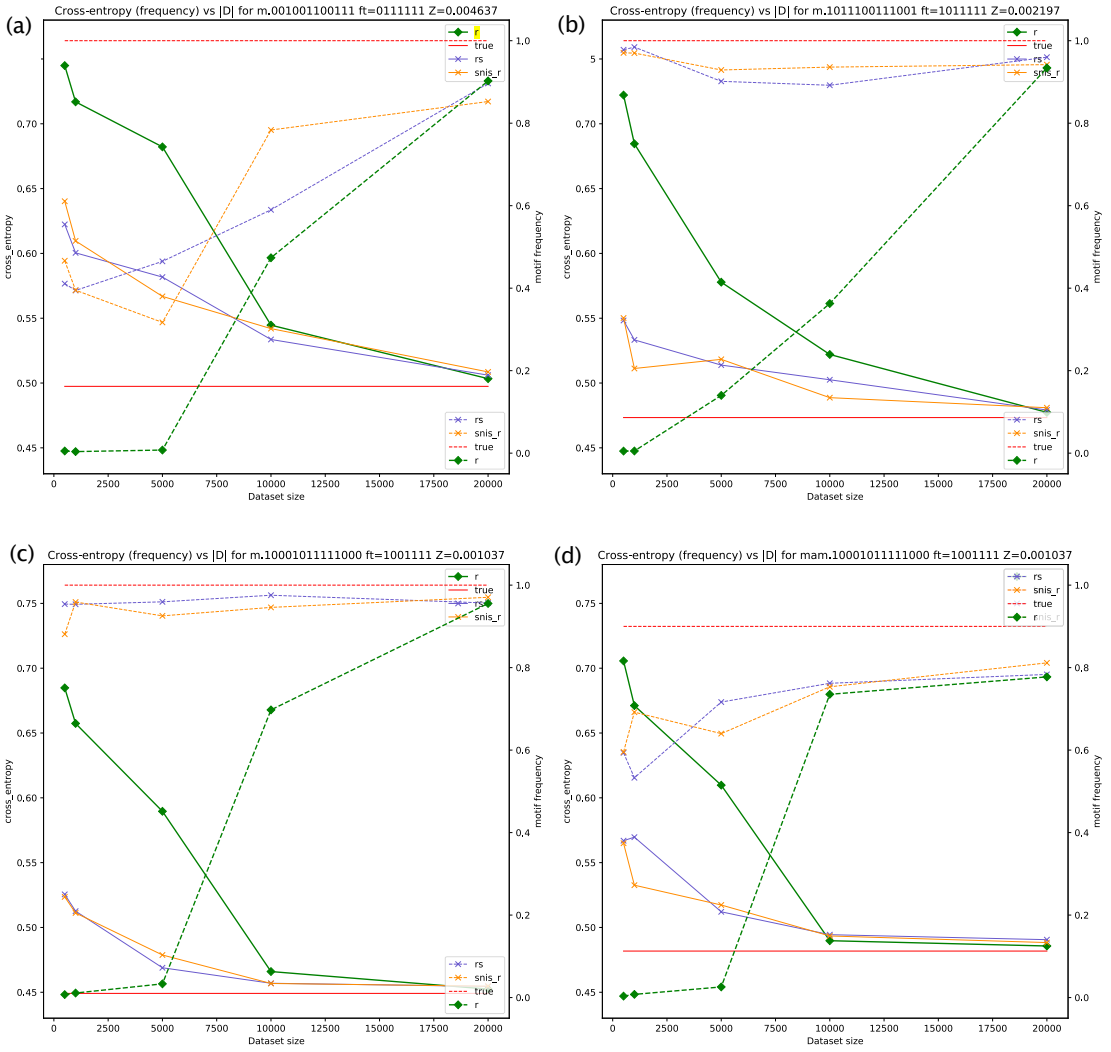

Figure 2: Cross-entropy in nats per character and frequency of sampling motif, depending on $|D|$. Two-stage Training. Features d_0, d_1, d_2, d_3 are on for all panels ($ft_{[4:7]} = \{1111\}$). Panel (a): pure D, features m_{+0} (super-motif) and $m_{/2}$ (sub-motif) on; (b): pure D, m (motif) and $m_{/2}$ (sub-motif) on; (c) pure D, m on; (d) mixture D, m on. The plain lines represent cross-entropy, the dashed lines motif frequency.

the process for generating the training data. By contrast, the four remaining features are "distractors": $d_0 = 0$ iff x begins with a 0, $d_1 = 0$ (resp. $d_2 = 0$, $d_3 = 0$) iff a certain random, but fixed, string of similar length to m (resp. of larger length, of smaller length) appears in x. We test different configurations of these features for training λ, and document the use/non-use of features with a bit-vector ft of length $|F|$, for instance $ft = 0111111$ means that all features are exploited, apart from m.[3]

[3]In the experiments reported here, one of the provided features, m, is a detector of the motif actually present in the data generating process, an extreme form of prior knowledge used to illustrate the technique. In general, milder forms of useful prior features can be provided. A simple formal example is to consider one real-valued (non binary) feature for the length, and one for the square of the length, an experiment that we did recently but do not report here; by matching the data expectations of these two additional features, the model is able to represent the mean and variance of length in the data. Here the prior knowledge provided to the model just tells it to be attentive to the distribution of length, a much weaker form of prior knowledge than telling it to be attentive to a specific motif.

7.3 Implementation aspects

7.3.1 Autoregressive models

The AMs are implemented in PyTorch[4] (Paszke et al., 2017) using a 2-layered LSTM (Hochreiter and Schmidhuber, 1997) with hidden-state size 200. The input is presented through one-hot encodings over the vocabulary $V = \{0, 1, \langle \text{EOS} \rangle\}$. These LSTMs are optimized with Adam (Kingma and Ba, 2014), with learning rate $\alpha = 0.001$, and

[4]https://github.com/parshakova/GAMS-for-Data-Efficient-Learning

with early stopping (patience $= 20$) over a validation set.

7.3.2 Training: Two-Stage and Cyclical

The implementation is described in (Algorithm 1). Here we provide some additional details.

Training-1 For training $P_\lambda(x)$ we test two regimes in Eq. 5, namely rs and $snis$; in both cases, we first train $r(x)$ on the whatever D is available, and use it as the proposal distribution. During rs, we compute the model's expectation over 10 accepted samples, update the λ's according to (5), and iterate. During $snis$, we keep a buffer of the last $5 \cdot 10^4$ samples from $r(x)$ to compute the weighted average of the feature moments. For the training of λ's, we use a basic SGD optimization with learning rate $\alpha(\text{\#epoch}) = \frac{\alpha_0}{1+\text{\#epoch}}, \alpha_0 = 10$. To assess the quality of $P_\lambda(x)$ for early stopping during training, we use the distance between the empirical and model moments:

$$\ell_1\text{_mom} = \left\| \frac{1}{|D|} \sum_{d \in D} \phi(d) - E_{x \sim p_\lambda(\cdot)}\, \phi(x) \right\|_1 . \quad (6)$$

Training-2 and Cyclical Training When distilling from P_λ in Training-2, we use a single proposal r, and systematically produce a distilled dataset of size DsSize $= 2 \cdot 10^4$, which corresponds to the highest value of $|D|$ among those considered for training r. In Cyclical Training, the distillation process is performed in several stages, with an evolving r for improving the rejection rate.

8 Results

8.1 Cross-entropy comparison

We conduct experiments to compare the cross-entropy (measured in nats) between the initial AM $r(x)$ relative to the test set T and the final AM $\pi_\theta(x)$ also relative to T; we vary the size of $|D| \in \{0.5, 1, 5, 10, 20\} \cdot 10^3$, the regimes (tReg) for Training-1 (rs or $snis$), the features employed, the rarity of the motifs. Figure 2 depicts the resulting curves at the end of the two-stage training (plain lines).

Here we show only a few experiments (a more extensive set is provided in the [SM]).

We observe that, for a small dataset size $|D|$, there is a big gap between the CE of $r(x)$ and the CE of $\pi_\theta(x)$. As $|D|$ increases, these cross-entropies become closer to one another, but a large gap persists for $|D| = 5000$.

We note that the presence of the "fully-predictive" feature m results in a $\pi_\theta(x)$ that has CE very close to the theoretical entropy, even in low $|D|$ regimes, where r on its own is very weak.[5] Thus, not only is the distilled AM much better than the initial AM, but this is an indication that P_λ itself (for which the cross-entropy is more difficult to compute exactly) is a good approximation of the true process.

By contrast, if the m feature is absent, then, while π_θ is still better than r in low $|D|$ regimes, it cannot reach the theoretical entropy in such regimes, because features such as m_{0+} and $m_{/2}$ can only partially model the data. With large $|D|$, on the other hand, r on itself does a good job at predicting the data, and P_λ adds little on top of its r component.

Finally, we note that the two regimes for training $P_\lambda(x)$, rs and $snis$, result in π_θ's with similar accuracies.

We also observe that with a good performance of $\pi_\theta(x)$, the moments of motif feature on the distilled dataset are close to the true ones (see [SM] Figure 4, 5, 7).

These trends are consistent across the experiments with different motifs, as can be checked in Table 3 and with the additional plots in the [SM].

8.2 Motif frequencies

In order to assess the *predictive* properties of obtained AMs, we also compare the frequency of motifs in strings sampled from r and from π_θ ($2 \cdot 10^3$ samples in total). From Figure 2 we see that when vary $|D|$, the frequency of motifs (dashed lines) is aligned with the CE performance. Namely, π_θ produces a higher fraction of strings with motif than r when $|D|$ is small ($|D| \in \{0.5, 1, 5\} \cdot 10^3$).

Detailed illustration To provide more intuition, we provide an illustration from one experiment in Table 1.

8.3 Mixture D_{mam} vs pure D_m

In our experiments, the strings in D_{mam} (motif-anti-motif) contain a motif with $p = 0.9$. However, if not all of the samples in D_{mam} contain the

[5] The CE of a model relative to the true underlying process (approximated by the test set T) can never be below the entropy of this process, due to the KL-divergence being non-negative.

1	$true$	101**10001011111000**1000001001001
2	r	011111000010111110001110001011

4	ft	$[m, _, _, d_0, d_1, d_2, d_3]$
5	λ's	$[-10.1, _, _, -0.15, -0.06, 0.0, -0.14]$
6	mom $true$	$[0.0, _, _, 0.47, 0.99, 1.0, 0.91]$
7	mom r	$[0.95, _, _, 0.53, 0.99, 1.0, 0.91]$
8	mom π_θ	$[0.0006, _, _, 0.43, 0.99, 0.99, 0.91]$
9	CEs	$true$: 0.45, r: 0.56, π_θ: 0.47
10	motif freqs	$true$: 1.0, r: 0.045, π_θ: 0.959

Table 1: Illustration. Setting is from Fig. 2, panel (c): n =30, motif = 10001011111000 (always present in D), ft = 1001111, $|D|$ = 5000, rs used for Training-1. Lines 1,2,3 show one example from $true, r, \pi_\theta$ respectively; with training set of size 5000, r is only able to generate the motif a fraction of the time (0.045, see line 10), but is better able to generate some submotifs (underlined); π_θ generates the motif frequently (0.959), as illustrated on line 3. With the features from ft (line 4), Training-1 produces a P_λ with first feature λ_m strongly negative (line 5), meaning that P_λ strongly penalizes the absence of the motif; the "distractor" features d_0, d_1, d_2, d_3 get a weight close to 0, meaning that they have little predictive power in combination with feature m. It is visible from lines 6,7,8 that π_θ is much better able to approximate the true feature expectations than r [features expectations (aka moments) under r (resp. π_θ) : $E_{x\sim r(\cdot)}\ \phi(x)$ (resp. $E_{x\sim \pi_\theta(\cdot)}\ \phi(x)$)] Finally (line 9), the CE of π_θ relative to the test set is close to the true entropy of the process, while that of r is much further away.

motif, then the motif feature itself is not fully predictive. It can be seen in panel (d) of Figure 2 that the π_θ achieved with P_λ trained on mixture D_{mam} has consistent behaviour with the results obtained on the pure D_m of panels (a,b,c).

8.4 Regimes in Training-1

For training GAM we consider two methods, $snis$ and rs. As described in the previous sections, their impact on P_λ leads to π_θ's that have similar CE's and motif frequencies. Despite such resemblance in terms of accuracy, these two methods differ in terms of speed (see Table 2). Namely, when r is close to white noise due to small $|D|$, then for the rare events rs rejects most samples not containing the motif due to the effect of the log linear term and negative value of the component λ_m corresponding to the m feature, while $snis$ is able to exploit all samples. Despite being faster than rs, $snis$ remains competitive in terms of CE.

8.5 Cyclical vs two-stage training

We conducted a small experiment to compare the performance of cyclical training with two-stage training in terms of speed and accuracy for a fixed motif m and features ft (see [SM] Table 4, Figure 3). We observed that CEs of the obtained π_θ's were about the same for different values of $|D|$ and Training-1 regimes. On the other hand, there was no systematic improvement in the training speed of one method over the other.

9 Discussion

The basic idea behind GAMs is very simple. First, we extend the representational power of the autoregressive model r by multiplying by a log-linear potential, obtaining an unnormalized model P_λ (Training-1). Then we try to "project" this extended representation again to an autoregressive model π_θ (Training-2). Our results showed that, under favorable prior knowledge conditions, the final π_θ was able to perform as well, when trained on small data, as the standard r, trained on large data. During our experiments, we noticed that training P_λ was actually easier than training π_θ from it. Intuitively, the small number of parameters to be fitted in the log-linear model requires less work and fewer data than the training of an autoregressive component.[6]

It is interesting to relate our study to certain aspects of Reinforcement Learning (RL).

First, consider Training-2. There, we have a "score" P_λ that we are trying to approximate through an autoregressive model π_θ, which is basically a sequential "policy". The main difference with RL is that we are not trying to find a policy that *maximizes* the score (which would be a bad idea for language modelling, as it would tend to concentrate the mass on a few sequences), but one that approximates P_λ in a *distributional* sense; our current distillation technique is only one way to approach this problem, but other techniques more in the spirit of RL are possible, a direction that we leave for future work.

Second, consider Training-1. Our approach, consisting in suggesting to the model a number of prior features, might look too easy and suspicious. But notice that in RL, one would typically directly provide to the model an externally defined *reward*, a very strong form of prior knowledge. Here, instead, we "only" indicate to the models which features it might attend to, and Training-1 then determines the "reward" P_λ through max-likelihood, a milder form of prior knowledge, more respectful for what the data has to say.[7]

Acknowledgements

Thanks to Matthias Gallé and Ioan Calapodescu for comments on a previous version of this paper and to the anonymous reviewers for their detailed reading and feedback.

[6] At a deeper level, there are extreme situations where the P_λ obtained at the end of Training-1 can perfectly represent the true process, but where no autoregressive model can actually fit P_λ: one way to obtain such situations consists in generating binary strings that satisfy a certain cryptographic predicate, associated with a specific feature; the importance of this feature can be easily detected through Training-1, but an autoregressive model has no chance of generalizing from distilled or true data, even in large quantities.

[7] We could say that while Training-2 addresses a question directly related to Reinforcement Learning, Training-1 addresses one related to *Inverse* Reinforcement Learning (Russell, 1998; Ng and Russell, 2000): it derives a reward from training evidence rather than imposing it externally.

Abstract

Answer selection aims at identifying the correct answer for a given question from a set of potentially correct answers. Contrary to previous works, which typically focus on the semantic similarity between a question and its answer, our hypothesis is that question-answer pairs are often in analogical relation to each other. Using analogical inference as our use case, we propose a framework and a neural network architecture for learning dedicated sentence embeddings that preserve analogical properties in the semantic space. We evaluate the proposed method on benchmark datasets for answer selection and demonstrate that our sentence embeddings indeed capture analogical properties better than conventional embeddings, and that analogy-based question answering outperforms a comparable similarity-based technique.

1 Introduction

Answer selection is the task of identifying the correct answer to a question from a pool of candidate answers. The standard methodology is to prefer answers that are semantically similar to the question. Often, this similarity is strengthened by bridging the lexical gap between the text pairs via learned semantic embeddings for words and sentences. The main drawback of this method is that question-answer (QA) pairs are modeled independently, and that the correspondence between different pairs is not considered in these embeddings. In fact, these methods only focus on the relationship that may exist between the entities that constitutes the QA pair at hand and are thus, limited to pairwise semantic structures.

Instead, we argue in this paper that questions and their correct answers often form analogical relations. For example, the question "Who is the president of the United States?" and its answer are

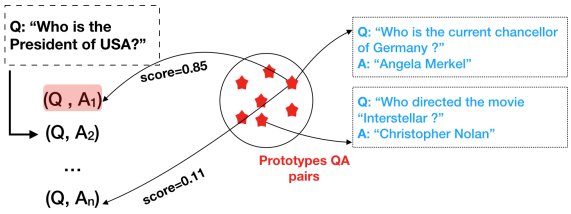

Figure 1: Illustration of analogy-based answer selection. Given a question and its candidate answers, each pair is compared to a QA prototype pair. The candidate answer with the highest score is assumed to be the correct answer.

in the same relation to each other as the question "Who is the current chancellor of Germany?" and "Angela Merkel". Thus, for modelling these relations, we need to look at quadruples of textual items in the form of two question-answer pairs, and want to reinforce that they are in the same relation to each other.

We expect that using analogies to identify and transfer positive relationships between QA pairs will be a better approach for tackling the task of answer selection than simply looking at the similarity between individual questions and their answers.

We use sentence embeddings as the mechanism to assess the relationship between two sentences, and aim to learn a latent representation in which their analogical relation is explicitly enforced in the latent space. Analogies are defined as relational similarities between two pairs of entities, such that the relation that holds between the entities of the first pair, also holds for the second pair. Loosely speaking, the quadruple of sentences is in *analogical proportion* if the difference between the first question and its answer is approximately the same as the difference between the second question and its answer.

This formulation is especially valuable because

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 910–919
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

analogies allow to put on relation pairs that are not directly or explicitly linked. Consequently, in the vector space, analogous QA pairs will be oriented in the same direction, whereas dissimilar pairs will not correspond.

The remainder of the paper is organized as follows: the next section will present related work on answer selection, metric learning, as well as laying down the foundations of analogical reasoning. In Section 3, we formally define analogies, and introduce our approach for learning such analogical embeddings. Finally, in Section 4, we evaluate the learnt representations to demonstrate that the found embeddings indeed respect the sought analogies, and to illustrate the benefits of analogies for the task of answer selection.

2 Related Work

Answer Selection. Answer selection is an important problem in natural language processing that has drawn a lot of attention in the research community (Lai et al., 2018). Given a question and a set of candidate answers, the task is to identify the correct answer(s) in this set. This task can be formulated as a classification or a ranking problem. Early works relied on computing a matching score between a question and its correct answer, and were characterized by the heavy reliance on feature engineering for representing the QA pairs. Representative works include (Filice et al., 2016), which studies the effects of various similarity, heuristic, and thread-based features, or (Tymoshenko and Moschitti, 2015), which analyzes the effect of syntactic and semantic features extracted by syntactic parser for answer re-ranking. Recently, deep learning methods have achieved excellent results in mitigating the difficulty of feature engineering. These methods are used to learn latent representations for questions and answers independently, and a matching function is applied to give the score of the two texts. The most representative works in this line of work include (Wang and Nyberg, 2015; Yin et al., 2016; Severyn and Moschitti, 2015; Tay et al., 2017).

Embeddings and Metric Learning. Our work is also related to representation learning usig deep neural networks. In fact, learning the embeddings of entities can be seen as a knowledge induction process, as those induced latent representations can be used to infer properties of unseen samples. Although many studies confirmed that embeddings obtained from distributional similarity can be useful in a variety of different tasks, (Levy et al., 2015) showed that the semantic knowledge encoded by general-purpose similarity embeddings is limited, and that enforcing the learnt representations to distinguish functional similarity from relatedness is beneficial. For this purpose, many task-specific embeddings have been proposed for a variety of tasks including (Riedel et al., 2013) for binary relation extraction and (FitzGerald et al., 2015) for semantic role labeling. This work aims to preserve more far reaching structures, namely analogies between pairs of entities.

Analogical Reasoning. Analogical reasoning has been an active research topic in classic artificial intelligence. It has been successfully used in different domains such as classification (Bounhas et al., 2014), clustering (Marx et al., 2002), dimensionality reduction (Memisevic and Hinton, 2004), or learning to rank (Fahandar and Hüllermeier, 2018). Gentner (1983) studies analogies with respect to human cognition, defines an analogy as a relational similarity over two pairs of entities, and differentiates it from the more superficial similarity defined by attributes. Since this general definition of analogy requires high-level reasoning which is not scalable to large-scale automated prediction systems, Miclet et al. (2008) define the concept of analogical dissimilarity between entities in the same semantic universe. The analogical dissimilarity allows to perform direct inference for unseen entities. Contrary to their direct inference setting, we enforce the analogical constraints in the learned embedding in the form of geometrical constraints, by imposing the co-linearity of the vector that maps the entities of each pair in the analogical proportion. It is worth mentioning that analogies have been found as the result of several word embedding models—inter alia (Mikolov et al., 2013; Pennington et al., 2014)—but those are allegedly only empirical observations, which we found to not carry over to our task.

3 Analogical Embeddings

In this section, we explain our approach towards generating semantic embeddings that preserve analogical proportions.

3.1 Analogical Reasoning

In this section, we briefly introduce key concepts in analogical reasoning, starting with analogical proportions.

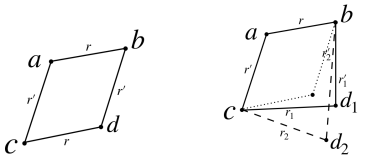
Definition 1 (Analogical Proportion) *Let a, b, c, d be four values from a domain $\mathbb{X}$. The quadruple (a, b, c, d) is said to be in analogical proportion $a : b :: c : d$ if a is related to b as c is related to d, i.e., $\mathcal{R}(a, b) \sim \mathcal{R}(c, d)$.*

This comparative relation between two pairs of entities can be expressed in many ways (Dubois et al., 2016), but the most noteworthy are:

- Arithmetic proportion: $(a - b) = (c - d)$
- Geometric proportion: $\frac{\min(ad, bc)}{\max(ad, bc)}$

In this work, we focus solely on the arithmetic interpretation of analogy.

An intuitive way of viewing analogies is through geometrical constraints in an Euclidean space. Enforcing the relational similarity between pairs of elements is equivalent to constraining the four elements to form a parallelogram.



The left graph of Figure 2 illustrates such an *analogical parallelogram*. As we can see, in an *analogical parallelogram*, there is not only a relation $\mathcal{R}$ holding between (a, b) and (c, d) respectively, but there must also hold a similar relation $\mathcal{R}'$ between (a, c) and (b, d).

We can now make a first step towards our problem, which is learning to identify correct answers according using analogical inference. Given the aforesaid quadruple, when one of the four elements is unknown, an analogical proportion becomes an analogical equation.

Definition 2 (Analogical Equation) *An* analogical equation *has the form*

$$a : b :: c : x \tag{1}$$

where x represents an unknown element that is in analogical proportion to a, b, c.

(a) (b)

Figure 2: Analogical parallelograms in $\mathbb{R}^n$. (a) shows the case where $(a - b) = (c - d)$. The geometrical structure is a parallelogram. If $(a - b) \sim (c - d)$, the resulting structure is a general quadrangle with almost parallel sides (b).

In our setting, an exact solution to an analogical equation can often not be expected. Instead, we aim at finding the element d_i, among n candidates, where the analogical proportion is as closely satisfied as possible. For example, in the right graph of Figure 2, neither d_1 nor d_2 are perfect solutions to the analogical equation $a : b :: c : x$, but d_1 seems to be a better solution than d_2.

In order to relax the equality constraint between the pairs of entities, and to generalize the formulation of analogical proportions beyond the Boolean case, Miclet et al. (2008) proposed to measure the degree of an analogical proportion using analogical dissimilarity.

Definition 3 (Analogical Dissimilarity) *In a Euclidean space, the degree of analogical dissimilarity of a quadruple (a, b, c, d) is defined as*

$$v(a, b, c, d) = \|(a - b) - (c - d)\| \tag{2}$$

This equation represents the relation $\mathcal{R}$ as the difference between the entities of the pair and $\sim$ as the difference between the previously the so expressed relation pairs. Obviously, $v(a, b, c, d) = 0$ if (a, b, c, d) are in analogical proportion, and the value increases the less similar $(a - b)$ and $(c - d)$ are to each other.

This allows us to re-frame the original problem of answer selection as a ranking problem, in which the goal is to select the candidate answer d which minimizes the degree of analogical dissimilarity:

$$d = \arg\min_i v(a, b, c, d_i)_{i=1,\ldots,N} \tag{3}$$

In the following sections, we will describe the details of the model by motivating the architectural choices.

3.2 Generating Quadruples

In this work, we consider QA pairs as relational data. We aim to transfer knowledge from pairs whose relation is well known, which we call *prototypes*, to unseen pairs. For this, we train a model to encode analogies in the latent representations of the sentences. For creating a instances of quadruples to train the model, we adapt state-of-the-art datasets.

An analogy quadruple has the following form:

$$[q_p : a_p :: q_i : a_{ij}]$$

"Where" questions	
`Sentence A`	"Where was Abraham Lincoln born?"
`Sentence B`	"On February 12, 1809, Abraham Lincoln was born Hardin County, Kentucky"
`Sentence C`	"Where was Franz Kafka born?"
`Sentence D`	"Franz Kafka was born on July 3, 1883 in Prague, Bohemia, now the Czech Republic."
"Who" questions	
`Sentence A`	"Who made the rotary engine automobile?"
`Sentence B`	"Mazda continued work on developing the Wankel rotary engine."
`Sentence C`	"Who discovered prions?"
`Sentence D`	"Prusiner won Nobel prize last year for discovering prions"
"When" questions	
`Sentence A`	"When was Leonardo da Vinci born?"
`Sentence B`	"Leonardo da Vinci was actually born on 15 April 1452 [...] "
`Sentence C`	"When did Mt St Helen last have significant eruption?"
`Sentence D`	"Pinatubo's last eruption [...] as Mt St Helen's did when it erupted in 1980."

Table 1: Example of analogy between sentences. `Sentence A` and `Sentence B` constitutes the prototype QA pair in the analogical quadruples `Sentence C` and `Sentence D` are the QA pair at hand.

where the q_p and a_p, respectively stand for the question and the answer of the prototype pair, whereas q_i is the i-th question and a_{ij} is the j-th candidate answer to q_i.

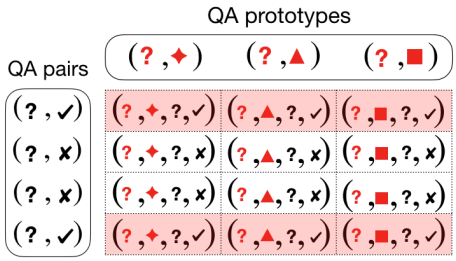


Figure 3: Procedure to generate analogical quadruples. The cells in red represent positive analogical quadruples, composed of a prototype QA pair, a question and its correct answer. In reverse, a negative quadruple contains a QA prototype, a question and one of its incorrect answer.

Given a set of questions and their relative candidates answers, we construct the analogical quadruples in two steps. First, we divide all the questions into three different subsets of wh-word questions: *"Who"*, *"When"* and *"Where"*. We focus on these three types because their answer type fall in distinct and easily identifiable categories:

- "Where" corresponds to an answer of type "Location"
- "Who" corresponds to an answer of type "Person"
- "When" corresponds to an answer of type "Date" or "Time"

Table 1 illustrates examples of quadruples for the three described categories. From these categories, we extract a variable number of QA pairs in order to form the prototype set. To generate positive quadruples, we select a prototype from one of the above-mentioned subsets and we associate a question from the same set and the correct answer among its candidates. This procedure provides a large number of analogical quadruples. On the other hand, to generate negative training samples we use the following approach: in the same subset, we associate a prototype, a question and a randomly selected wrong answer among its candidates. This is done in order to purposely break the analogical relation between a prototype QA pair and the QA pair at hand. This approach will generate a set of hard examples to help improve the training. Figure 3 illustrates the procedure.

To summarise, ranking by analogical dissimilarity is performed in three steps:

1. Given a prototype QA pair, a question and N candidate answers, N quadruples are generated.
2. The analogical dissimilarity score is computed for each quadruple.
3. The N candidates are consequently ranked by the analogical dissimilarity score.

The next section closely describe the architectural choices of the model.

3.3 Quadruple Siamese Network

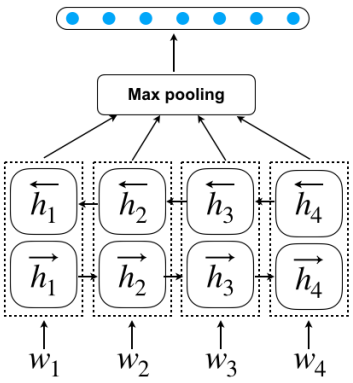

Figure 4: BiGRU with max pooling.

We recall that our focus is on learning an embedding function that pushes analogous QA pairs with similar mappings to be mutually close by enforcing a geometrical constraint in the vector space. This constraint states that the vector shift that maps the entities of the first pair should be similar to the vector shift of the second pair, according to the degree of analogical dissimilarity that holds between the two pairs $(a, b), (c, d)$.

To tackle this problem, we propose a Siamese network architecture as shown in Figure 5. In the next paragraphs, we describe the notation used and the details of each component of the model.

Notation. Let $\mathcal{Q}$ and $\mathcal{A}$ be the space of all questions and candidate answers. We denote a quadruple of sentences as (a, b, c, d), where $a, c \in \mathcal{Q}$ and $b, d \in \mathcal{A}$. Quadruples are assigned a label $y = 1$ if the analogical proportion holds, and 0 otherwise. θ denotes the parameters to be learnt that map the relation from a to b, and c to d respectively. Let $x.$ refer to the latent representation of one sentence in the quadruple.

Architecture. The Siamese network takes as input four sentences. The sub-networks in the Siamese model share the parameters and learn the vector representations for every sentence received as input. A sentence $S_i = w_{i1}, ...w_{ik}$ where w_{ij} represents the j^{th} word in the sentence S_i, $\forall i \in 1 \leq i \leq n$ and $\forall j \in 1 \leq j \leq k$. Words are mapped into word embeddings $x_{ij} = Ew_{ij}$, where $E^{d,|V|}$ is a matrix of vectors of size d, and V is the vocabulary. Out-of-vocabulary words are initialized by a random vector. We use bidirectional gated recurrent units (GRUs) (Cho et al., 2014) over the input sentence. For a sentence of T words, the network encodes T hidden states $h_1, ..., h_T$ such that:

$$\overrightarrow{h_t} = \overrightarrow{GRU}_t(w_1, ..., w_T)$$
$$\overleftarrow{h_t} = \overleftarrow{GRU}_t(w_1, ..., w_T)$$
$$h_t = [\overrightarrow{h_t}, \overleftarrow{h_t}]$$

In order to obtain a fixed-size vector, we select the maximum value over each dimension of h_t using max pooling. After this step, we obtain four vectors of dimension d, one for each input sentence of the quadruple.

Training Strategy. The next step is to get the semantic relation between the pairs of input sentences. Given a pair a vectors, (x_i, x_j), the arithmetic proportion expects the difference of the vectors to encode the relational similarity between the entities that constitutes the pair. We let the network predict four d-dimensional embedding vectors, which we merge through a pairwise subtraction. Let $f_W(\cdot)$ be the projection of an input sentence in the embedding space computed by the network function f_W. Furthermore, let

$$f_{ab} = f_W(a) - f_W(b) \quad (4)$$
$$f_{cd} = f_W(c) - f_W(d) \quad (5)$$

be the pairwise differences between the embedding vectors. In order to separate instances of analogical proportion, similar pairs need to be mapped mutually close to each other, whereas dissimilar instances should be pushed apart.

For the energy of the model, we use the cosine similarity between the vector shifts of each pair of the quadruple:

$$E_W(f_{ab}, f_{cd}) = \frac{f_{ab} \cdot f_{cd}}{\|f_{ab}\|\|f_{cd}\|} \quad (6)$$

We argue that this is an appropriate energy function since the goal is for the pairs of parallel vectors to be parallel which maximises the analogical parallelogram likelihood.

We propose to use the contrastive loss (Hadsell et al., 2006) to perform the metric learning. This loss function has two terms, one for the similar and and another dissimilar samples. The similar instances are denoted by a label $y = 1$ whereas the dissimilar pairs are represented by $y = 0$. Thus, the loss function has the following form:

$$\mathcal{L}_W = y\,\mathcal{L}_+(f_{ab}, f_{cd}) + (1-y)\mathcal{L}_-(f_{ab}, f_{cd}) \quad (7)$$

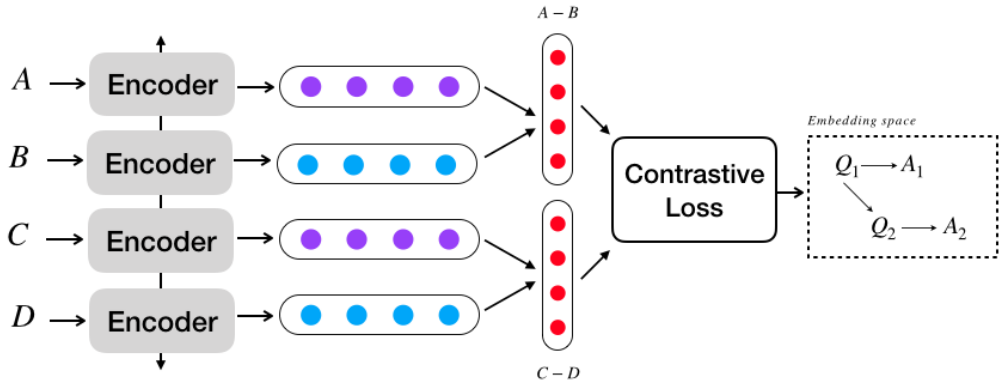

Figure 5: Siamese architecture.

Each term is expressed by:

$$\mathcal{L}_+(f_{ab}, f_{cd}) = (1 - E_W)^2 \quad (8)$$

$$\mathcal{L}_-(f_{ab}, f_{cd}) = \max((E_W - m)^2, 0) \quad (9)$$

This loss function measures how well the model learns to encode similar transformations such that analogous pairs are mutually close and form an analogical parallelogram in the embedding space, while pushing dissimilar transformations apart. Given a question and a pool of candidate answers, the goal is to rank the correct answer in the first position, based on how well each sentence completes the analogical equation according to (6).

This architecture is summarized in Figure 5. We learn all the parameters of the model through a gradient based method that minimizes the L2-regularized loss. Further details about the implementation are given in section 4.1.

4 Experiment

In this section, we present an evaluation of our approach in two experiments: first, in Section 4.2, we confirm that the found analogical embeddings do indeed improve the analogical parallelogram structure illustrated in Figure 2 over commonly used word- and sentence-based embeddings. In Section 4.3 we then show that this also results in improved performance for question answering. Before that, we start with a brief description of our experimental setup.

4.1 Experimental Setup

We begin the assessment of our model with a direct evaluation, which is ranking candidate answers in the same setting as during the training of the embedding. We generate quadruples with the same prototypes used for the training and we look for the correct answers by iteratively solving the analogical equations. We compare our model to commonly used sentence representations methods to evaluate the proposed approach results with respect to general purpose sentence embedding and word embedding methods. In the next paragraphs we present the experimental setup and the results obtained.

Datasets. We validate the proposed method on two datasets: WikiQA (Yang et al., 2015), an open domain QA dataset with answers collected over Wikipedia and TrecQA, which was created from the TREC Question Answer Track. Both resources are well established for benchmarking answer selection. We split each dataset into three subsets, which contain only "who", "where" and "when" questions. Table 2 reports the statistics of the two datasets.

	WikiQA			TrecQA		
type	train	dev	test	train	dev	test
"Who"	119	15	34	190	11	8
"When"	86	11	16	116	13	19
"Where"	71	17	22	96	9	11
Comb.	276	43	72	402	33	38

Table 2: Dataset by question type.

Evaluation metrics. We assess the performance of our method by measuring the Mean Average Precision (MAP) and the Mean Reciprocal Rank (MRR) for the generated quadruples in the test set. Given a set of questions Q, MRR is computed as follows:

$$\text{MRR} = \frac{1}{|Q|} \sum_{i=1}^{|Q|} \frac{1}{rank_i} \quad (10)$$

where $rank_i$ represents the rank position of the first correct candidate answer for the i^{th} question. In other words, MRR is the average of the reciprocal ranks of results for the questions in set Q.

MAP is calculated as follows:

$$\text{MAP} = \frac{1}{|Q|}\sum_{j=1}^{|Q|}\frac{1}{m_j}\sum_{k=1}^{|m_j|}\text{Precision}(\pi_{jk}) \quad (11)$$

where $q_j \in Q$ is a question whose candidate answers are $a_1, ..., a_{m_j}$ and π_{jk} is the rank associated with those candidate answers. While MRR measures the rank of any correct answer, MAP computes the rank of all correct answers. Generally, MRR is higher than MAP on the same set of ranked objects.

Implementation details. We initiate the embedding layer with FastText vectors. These weights are not updated during training. The dimension of the output of the sentence encoder is 300. For alleviating overfitting we apply a dropout rate of 0.5. The model is trained with Adam optimizer with a learning rate of 0.001 and a weight decay rate of 0.01.

4.2 Quality of Analogical Embedding

Baselines. To support our claim that the learnt representations of our model encode the semantic of question answer pairs better than pre-trained sentence representation models, we choose four baselines commonly used to encode sentences:

1. *Word2Vec and Glove* (Mikolov et al., 2013; Pennington et al., 2014): We use the simple approach of averaging the word vectors for all words in a sentence. This method has the drawback of ignoring the order of the words of the sentence, but has shown to perform reasonably well.

2. *InferSent* (Conneau et al., 2017): Sentence embeddings obtained from training on Natural Language Inference dataset.

3. *Sent2Vec* (Pagliardini et al., 2017): A method to learn sentence embeddings such that the average of all words and n-grams can serve as sentence vector.

For each document in test set, we generate analogical quadruples as explained in section 3.2. Given a question q_i in the test set with k candidate answers, we obtain $p \times k$ possible quadruples, where p is the cardinality of the prototype set. The network encodes each sentence in the quadruple and computes the cosine similarity (6) between the obtained vector shifts.

Not every prototype QA pair will fit to the QA pair at hand, so we compute $p \times m$ scores, and choose only the prototype that leads to the highest analogical score for each document and discard the other comparisons. One might think about using the average of the scores and sorting the candidate answers accordingly, but this strategy introduces noise in the analogical inference procedure.

Results. We applied the described procedure to vectors obtained from our network as well as from the baseline representation methods. The results are shown in Table 3.

In order to better perceive the analogical properties of the baselines and the proposed approach, we also include a random baseline in the comparison. We observe that averaging word embeddings such as Glove or Word2Vec performs better than the dedicated sentence representations in the WikiQA dataset. This might be due to the fact that word embeddings have shown to encode some analogical properties. On the other hand, sentence embeddings have been trained with a particular learning objective, for example, InferSent has been train for the task of claim entailment with a classification objective and might not be suitable for representing relations between pairs of sentences. Nevertheless, ranking by the cosine similarity of the difference vectors do not lead to acceptable performances. This confirms our hypothesis that pre-trained sentence representation do not preserve analogical properties.

Similarly, we measure the influence of the number of prototypes on the performances.

	Model	WikiQA	
		MAP	MRR
W.E	Glove	0.464	0.475
	Word2Vec	0.4329	0.453
S.E	InferSent	0.399	0.404
	Sent2Vec	0.481	0.486
	This work	**0.6771**	**0.6841**

Table 3: Evaluation on quadruples. W.E. indicates averaging over word embeddings approach. S.E indicates dedicated sentence embeddings.

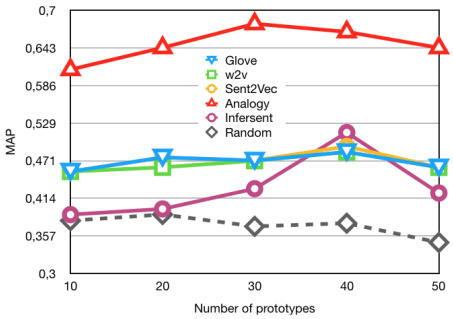

Figure 6: MAP for different number of prototypes.

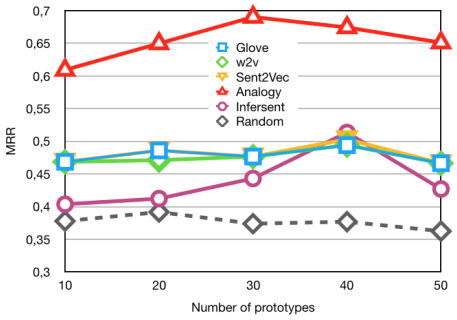

Figure 7: MRR for different number of prototypes.

We vary the number of prototypes pair $p \in \{10, 20, 30, 40, 50\}$ and measure the MAP and the MRR for both datasets. The results are shown in Figures 6 and 7. We can observe that the best performances are obtained for $p = 30$ and that after both MAP and MRR decrease. The reason might be that a high number of prototypes brings more comparisons and increases the probability of spurious interactions between QA prototypes and QA pairs.

4.3 Question-Answering Performance

A natural benchmark model for our work is the approach of Tam et al. (2017), which is similar to ours in that it proposed to replace wh-word in questions with appropriate named entities. This approach leverages typological information from a named entity recognizer and the word vector space.

It showed that simply replacing the wh-word, with a named entity that has the highest cosine similarity with all the candidate answers for a given question. This substitution is operated for ”where”, ”when” and ”who” types of questions. Finally, the transformed QA pair is fed to a network suited for the task of answer selection. This study demonstrated that this simple pre-processing step improves the state of the art results for the task of answer selection.

Alike our experimental setup, they divide the dataset in three categories, namely ”when”, ”who” and ”where”, which is the same division we used for our experimental setup, and evaluate their method on the split dataset and the full dataset. We will consider their work as our baseline in order to evaluate the capabilities of the analogy based embeddings. Moreover, we compare our approach to a setup which doesn't exploit analogical properties. This is to say, a Siamese network that takes as input a question and a candidate answer, generate the respective representations and compute the cosine similarity of the obtained sentence embeddings. The described baseline corresponds to the model proposed by (Tan et al., 2015) except for the fact that we use BiGRU for fair comparison.

	WikiQA		
	Baseline	Tam et al.	Analogy
”Who”	0.663	0.702	**0.763**
”When”	0.582	0.664	**0.701**
”Where”	0.568	**0.616**	0.602
Comb.	0.609	0.678	**0.684**

Table 4: MRR on WikiQA.

	TrecQA		
	Baseline	Tam et al.	Analogy
”Who”	0.787	0.781	**0.981**
”When”	0.797	**0.921**	0.863
”Where”	0.894	0.864	**0.929**
Comb.	0.837	0.875	**0.909**

Table 5: MRR on TrecQA.

The results are shown in Tables 4 and 5.

We observe that simply computing the cosine similarity between the difference vector of the prototype QA pair and the QA pair at hand with the learnt embedding from the proposed approach lead to significant improvements for some particular type of questions. The bold numbers in Tables 4 and 5 indicate the best results for each dataset. We can see that our method improves the MRR of at least two of questions types by a relevant margin. The last row of the same tables confirms that enforcing analogical properties in the embedding space generally improves the overall MRR for these three subsets.

5 Conclusion

This work introduced a new approach to learn sentence representations for answer selection, which preserve structural similarities in the form of analogies. Analogies can be seen as a way of injecting reasoning ability, and we express this by requiring common dissimilarities implied by analogies to be reflected in the learned feature space. We showed that explicitly constraining structural analogies in the learnt embeddings leads to better results over the distance-only embeddings. We believe that it is worth-while to further explore the potential of analogical reasoning beyond their common use in word embeddings, as it is a natural mean of learning and generalizing about relations between entities. The focus of this work has been on answer selection, but analogical reasoning can be useful in many other machine learning tasks such as machine translation or visual question answering. As a next step, we plan to explore other forms of analogies that involve modelling across domains.

Abstract

We propose a simple and effective method to inject word-level information into character-aware neural language models. Unlike previous approaches which usually inject word-level information at the input of a long short-term memory (LSTM) network, we inject it into the softmax function. The resultant model can be seen as a combination of character-aware language model and simple word-level language model. Our injection method can also be used together with previous methods. Through the experiments on 14 typologically diverse languages, we empirically show that our injection method, when used together with the previous methods, works better than the previous methods, including a gating mechanism, averaging, and concatenation of word vectors. We also provide a comprehensive comparison of these injection methods.

1 Introduction

Language modeling (LM) is an important task in the natural language processing field, with various applications such as speech recognition (Mikolov et al., 2010a), machine translation (Koehn, 2009) and summarization (Filippova et al., 2015). Recently, neural language models (NLMs) have shown a great success and are better than traditional count-based methods (Bengio et al., 2003; Mikolov et al., 2010b). Standard NLMs usually maintain a fixed vocabulary and map each word to a continuous representation. These word representations obtained through NLMs are usually close to each other in the induced vector space if they are semantically similar. However, there are two main problems of standard NLMs. One is that they cannot handle out-of-vocabulary words. These words are usually replaced with a special unknown symbol. Another problem is that these models are not effective for learning the relationships between words for infrequent words. For example, although words "husbandman" and "salesman" share the suffix "man" in their surface forms, standard NLMs cannot capture such information in obtaining the relationship between the two words. A common way to deal with these issues is to use character information of each word to calculate the word representation, and it is often referred to as character-aware NLMs (Ling et al., 2015; Kim et al., 2016; Vania and Lopez, 2017; Gerz et al., 2018). Our research focuses on utilizing advantages of both character-level information and word-level information in character-aware NLMs.

Previous work usually combines word-level information and character-level information at the input of LSTM layers through a gating mechanism, or averaging or concatenation of word vectors. Because these approaches generally target at the input vectors, the word-level information cannot be explicitly taken into account at the output layer for predicting the next word.

To deal with this problem, we propose an improved character-aware neural language model that takes into account the injected word-level information at the output layer. This model is strongly inspired by the success of n-gram language models. Our model can predict the next word using the embeddings of the words in the current n-gram window, in addition to the hidden state of the LSTM layer. Specifically, we also use a gate to control how much word-level information should be taken before injecting it into the softmax function. After that, we combine the gated word-level information with the output of LSTM. Lastly, we feed these mixed information to the softmax function for word prediction. In our method, we can also take into account the information of previous words when injecting word-level information into the softmax function.

Our injection method is simple and easy to im-

plement [1]. We found our method effective compared with several common previous methods on 14 datasets with typologically diverse languages. In addition, the improvements can be further obtained when our injection method is used together with the previous methods. We also conducted a comprehensive comparison of these injection methods. Finally, we set up several experiments to check the effects of infrequent words on our model, and we also compared our model with several previous work on 6 common language modeling datasets. Our results show that:

- Compared with the previous injection methods (i.e., the gating mechanism, averaging, addition, and concatenation of word vectors), our injection method performs best on the majority of languages.

- Our injection method works effectively even when used alone, and the combination of our injection method and the previous injection methods performs better than the previous injection methods.

- When injecting word-level information into character-aware NLMs, discarding rare words in the training data can help improve the performance.

2 Related Work

Many work have attempted to improve character-aware NLMs in recent years. For example, Assylbekov and Takhanov (2018) proposed several ways of reusing weights in character-aware NLMs. Gerz et al. (2018) achieved an improved result on 50 typologically diverse languages by injecting subword-level information into word vectors at the softmax. For a thorough review of past researches, readers are recommended to read the work by Vania and Lopez (2017), who performed a systematic comparison across different models based on different subword units (characters, character trigrams, BPE, etc.).

One direction related to our research is to inject word-level information into character-aware neural models. Aside from language modeling, Santos and Zadrozny (2014) and dos Santos and Guimarães (2015) first used a convolutional neural network (CNN) to encode characters and then concatenated these encoded character-level representations and word-level representations for part-of-speech tagging and named entity recognition. Luong and Manning (2016) introduced a character-word neural machine translation model that only consults character-level representations for rare words encoded with a deep LSTM.

As research efforts for language models, Kang et al. (2011) used a simple character-word NLM designed for Chinese. Miyamoto and Cho (2016) introduced a gate mechanism between word embeddings and character embeddings obtained from a bidirectional LSTM (BiLSTM) for English. Verwimp et al. (2017) directly concatenated word and character embeddings without other subnetworks to encode the characters for English and Dutch.

Although there are a number of research efforts for using both character-level and word-level information, they feed the two types of information only to LSTM, while our model also injects the word-level information into the softmax function. Previous work on this topic has usually been tested in a limited number of languages and lacks a comprehensive comparison of different injection methods. We will compare our method with the previous methods mentioned in this section on 14 typologically diverse languages.

3 Model Description

For language modeling, we basically use a LSTM network (Hochreiter and Schmidhuber, 1997). We denote the hidden state of LSTM for the t-th word w_t as $\mathbf{h}_t \in \mathbb{R}^d$, where d is the embedding size. We incorporate word-level information using the neural network shown in Figure 1. We describe the details in the following subsections.

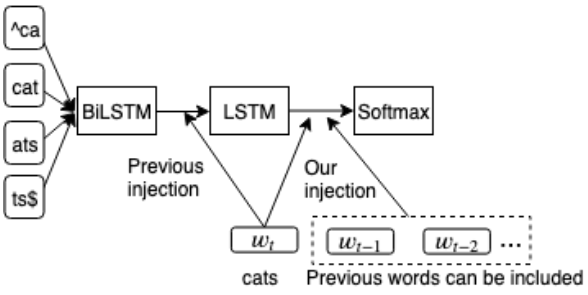

Figure 1: Our character-aware LSTM language model with injection of word-level information with an example word "cats". Symbols ^ and $ respectively represent the start and the end of a word.

[1] https://github.com/yukunfeng/char_word_lm

3.1 Input Word Representations

We use BiLSTM to encode character n-grams to obtain character-level representation. We set n to 3 for all the languages except Japanese and Chinese, for which we set n to 1. This is because BiLSTM over character 3-grams obtained best results on most LM datasets in the work of Vania and Lopez (2017), but Japanese and Chinese are more ideographic than the others, and it is expected that a smaller n works better.

Given a word w_t, we denote its embedding from a lookup table $\mathbf{W}_{in} \in \mathbb{R}^{d \times |V|}$ as $\mathbf{w_t} \in \mathbb{R}^d$, where $|V|$ is the vocabulary size. We compute the character-level representation of w_t as follows:

$$\mathbf{c}_t = \mathbf{W}_f \mathbf{h}_l^{fw} + \mathbf{W}_b \mathbf{h}_0^{bw} + \mathbf{b}, \quad (1)$$

where $\mathbf{h}_l^{fw}$, $\mathbf{h}_0^{bw} \in \mathbb{R}^d$ are the last states of the forward and backward LSTMs respectively. $\mathbf{W}_f$, $\mathbf{W}_b \in \mathbb{R}^{d \times d}$ and $\mathbf{b} \in \mathbb{R}^d$ are trainable parameters. We define the following methods to obtain the combination $\mathbf{w}'_t$ from $\mathbf{w}_t$ and $\mathbf{c}_t$:

- **gate**: we use the same gating mechanism as Miyamoto and Cho (2016), which is described later to combine $\mathbf{w}_t$ and $\mathbf{c}_t$.
- **avg, add, cat**: we obtain $\mathbf{w}'_t$ through averaging, addition and concatenation of $\mathbf{w}_t$ and $\mathbf{c}_t$, respectively.

In the gating mechanism, we compute $\mathbf{w}'_t$ as follows:

$$g_{w_t}^{in} = \sigma\left(\mathbf{v}_g^\top \mathbf{w}_t + b_g\right), \quad (2)$$

$$\mathbf{w}'_t = (1 - g_{w_t}^{in})\mathbf{w}_t + g_{w_t}^{in}\mathbf{c}_t, \quad (3)$$

where $\mathbf{v}_g \in \mathbb{R}^d$ and $b_g \in \mathbb{R}$ are trainable parameters and $\sigma(\cdot)$ is a sigmoid function.

3.2 Representation of Input to Softmax

Our proposal is to combine $\mathbf{h}_t$ with $\mathbf{w_t}$ to better inform the softmax function of word-level information. Combination $\mathbf{h}'_t$ is computed as follows:

$$\mathbf{h}'_t = \mathbf{h}_t + g_{w_t}^{out}\mathbf{w}_t, \quad (4)$$

where $g_{w_t}^{out}$ is a gate value. In our experiments, we set up two types of gate. One is a fixed value, $g_{w_t}^{out} = 0.5$. The other is similar to the definition in Eq. (2), which adaptively outputs a gate value depending on w_t:

$$g_{w_t}^{out} = \sigma\left(\mathbf{v}_k^\top \mathbf{w}_t + b_k\right), \quad (5)$$

where $\mathbf{v}_k^\top \in \mathbb{R}^d$ and $b_k \in \mathbb{R}$ are trainable parameters. In Eq. (4), the gate is used only on word-level information to decide how much information $\mathbf{w}_t$ should be taken [2].

In Eq. (4), if we remove the term $\mathbf{h}_t$, the resultant model is a simple word-level language model $P(w_{t+1}|w_t)$. Based on this observation, we can simply extend our method to contain the word-level information for previous words without extra parameters:

$$\mathbf{h}_t^{word} = \sum_{i=1}^{n} \frac{1}{i}\mathbf{w}_{t+1-i}, \quad (6)$$

where n is the number of the current and previous words used to calculate $\mathbf{h}_t^{word}$. We simply give smaller weights inversely proportional to distance i to the embeddings of the previous words. For example, when $n = 2$, $\mathbf{h}_t^{word}$ is computed as $\mathbf{w}_t + \frac{1}{2}\mathbf{w}_{t-1}$, which is used to calculate $P(w_{t+1}|w_t, w_{t-1})$. The hidden state $\mathbf{h}'_t$ now can be calculated as follows:

$$\mathbf{h}'_t = \mathbf{h}_t + g_{w_t}^{out}\mathbf{h}_t^{word}. \quad (7)$$

3.3 Language Modeling

The language modeling task is to compute the probability of a given sentence $w_1, \ldots, w_T$:

$$P(w_1, \ldots, w_T) = \prod_{t=1}^{T} P(w_t|w_1, \ldots, w_{t-1}). \quad (8)$$

We use a softmax function based on $\mathbf{h}'_t$ to generate a probability distribution over the vocabulary:

$$P(w_{t+1}|w_1, \ldots, w_t) = \text{softmax}(\mathbf{W}_{out}^T \mathbf{h}_t{}'), \quad (9)$$

where $\mathbf{W}_{out} \in \mathbb{R}^{d \times |V|}$ is output word embeddings.

4 Model Variants

The hyper-parameters of our models are shown in Table 1. The learning rate is decreased if no improvement is observed in the validation dataset. Several baseline models and our models are listed as follows:

- **Char-BiLSTM-LSTM**: We use BiLSTM to encode characters without injecting word-level information.

[2] We have tested the above other methods, such as avg, add and cat, for combining $\mathbf{h}_t$ and $\mathbf{w}_t$, in place of gate, and found these methods did not work well.

Embedding size d	650
LSTM layers	2
Dropout	0.5
Optimizer	SGD
Learning rate	20
Learning rate decay	4
Parameter init: rand uniform	[-0.1,0.1]
Batch size	20
LSTM sequence length	35
Gradient clipping	0.25
Epochs	40

Table 1: Hyper-parameters of our model. We use d for the sizes of the character/word embeddings and for the number of hidden units of LSTM and BiLSTM.

- **Word-LSTM**: Standard word-level LSTM model.

- **Char-BiLSTM-gate/avg/add/cat-Word-LSTM**: We combine character-level and word-level information at the input of LSTM through gate/avg/add/cat methods, mentioned in Sec. 3.1.

- **Char-BiLSTM-LSTM-Word**: We inject word-level information only into the softmax function. This is our injection method.

- **Char-BiLSTM-gate/avg/add/cat-Word-LSTM-Word**: We combine our injection method and previous injection methods, which means we inject word-level information both at the input of LSTM and into the softmax function.

For both Char-BiLSTM-LSTM-Word and Char-BiLSTM-gate/avg/add/cat-Word-LSTM-Word, we use $g = 0.5$/adaptive and $n = 1/2/3$ to represent our specific injection method. For example, Char-BiLSTM-LSTM-Word ($g = 0.5, n = 2$) represents that we use a fixed gate value on word-level information in Eq. (4) and we inject the information of the current word and the preceding word into the softmax function.

5 Experiments on 14 Languages

5.1 Datasets

Common language modeling datasets for evaluating character-aware NLMs are from the work of Botha and Blunsom (2014). While these datasets contain languages with rich morphology, they have only 5 different languages. Perhaps, the most large-scale language modeling datasets are from the work of Gerz et al. (2018), who released 50 language modeling datasets covering typologically diverse languages. The difference between the newly released datasets and the previous common datasets is that unseen words are kept in test set. Thus, on the datasets, we can test our methods in a real LM setup. The languages from the work of Gerz et al. (2018) were selected to represent a wide spectrum of different morphological systems and contain many low-frequency or unseen words. Thus, these datasets should be desirable for checking the performance of character-aware NLMs [3].

To simplify the experiments without losing the wide coverage, we only chose datasets of 14 languages from these datasets and tried to cover different language typologies as well as different type/token ratios (TTRs). The statistics of our chosen datasets are shown in Table 2. We used all the words observed in training data and one special unknown token for out-of-vocabulary words as the output vocabulary to make the setting the same as Gerz et al. (2018).

5.2 Comparison of Baseline Models

The results of Word-LSTM and Char-BiLSTM-LSTM are shown in Table 3. We also showed the results of Word-LSTM and Char-CNN-LSTM from the work of Gerz et al. (2018). The embedding size and the number of LSTM layers are the same as those for the models in Gerz et al. (2018). As shown in the table, both the Word-LSTM and Char-BiLSTM-LSTM baselines are better than the Word-LSTM and Char-CNN-LSTM from the work of Gerz et al. (2018) on all the datasets [4]. Both Char-BiLSTM-LSTM and Char-CNN-LSTM from Gerz et al. (2018) are better than their respective Word-LSTM on all the datasets. One possible reason is that all the unseen words in the test set in the 14 datasets cannot be handled by Word-LSTM in the testing phase. However, character-aware models can encode the characters from these unseen words, making them possible to process these words. It is also shown that as TTR increases, Char-BiLSTM-LSTM achieves the better result than Word-LSTM. This may be because high-TTR languages have more low-frequency words and unseen tokens, as shown in Table 2. Since frequent

[3] To test our models against previous work, we also include experiments on common datasets, as described later.

[4] We have made the experimental setting the same as that of the work of Gerz et al. (2018), and the perplexity scores are comparable.

words still occupy the majority of both training and test data, injecting word-level information is still helpful for improving these character-aware models, as shown below.

5.3 Comparison of Different Injection Methods

The results of all the other different injection methods on 14 language modeling datasets are also shown in Table 3. In our experiments, Char-BiLSTM-gate-Word-LSTM underperforms Char-BiLSTM-LSTM on all the datasets. This indicates the gate method is not effective in our experiments. Char-BiLSTM-cat-Word-LSTM achieves better results than Char-BiLSTM-gate-Word-LSTM on all the datasets, but still underperforms Char-BiLSTM-LSTM on 8 out of 14 datasets. Char-BiLSTM-avg-Word-LSTM outperforms Char-BiLSTM-cat-Word-LSTM on 9 out of 14 datasets, which indicates the simple average method is better than the gating mechanism and the concatenation method in our tasks. However, Char-BiLSTM-avg-Word-LSTM still has no obvious improvements, compared with Char-BiLSTM-LSTM on most datasets.

We found some previous work also has similar results in the language modeling task. Kim et al. (2016) used a Char-CNN-LSTM model without injecting word-level information. They reported that some basic methods (e.g., concatenation, averaging and adaptive weighting schemes) for injecting word-level information degraded the performance of their Char-CNN-LSTM. Miyamoto and Cho (2016) showed the concatenation method for injecting word-level information into their Char-BiLSTM-LSTM also degraded their Word-LSTM model.

Char-BiLSTM-add-Word-LSTM achieves more improved results than Char-BiLSTM-LSTM on 13 out of 14 datasets and also performs best in general among Char-BiLSTM-avg/add/gate/cat-Word-LSTM. The addition method works better

than other previous injection methods in general in our tasks, while this simple method is less mentioned in the previous work. In conclusion, the performance of the previous injection methods in our experiments was in the descending order of add, avg, cat and gate.

Our Char-BiLSTM-LSTM-Word ($g = 0.5, n = 1$) and Char-BiLSTM-LSTM-Word ($g = \text{adaptive}, n = 1$) work effectively, and both of them achieve better results than Char-BiLSTM-LSTM. A simple fixed gate value in our injection method may be effective enough. Char-BiLSTM-LSTM-Word ($g = 0.5, n = 1$) works better than Char-BiLSTM-LSTM-Word ($g = \text{adaptive}, n = 1$) on most datasets. When compared with other injection methods, Char-BiLSTM-LSTM-Word ($g = 0.5, n = 1$) achieves the best results on most datasets (bold scores in Table 3). This suggests that our injection method, aiming at the different position from the input of LSTM, the softmax function, makes good use of word-level information.

5.4 Combination of Injection Methods

To avoid too many combinations of our injection method and other previous methods, we only chose to combine our Char-BiLSTM-LSTM-Word ($g = 0.5, n = 1$) with the other previous injection methods, because Char-BiLSTM-LSTM-Word ($g = 0.5, n = 1$) performs better than Char-BiLSTM-LSTM-Word ($g = \text{adaptive}, n = 1$), as mentioned above. The results of the combination of our Char-BiLSTM-LSTM-Word ($g = 0.5, n = 1$) and the previous injection methods are shown in Table 4.

When our injection method is used together with gate/avg/cat/add methods, obvious improvements can be observed on most datasets. Among them, Char-BiLSTM-add-Word-LSTM-Word ($g = 0.5, n = 1$) obtained the best results on most datasets (bold scores in Table 4). The result indicates that the previous injection methods do not make full use of word-level information, while our method, which injects the word-level information into the different position, specifically, the softmax, can help the previous models make better use of the word-level information.

5.5 Including Word-level Information for Previous Words

As mentioned in Sec. 3.1, we can include word-level information for previous words when injecting it into the softmax function. The number of words used in our injection method is denoted by n. In our experiments, we only set n to 1, 2 and 3, as we observed no obvious improvements when using a larger n. Since Char-BiLSTM-add-Word-LSTM-Word ($g = 0.5, n = 1$) performs best in general on most datasets, as mentioned above, we only changed n for this model. Note that our Char-BiLSTM-add-Word-LSTM-Word ($g = 0.5, n = 2/3$) does not need extra parameters as we just reuse the word embeddings from the lookup table $\mathbf{W}_{in}$ to compute word-level information. In addition, the computational time of our injection method should be low, since the involved computation is simple. The result is shown in Table 5.

In general, Char-BiLSTM-add-Word-LSTM-Word ($g = 0.5, n = 2$) achieves the best result on most datasets. Char-BiLSTM-add-Word-LSTM-Word ($g = 0.5, n = 3$) does not obtain further improvements on most datasets. Since our current method for including word-level information for previous words is simple, a more advanced method can be further exploited in future work.

5.6 Effects of Infrequent Words

In order to check whether infrequent words help our character-aware NLMs, we set up several experiments by discarding some infrequent words based on their word frequency. Note that we maintain two independent vocabularies. One is the input vocabulary and is used to inject word-level information. We obtain the word embeddings in our and previous injection methods through the lookup table $\mathbf{W}_{in}$, as described in Sec. 3.1. The other is the output vocabulary and is used for word prediction, as described in Sec. 3.3. When we discard the infrequent words, we only narrow down the input vocabulary and do not change the output vocabulary. Thus, the perplexity scores are still comparable with the scores in the above experiments. For example, when our model processes the sentence "the salesman brought some samples" in training phase, where 'salesman' is an infrequent word in training data, our model can still try to predict the word 'salesman' given the previous word 'the', because 'salesman' is in our output vocabulary. When inputting the word 'salesman' to predict the word 'brought', we do not inject word-level information for the word 'salesman'. We only use its character-level representation obtained through our BiLSTM over characters to perform the lan-

guage modeling task.

We denote the frequency threshold as θ and set its value among 5, 15 and 25. If the frequency of a word seen in the training data is less than or equal to θ, we discard it. We refer the model that discards infrequent words as Char-BiLSTM-add-Word-LSTM-Word ($g = 0.5, n = 1, \theta = 5/15/25$). The result is shown in Table 7.

When discarding the words whose frequency is less than or equal to 15, the model obtains better results only on 2 out of 14 datasets than Char-BiLSTM-add-Word-LSTM-Word ($g = 0.5, n = 1$). This indicates some infrequent words are still helpful. When we increase the frequency threshold further to 25, the performance of the model has dropped compared with Char-BiLSTM-add-Word-LSTM-Word ($g = 0.5, n = 1, \theta = 15$) as more frequent words are discarded. However, we found a relatively small frequency threshold $\theta = 5$ works quite effectively. Char-BiLSTM-add-Word-LSTM-Word ($g = 0.5, n = 1, \theta = 5$) achieves better results than Char-BiLSTM-add-Word-LSTM-Word ($g = 0.5, n = 1$) on 7 out of 14 datasets. It seems to be the trend that discarding infrequent words with $\theta = 5$ is useful for high TTR languages. Note that we arranged our datasets from low TTR to high TTR in Table 7. Since many of the words in natural languages are rare as described in Zipf's law, we can reduce the size of the input vocabulary significantly even with a small θ. The size for the full input vocabulary and the reduced vocabulary with different frequency threshold value is shown in Table 8. As we can see, when θ is set to 5, our model achieves better results with fewer parameters.

6 Experiments on 6 Common Datasets

In addition to the above datasets, we also set up 6 common language modeling datasets: English Penn Treebank (PTB) (Marcus et al., 1993) and 5 non-English datasets with rich morphology from the 2013 ACL Workshop on Machine Translation[5], which have been commonly used for evaluating character-aware NLMs (Botha and Blunsom, 2014; Kim et al., 2016; Bojanowski et al., 2017; Assylbekov and Takhanov, 2018). Since some of previous work has tested their model on PTB, we also included PTB in our experiment. We used the preprocessed small version of non-English datasets by Botha and Blunsom (2014) and followed the same split as the previous work. The data statistics is provided in Table 9.

The results of our proposed models and previous work are shown in Table 6. We used Char-BiLSTM-LSTM and Char-BiLSTM-add-Word-LSTM as baseline models. For our models, we set the frequency threshold θ to 5 and also set n to 2 as these settings help improve our character-aware NLMs, as discussed in Sec. 5.6 and Sec. 5.5. The language models used in the previous work are improved at different aspects, and most of them are also based on standard LSTM, like ours. Botha

Table 9: The data statistics of our 6 language modeling datasets.

and Blunsom (2014) used the morphological log-bilinear (MLBL) model, which takes into account morpheme information. Kim et al. (2016) used CNN as their character encoder, and also trained an LSTM language model, where the input representation of a word is the sum of the morpheme embeddings of the word. Bojanowski et al. (2017) trained the word embeddings through skip-gram models with subword-level information, and used these word embeddings to initialize the lookup table of word embeddings of a word-level language model. Assylbekov and Takhanov (2018) focused on reusing embeddings and weights in a character-aware language model. The input of their model is also the sum of the morpheme embeddings of the word. As shown in the table, Char-BiLSTM-LSTM underperforms the previous work on PTB. One reason may be that we did not tune the hyper-parameters of our models on PTB. The hyper-parameters were simply kept the same in all the experiments on 20 datasets. As we can see, Char-BiLSTM-LSTM achieves better results than most previous work on non-English datasets. Our models also achieve the best results on non-English datasets.

7 Conclusion

In addition to combining character-level and word-level information at the input of LSTM,

which is a widely used combination manner, we proposed to also inject word-level information into the softmax function in a character-aware neural language model. We gave a detailed comparison with previous methods, and the result showed our proposal works effectively on typologically diverse languages. For future work, it would be interesting to see how our model works for other tasks such as text generation.

Acknowledgments

We would like to thank anonymous reviewers for their constructive comments.

On Model Stability as a Function of Random Seed

Abstract

In this paper, we focus on quantifying model stability as a function of random seed by investigating the effects of the induced randomness on model performance and the robustness of the model in general. We specifically perform a controlled study on the effect of random seeds on the behaviour of attention, gradient-based and surrogate model based (LIME) interpretations. Our analysis suggests that random seeds can adversely affect the consistency of models resulting in counterfactual interpretations. We propose a technique called *Aggressive Stochastic Weight Averaging (ASWA)* and an extension called *Norm-filtered Aggressive Stochastic Weight Averaging (NASWA)* which improves the stability of models over random seeds. With our ASWA and NASWA based optimization, we are able to improve the robustness of the original model, on average reducing the standard deviation of the model's performance by 72%.

1 Introduction

There has been a tremendous growth in deep neural network based models that achieve state-of-the-art performance. In fact, most recent end-to-end deep learning models have surpassed the performance of careful human feature-engineering based models in a variety of NLP tasks. However, deep neural network based models are often brittle to various sources of randomness in the training of the models. This could be attributed to several sources including, but not limited to, random parameter initialization, random sampling of examples during training and random dropping of neurons. It has been observed that these models have, more often, a set of *random seeds* that yield better results than others. This has also lead to research suggesting random seeds as an additional hyper-parameter for tuning (Bengio, 2012)[1]. One possible explanation for this behavior could be the existence of multiple local minima in the loss surface. This is especially problematic as the loss surfaces are generally non-convex and may have multiple saddle points making it difficult to achieve model stability.

if high crimes were any more generic it would have a universal product code instead of a title

$(\Pr(Y_{negative}) = 0.98)$

Figure 1: Importance based on attention probabilities for two runs of the same model with **same parameters and same hyperparameters**, but with **two different random seeds** (color magnitudes: pink<magenta<red)

Recently the NLP community has witnessed a resurgence in interpreting and explaining deep neural network based models (Jain et al., 2019; Jain and Wallace, 2019; Alvarez-Melis and Jaakkola, 2017). Most of the interpretation based methods involve one of the following ways of interpreting models: a) sample oriented interpretations: where the interpretation is based on changes in the prediction score with either upweighting or perturbing samples (Jain et al., 2019; Jain and Wallace, 2019; Koh and Liang, 2017); b) interpretations based on feature attributions using attention or input perturbation or gradient-based measures; (Ghaeini et al., 2018; Feng et al., 2018; Bach et al., 2015); c) interpretations using surro-

gate linear models (Ribeiro et al., 2016) – these methods can provide local interpretations based on input samples or features. However, the presence of inherent randomness makes it difficult to accurately interpret deep neural models among other forms of pathologies (Feng et al., 2018).

In this paper, we focus on the stability of deep neural models as a function of random-seed based effects. We are especially interested in investigating the hypothesis focusing on model stability: do neural network based models under different random seeds allow for similar interpretations of their decisions? We claim that for a given model which achieves a substantial performance for a task, the factors responsible for any decisions over a sample should be approximately consistent irrespective of the random seed. In Figure 1, we show an illustration of this question where we visualize the attention distributions of two CNN based binary classification models for sentiment analysis, trained with the same settings and hyper-parameters, but with *different seeds*. We observe that both models obtain the correct prediction with significantly high confidence. However, we note that both the models attend to completely different sets of words. This is problematic, especially when interpreting these models under the influence of such randomness. We observe that on average $40-60\%$ of the most important interpretable units are different across different random seeds for the same model. This phenomenon also leads us to the question on the exact nature of interpretability – are the interpretations specific to an instantiation of the model or are they general to a class of models?

We also provide a simple method that can, to a large extent, ameliorate this inherent random behaviour. In Section 3.1, we propose an aggressive stochastic weight averaging approach that helps in improving the stability of the models at almost zero performance loss while still making the model robust to random-seed based instability. We also propose an improvement to this model in Section 3.2 which further improves the stability of the neural models. Our proposals significantly improve the robustness of the model, on average by 72% relative to the original model and on Diabetes (MIMIC), a binary classification dataset, by 89% (relative improvement). All code for reproducing and replicating our experiments is released in our repository[2].

2 Measuring Model Stability

In this section, we describe methods that we use to measure model stability, specifically — prediction and interpretation stability.

2.1 Prediction Stability

We measure prediction stability using standard measures of the mean and the standard deviations corresponding to the accuracy of the classification based models on different datasets. We ensure that the models are run with exactly the same configurations and hyper-parameters but with different random seeds. This is a standard procedure that is used in the community to report the performance of the model.

2.2 Interpretation Stability

For a given task, we train a set of models only differing with random-seeds. For every given test sample, we obtain interpretations using different instantiations of the models. We define a model to be stable if we obtain similar interpretations regardless of different random-seed based instantiations. We use the following metrics to quantify stability:

a) **Relative Entropy quantification ($\mathcal{H}$):** Given two distributions over interpretations, for the same test case, from two different models, it measures the relative entropy between the two probability distributions. Note that, the higher the relative entropy the greater the dissimilarity between the two distributions.

$$\mathcal{H} = \sum_{i \in d} \mathrm{Pr}_1 \cdot \log \frac{\mathrm{Pr}_1}{\mathrm{Pr}_2}$$

where, Pr_1 and Pr_2 are two attention distributions of the same sample from two different runs of the model and d is the number of tokens in the sample. Given n differently seeded models, for each test instance, we calculate the relative entropy obtained from the corresponding averaged pairwise interpretation distributions.

b) **Jaccard Distance ($\mathcal{J}$):** It measures the dissimilarity between two sets. Here higher values of $\mathcal{J}$ indicate larger variances. We consider top-n tokens which have the highest attention for comparison. Note that, Jaccard distance is over sets of

[2] https://github.com/rishj97/ModelStability

word indices and do not take into account the attention probabilities explicitly. Jaccard distance is defined as:

$$\mathcal{J} = (1 - \frac{A \cap B}{A \cup B}) * 100\%$$

where, A and B are the sets of most relevant items. We specifically decided to use 'most' relevant (top-n items) as the tail of the distribution mostly consists of values close to 0.

Interpretation methods under study: In this paper we study interpretation stability using the following three interpretation methods:

1. *Attention based interpretation:* We focus on attention probabilities as the mode of interpretation and consider the model to be stable if different instantiations of the model leads to similar attention distributions. Our major focus in this paper is attention based interpretation. As we use Jain et al. (2019) as a testbed for our investigation, we focus heavily on attention. Also, as the attention layer has a linear relationship with the prediction, we consider attention to be more indicative of the model stability.

2. *Gradient-based feature importance:* Given a sample, we use the input gradients of the model corresponding to each of the word representations and compute the magnitude of the change as a local explanation. We refer the reader to Baehrens et al. (2010) for a good introduction to gradient-based interpretations. As all of our models are differentiable, we use this as an alternative method for interpretation. We follow the standard procedure as followed in Feng et al. (2018) and note that we do not follow Jain and Wallace (2019) and do not disconnect the computational graph at the attention module. We obtain probabilistic gradient scores by normalizing over the absolute values of gradient values.

3. *LIME based interpretation:* We use locally interpretable model-agnostic interpretations (Ribeiro et al., 2016) that learns a surrogate interpretable model locally around the predictions of the deep neural based model. We obtain LIME based interpretations for every instantiation of the models. We then use Jaccard Distance to measure the divergence.

We note that, we observe similar patterns across the three interpretation methods and the interpretations consistently differ with random seeds.

3 Reducing Model Instability with an Optimization Lens

We observe that different instantiations of the model can cause the model have different starts on the optimization surface. Further, stochastic sampling might result in different paths. Both of these factors can lead to different local minimas potentially leading to different solutions. With this observation as our background we propose two, closely related, methods to ameliorate divergence: Agressive Stochastic Weight Averaging and Norm-filtered Agressive Stochastic Weight Averaging. We describe these two in the following subsections.

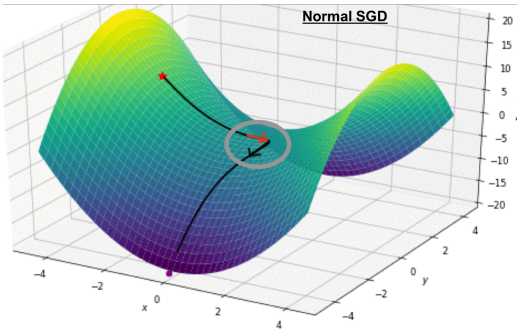
3.1 Aggressive Stochastic Weight Averaging (ASWA)

Stochastic weight averaging (SWA) (Izmailov et al., 2018) works by averaging the weights of multiple points in the trajectory of gradient descent based optimizers. The algorithm typically uses modified learning rate schedules. SWA is itself based on the idea of maintaining a running average of weights in stochastic gradient descent based optimization techniques (Ruppert, 1988; Polyak and Juditsky, 1992). The principle idea in SWA is averaging the weights that are maximally distant helps stabilize the gradient descent based optimizer trajectory and improves generalization. Izmailov et al. (2018) use the analysis of Mandt et al. (2017) to illustrate the stability arguments where they show that, under certain convexity assumptions, SGD iterations can be visualized as sampling from a Gaussian distribution centred at the *minima* of the loss function. Samples from high-dimensional Gaussians are expected to be concentrated *on the surface of the ellipse* and not close to the *mean*. Averaging iterations is shown to stabilize the trajectory and further improve the width of the solutions to be closer to the *mean*.

In this paper, we focus on the stability of deep neural models as a function of random-seeds. Our proposal is based on SWA, but we extend it to the extremes and call it *Aggressive Stochastic Weight Averaging*. We assume that, for small batch size, the loss surface is locally convex. We further relax

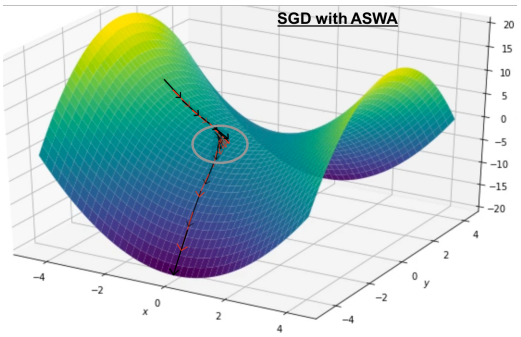
the conditions for the optimizer and assume that the optimizer is based on some version of gradient descent — this means that our modification is valid even for other pseudo-first-order optimization algorithms including Adam (Kingma and Ba, 2014) and Adagrad (Duchi et al., 2011).

We note that, Izmailov et al. (2018) suggest using SWA usually after 'pre-'training the model (at least until 75% convergence) and followed by sampling weights at different steps either using large constant or cyclical learning rates. While, SWA is well defined for convex losses (Polyak and Juditsky, 1992), Izmailov et al. (2018) connect SWA to non-convex losses by suggesting that the loss surface is *approximately* convex after convergence. In our setup, we investigate the utility of averaging weights over every iteration (an iteration consists of one batch of the gradient descent). Algorithm 1 shows the implementation pseudo-code for SWA. We note that, unlike Izmailov et al. (2018), we average our weights at *each batch* update and assign the ASWA parameters to the model at the end of each epoch. That is, we replace the model's weights for the next epoch with the averaged weights.



Algorithm 1: Aggressive SWA algorithm

Require:



e = Epoch number
m = Total epochs
i = Iteration number
n = Total iterations
α = Learning rate
$\mathcal{O}$ = Stochastic Gradient optimizer function

$e \leftarrow 0$;
while $e < m$ **do**
  $i \leftarrow 1$
  while $i \leq n$ **do**
    $W_{swa} \leftarrow W_{swa} + \frac{(W - W_{swa})}{(e*n+i+1)}$;
    $W \leftarrow W - \mathcal{O}(\alpha, W)$;
    $i \leftarrow i + 1$
  $W \leftarrow W_{swa}$;
  $e \leftarrow e + 1$

In Figure 2, we show an SGD optimizer (with momentum) and the same optimizer *with SWA* over a 3-dimensional loss surface with a saddle point. We observe that the original SGD reaches the desired minima, however, it almost reaches the saddle point and does a course correction and reaches minima. On the other hand, we observe that SGD with ASWA is very conservative, it repeatedly restarts and reaches the minima without reaching the saddle point. We empirically observe that this is a desired property for the stability of models over runs of the same model that differ only over random instantiations. The grey circles in Figure 2 highlight this conservative behaviour of SGD with ASWA optimizer, especially when compared to the standard SGD. Further, Polyak and Juditsky (1992) show that for convex losses, averaging SGD proposals achieves the highest possible rate of convergence for a variety of first-order SGD based algorithms.

(a) Trajectory for Stochastic Gradient Descent

(b) Trajectory for Stochastic Gradient Descent with ASWA

Figure 2: Trajectory for gradient descent algorithms with red and black arrows on (b) indicating movements from consecutive epochs with restarts. Conservative behaviour of ASWA algorithm helps avoid the saddle point without ever reaching it.

3.2 Norm-filtered Aggressive Stochastic Weight Averaging (NASWA)

We observe that the ASWA algorithm is especially beneficial when the norm difference of the parameters of the model are high. We hypothesise that in general, the norm difference indicates the divergence between optimizers' steps and we observe that the larger the norm difference, the greater the change in the trajectory. Therefore, we propose to

Algorithm 2: Norm-filtered Aggressive SWA algorithm

Require:

e = Epoch number
m = Total epochs
i = Iteration number
n = Total iterations
α = Learning rate
$\mathcal{O}$ = Stochastic Gradient optimizer function
N_s = List of previous iterations' norm differences

$e \leftarrow 0$;
while $e < m$ **do**
  $i \leftarrow 1$
  while $i \leq n$ **do**
    $N_{cur} \leftarrow \|W - W_{swa}\|_1$;
    $N_{mean} \leftarrow \frac{\sum_{i=1}^{|N_s|} N_s[i]}{|N_s|}$;
    if $N_{cur} > N_{mean}$ **then**
      $W_{swa} \leftarrow W_{swa} + \frac{(W - W_{swa})}{(e*n+i+1)}$;
      $N_s \leftarrow [N_{cur}]$;
    else
      $N_s \leftarrow N_s + [N_{cur}]$;
    $W \leftarrow W - \mathcal{O}(\alpha, W)$;
    $i \leftarrow i + 1$
  $W \leftarrow W_{swa}$;
  $e \leftarrow e + 1$

maintain a list that stores the norm differences of the previous iterations. If the norm difference of the current iteration is greater than the average of the list, we update the ASWA weights and reinitialize the list with the current norm difference. When the norm difference, however, is less than the average of the list, we just append the current norm difference to the list. After the completion of the epoch, we assign the ASWA parameters to the model. This is shown in Algorithm 2. We call this approach *Norm-filtered Aggressive Stochastic Weight Averaging*.

4 Experiments

We base our investigation on similar sets of models as Jain and Wallace (2019). We also use the code provided by the authors for our empirical investigations for consistency and empirical validation. We describe our models and datasets used for the experiments below.

4.1 Models

We consider two sets of commonly used neural models for the tasks of binary classification and multi-class natural language inference. We use CNN and bi-directional LSTM based models with attention. We follow (Jain and Wallace, 2019) and use similar attention mechanisms using a) additive attention (Bahdanau et al., 2014); and b) scaled dot product based attention (Vaswani et al., 2017). We jointly optimize all the parameters for the model, unlike Jain and Wallace (2019) where the encoding layer, attention layer and the output prediction layer are all optimized separately. We experiment with several optimizers including Adam (Kingma and Ba, 2014), SGD and Adagrad (Duchi et al., 2011) but most results below are with Adam.

For our ASWA and NASWA based experiments, we use a constant learning rate for our optimizer. Other model-specific settings are kept the same as Jain and Wallace (2019) for consistency.

Dataset	Avg. Length	Train Size	Test size
IMDB	179	12500 / 12500	2184 / 2172
Diabetes(MIMIC)	1858	6381 / 1353	1295 / 319
SST	19	3034 / 3321	652/653
Anemia(MIMIC)	2188	1847 / 3251	460 / 802
AgNews	36	30000 / 30000	1900 / 1900
ADR Tweets	20	14446 / 1939	3636 / 487
SNLI	14	182764 / 183187 / 183416	3219 / 3237 / 3368

Table 1: Dataset characteristics. Train size and test size show the cardinality for each class. SNLI is a three-class dataset while the rest are binary classification

4.2 Datasets

The datasets used in our experiments are listed in Table 1 with summary statistics. We further pre-process and tokenize the datasets using the standard procedure and follow Jain and Wallace (2019). We note that IMDB (Maas et al., 2011), Diabetes(MIMIC) (Johnson et al., 2016), Anemia(MIMIC) (Johnson et al., 2016), AgNews (Zhang et al., 2015), ADR Tweets (Nikfarjam et al., 2015) and SST (Socher et al., 2013) are datasets for the binary classification setup. SNLI (Bowman et al., 2015) is a dataset for the multiclass classification setup. All of the datasets are in English, however we expect the behavior to persist regardless of the language.

4.3 Settings and Hyperparameters

We use a 300-dimenstional embedding layer which is initialized with FastText (Joulin et al., 2016) based free-trained embeddings for both CNN and the bi-directional LSTM based models.

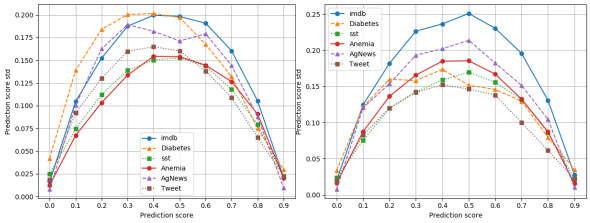
We use a 128-dimensional hidden layer for the bi-directional LSTM and a 32-dimensional filter with kernels of size $\{1, 3, 5, 7\}$ for CNN. For others, we maintain the model settings to resemble the models in Jain and Wallace (2019). We train all of our models for 20 Epochs with a constant batch size of 32. We use early stopping based on the validation set using task-specific metrics (Binary Classification: using `roc-auc`, Multiclass and question answering based dataset: using `accuracy`).

Dataset	CNN(%)	CNN+ASWA(%)	CNN+NASWA(%)
IMDB	89.8 (±0.79)	90.2 (±0.25)	90.1 (±0.29)
Diabetes	87.4 (±2.26)	85.9 (±0.25)	85.9 (±0.38)
SST	82.0 (±1.01)	82.5 (±0.39)	82.5 (±0.39)
Anemia	90.6 (±0.98)	91.9 (±0.20)	91.9 (±0.19)
AgNews	95.5 (±0.23)	96.0 (±0.11)	96.0 (±0.07)
Tweet	84.6 (±2.65)	84.4 (±0.54)	84.4 (±0.54)

Table 2: Performance statistics obtained from 10 differently seeded CNN based models. Table compares accuracy and its **standard deviation** for the normally trained CNN model against the ASWA and NASWA trained models, whose deviation drops significantly, thus, indicating increased robustness.

5 Results

In this section, we summarize our findings for 10 runs of the model with 10 different random seeds but with identical model settings.



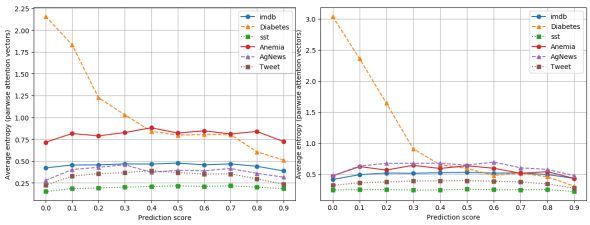
5.1 Model Performance and Stability

We first report model performance and prediction stability. The results are reported in Table 2.

Dataset	LSTM(%)	LSTM+ASWA(%)	LSTM+NASWA(%)
IMDB	89.1 (±1.34)	90.2 (±0.32)	90.3 (±0.17)
Diabetes	87.7 (±1.44)	87.7 (±0.60)	87.8 (±0.55)
SST	81.9 (±1.11)	82.0 (±0.60)	82.1 (±0.57)
Anemia	91.6 (±0.49)	91.8 (±0.34)	91.9 (±0.36)
AgNews	95.5 (±0.32)	96.1(±0.17)	96.1 (±0.10)
Tweet	84.7 (±1.79)	83.8 (±0.45)	83.9 (±0.45)

Table 3: Performance statistics obtained from 10 differently seeded LSTM based models.

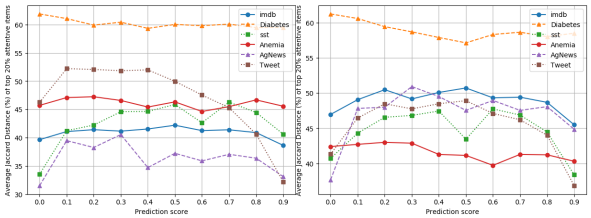
We note that the original CNN based models, on an average, have a standard deviation of $\pm 1.5\%$. Which seems standard, however, we note that ADR Tweets dataset has a very high standard deviation of $\pm 2.65\%$. We observe that ASWA and NASWA are almost always able to achieve higher performance with a very low standard deviation. This suggests that both ASWA and NASWA are extremely stable when compared to the standard model. They significantly improve the robustness, on an average, by 72% relative to the original model and on Diabetes (MIMIC), a binary classification dataset, by 89% (relative improvement). We observe similar results for the LSTM based models in Table 3.



(a) CNN models (b) LSTM models

Figure 3: Prediction's standard deviation for CNN and LSTM based models for all binary classification datasets under consideration. Predictions are bucketed in intervals of size 0.1, starting from 0 (containing predictions from 0 to 0.1), until 0.9

We further analyze the prediction score stability by computing the mean standard deviation over the binned confidence intervals of the models in Figure 3a. We note that on an average, the standard deviations are on the lower side. However, we observe that the mean standard deviation of the bins close to 0.5 is on the higher side as is expected given the high uncertainty. On the other hand both, ASWA and NASWA based models are relatively more stable than the standard CNN based model. We observe similar behaviours for the LSTM based models in Figure 3b. This suggests that our proposed methods, ASWA and NASWA, are able to obtain relatively better stability without any loss in performance. We also note that both ASWA and NASWA had relatively similar performance over more than 10 random seeds.



5.2 Attention Stability

(a) CNN models (b) LSTM models

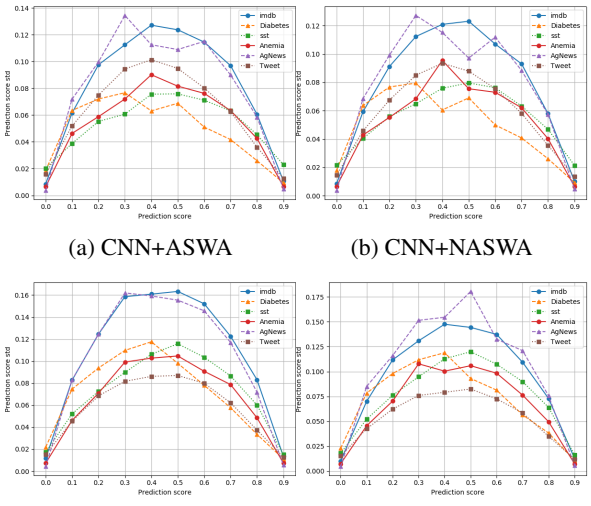


Figure 4: Average attention entropy against the bucketed predictions for CNN and LSTM based models. Figure highlights the high entropy between attention based distributions from differently seeded models (especially for the Diabetes-MIMIC datatset), indicating towards model instability.

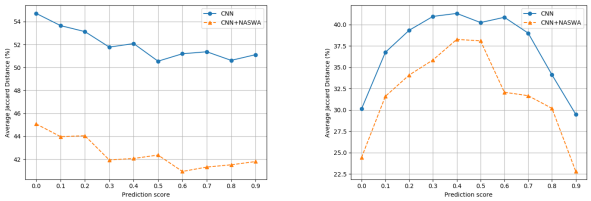
We now consider the stability of attention distributions as a function of random seeds. We first plot the results of the experiments for *standard* CNN based binary classification models over uniformly binned prediction scores for positive labels in Figure 4a. We observe that, depending on the datasets, the attention distributions can become extremely unstable (high entropy). We specifically highlight the Diabetes(MIMIC) dataset's entropy distribution. We observe similar, but relatively worse results for the LSTM based models in Figure 4b. In general, we would expect the entropy distribution to be close to zero however, this doesn't seem to be the case. This means that using attention distributions to interpret models may not be reliable and can lead to misinterpretations.

(a) CNN models (b) LSTM models

Figure 5: Jaccard distance highlighting instability in attention distributions of CNN and LSTM based models.



(a) CNN+ASWA (b) CNN+NASWA

(c) LSTM+ASWA (d) LSTM+NASWA

Figure 6: Improved prediction stability from ASWA and NASWA for CNN and LSTM based models

We use the top 20% of the most important items (indices) in the attention distribution for each dataset over 10 runs and plot the Jaccard distances for CNN and LSTM based models in Figure 5a and Figure 5b. We again notice a similar trend of unstable attention distributions over both CNN and LSTM based attention distribution.

(a) Diabetes (b) SST

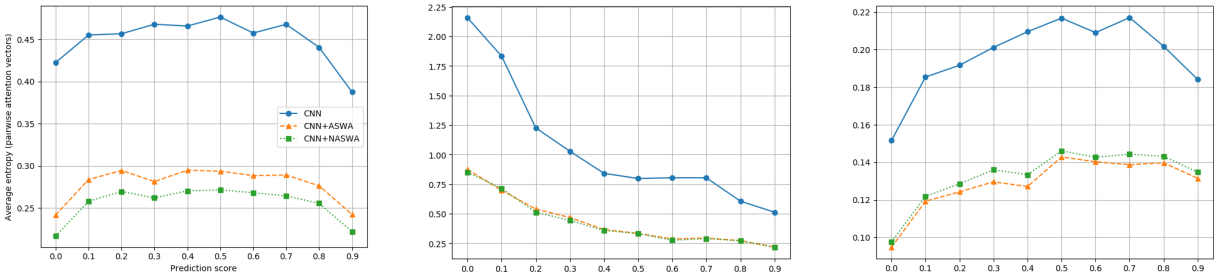


Figure 7: Gradient based interpretations' stability improvement from NASWA on CNN based models. The Jaccard distance is calculated using the top 20% attentive items.

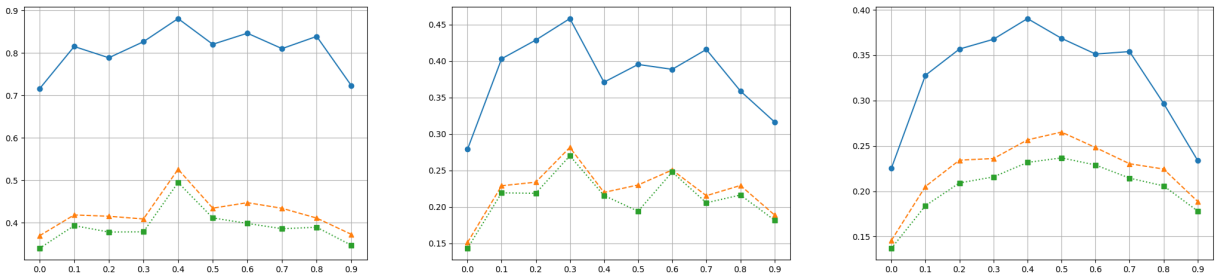
In the following sections for space constraints, we focus on CNN based models with additive attention. Our results on LSTM based models are provided in the attached supplementary material. We note that the observations for LSTM models are, in most cases, similar to the behaviour of the CNN based models. Scaled dot-product based models are also provided in the supplementary material and we notice a similar trend as the additive attention.



We now focus on the effect of ASWA and NASWA on binary and multi-class CNN based neural models separately.

Binary Classification In Figure 8, we plot the results of the models with ASWA and NASWA. We observe that both these algorithms significantly improve the model stability and decrease the entropy between attention distributions. For example, in Figure 8b, both ASWA and NASWA decrease the average entropy by about 60%. We further notice that NASWA is slightly better performing in most of the runs. This empirically validates the hypothesis that averaging the weights from divergent weights (when the norm difference is higher than the average norm difference) helps in stabilizing the model's parameters, resulting in a more robust model.

Multi-class Classification In Figure 9, we plot the entropy between the attentions distributions of the models for the SNLI dataset (CNN based model), separately for *each label* (*neutral*, *contradiction*, and *entailment*). We notice, similar observations as the binary classification models, the ASWA and NASWA algorithms are able to significantly improve the entropy of the attention distributions and increases the robustness of the model

with random seeds.

5.3 Gradient-based Interpretations

We now look at an alternative method of interpreting deep neural models and look into the consistency of the gradient-based interpretations to further analyze the model's instability. For this setup, we focus on binary classifier and plot the results on the SST and the Diabetes dataset in particular since they cover the low and the high end of the entropy spectrum (respectively). We notice similar trends of instability in the gradient-based interpretations from model inputs as we did for the attention distributions. Figure 7 shows that the entropy between the gradient-based interpretations from differently seeded models closely follows the same trend as the attention distributions. This result further strengthens our claim on the importance of model stability and shows that over different runs of the same model with different seeds, we may get different interpretations using gradient-based feature importance. Moreover, Figure 7 shows the impact of ASWA towards making the gradient-based interpretations more consistent, thus, significantly increasing the stability.

5.4 LIME based Interpretations

We further evaluated the surrogate model based interpretability using LIME (Ribeiro et al., 2016). LIME obtains a locally linear approximation of the model's behaviour for a given sample by perturbing it and learning a sparse linear model around it. We focus on AgNews and SST based datasets and obtain interpretability estimates using LIME. Once again, we notice a similar pattern of instability as the other two interpretability methods. In Figure 10 we present our results from the LIME based interpretations with Jaccard distance as the measure. Note that we measure the Jaccard distance over the top 20% most influential items. We

(a) AgNews (b) SST

Figure 10: LIME based interpretations' stability improvement from NASWA on CNN based models. The Jaccard distance is calculated using the top 20% attentive items.

observe once again that NASWA helps in reducing the instability and results in more consistent interpretations.

In all our experiments, we find that a significant proportion of interpretations are dependent on the instantiation of the model. We also note that we perform experiments over 100 random seeds for greater statistical power and see similar patterns[3].

6 Discussion

Recent advances in adversarial machine learning (Neelakantan et al., 2015; Zahavy et al., 2016) have investigated robustness to random initialization based perturbations, however, to our knowledge, no previous study investigates the effect of random-seeds and its connection on model interpretation. Our study analyzed the inherent lack of robustness in deep neural models for NLP. Recent studies cast doubt on the consistency and correlations of several types of interpretations (Doshi-Velez and Kim, 2017; Jain and Wallace, 2019; Feng et al., 2018). We hypothesise that some of these issues are due to the inherent instability of the deep neural models to random-seed base perturbations. Our analysis (in Section 4) leads to the hypothesis that models with different instantiations may use completely different optimization paths. The issue of variance in all black-box interpretation methods over different seeds will continue to persist until the models are fully robust to random-seed based perturbations. Our work however, doesn't provide insights into instabilities of different layers of the models. We hypothesise that it might further uncover the reasons for the relatively lower correlation between different black-box interpretation methods as these are effectively based off on different layers and granularity.

[3]These results are provided in the appendix.

There has been some work on using noisy gradients (Neelakantan et al., 2015) and learning from adversarial and counter-factual examples (Feng et al., 2018) to increase the robustness of deep learning models. Feng et al. (2018) show that neural models may use redundant features for prediction and also show that most of the black-box interpretation methods may not be able to capture these second-order effects. Our proposals show that aggressively averaging weights leads to better optimization and the resultant models are more robust to random-seed based perturbation. However, our research is limited to increasing consistency in neural models. Our approach further uses first order based signals to boost stability. We posit that second-order based signals can further enhance consistency and increase the robustness.

7 Conclusions

In this paper, we study the inherent instability of deep neural models in NLP as a function of random seed. We analyze model performance and robustness of the model in the form of attention based interpretations, gradient-based feature importance and LIME based interpretations across multiple runs of the models with different random seeds. Our analysis strongly highlights the problems with stability of models and its effects on black-box interpretation methods leading to different interpretations for different random seeds. We also propose a solution that makes use of weight averaging based optimization technique and further extend it with norm-filtering. We show that our proposed methods largely stabilize the model to random-seed based perturbations and, on average, significantly reduce the standard deviations of the model performance by 72%. We further show that our methods significantly reduce the entropy in the attention distribution, the gradient-based feature importance measures and LIME based interpretations across runs.

Abstract

Work on Abusive Language Detection has tackled a wide range of subtasks and domains. As a result of this, there exists a great deal of redundancy and non-generalisability between datasets. Through experiments on cross-dataset training and testing, the paper reveals that the preconceived notion of including more non-abusive samples in a dataset (to emulate reality) may have a detrimental effect on the generalisability of a model trained on that data. Hence a hierarchical annotation model is utilised here to reveal redundancies in existing datasets and to help reduce redundancy in future efforts.

1 Introduction

With the growth of the internet and the increasingly smaller barrier to entry, social media have become viable platforms for people to make their views known. These easily accessible fora for discourse have given a voice to many minorities and individuals to share their stories. The caveat, however, is that these platforms can be misused to spread hate and harass other individuals, which has given birth to terms such as cyberbullying and trolling. Online harassment has been a point of criticism levied against social media giants such as Facebook and Twitter, who have come under increased pressure to address this misuse. To this end, they have ensured that their community guidelines explicitly ban the usage of profanity/hate speech to harass and bully individuals.

The detection of Online Abuse has proven to be a layered and complex issue. For example, profanity is often treated as a sign of hate speech or offensive language, but profanity can also be used in a wide variety of expressive ways to convey informality, humour, and emphasis. This usage of profanity outside of abuse/insults, coupled with implicit insults that may not contain any profanity, makes the task of classifying abuse online a balancing act of sorts, forming the crux of what makes this task hard to tackle: stricter guidelines may hamper a well-meaning individual's freedom of speech, while more lenient guidelines may empower those who exploit them.

As it stands, the intricacies of free speech do not translate well to machine understanding. This has led to the continued use of human moderators in the abusive language detection space. Content is flagged by users, reviewed by a human and removed if it violates the platform's community guidelines. The main problem with this system is the sheer volume of content to be reviewed, giving human moderators very little time to arrive at a decision. Another issue that was highlighted by Roberts (2019) is the impact that reviewing online abuse can have on a worker's mental well-being. These issues have led to many social media giants, such as Facebook, to seek machine learning-based solutions — to replace or supplement the current human moderator system.

Automatic detection of abusive language online can be seen as a union of the plethora of subtasks that have been tackled: Cyberbullying, Hate Speech (also further constrained as racism, sexism, and harassment of particular minorities), Trolling, etc. Research in the field tends to focus on one of the particular subtasks. It has been argued by some (Schmidt and Wiegland, 2017; Waseem et al., 2017b) that due to this phenomenon where works tackle restricted subsets of abusive language, it has become difficult to make judgements about whether the features being used can perform well in other subtasks of abusive language detection — as they are often only evaluated on a single dataset, specific to one domain and subtask, and annotated in a specific way.

Waseem et al. (2017b) proposed that there exists an overlap between these subtasks and subsequently proposed a typology that emphasises identifying the target of abuse and whether the abuse is implicit or explicit. Their typology could potentially be applied to all stages of system development, from data collection to the final model building. This, they hoped, would help to synthesise the different subtasks. This idea was expanded upon in the Offensive Language Identification Dataset (OLID; Zampieri et al. 2019a) to a hierarchical, three-level annotation model.

After further discussing related research in the next section, this work looks at various publicly available datasets in the field (Section 3), and performs both in-domain (Section 4) and cross-dataset training and testing to observe whether models trained on one dataset generalise well when tested against other datasets (Section 5). It also makes some qualitative assessments on why models trained on specific datasets generalise better than others. Additionally, the OLID dataset based on the typology by Waseem et al. (2017b) is used to observe whether the hierarchical annotation model is sufficient to synthesise the various subtasks of abusive language detection. To this end, experiments were run using BERT, Bidirectional Encoder Representations from Transformers (Devlin et al., 2018), to compare its performance to other popular models that have been used for abusive language detection (Section 6).

2 Previous Work

Abusive language detection has served as an umbrella term for a wide variety of subtasks. Research in the field has typically focused on a particular subtask: Hate Speech (Davidson et al., 2017; Founta et al., 2018; Gao and Huang, 2017; Golbeck et al., 2017), Sexism/Racism (Waseem and Hovy, 2016), Cyberbullying (Xu et al., 2012; Dadvar et al., 2013), Trolling and Aggression (Kumar et al., 2018a), and so on. Datasets for these tasks have been collected from various social media platforms, such as Twitter (Waseem and Hovy, 2016; Davidson et al., 2017; Founta et al., 2018; Burnap and Williams, 2015; Golbeck et al., 2017), Facebook (Kumar et al., 2018a), Instagram (Hosseinmardi et al., 2015; Zhong et al., 2016), Yahoo! (Nobata et al., 2016; Djuric et al., 2015; Warner and Hirschberg, 2012), YouTube (Dinakar et al., 2011), and Wikipedia (Wulczyn et al., 2017), with annotation typically carried out on crowdsourcing platforms such as CrowdFlower (Figure Eight)[1] and Amazon Mechanical Turk.[2]

All these datasets represent multi-class classification problems, with the exception of the Kaggle's Toxic Comment Classification challenge,[3] which entails multi-label classification, and OLID (Zampieri et al., 2019a) used in the SemEval-2019 'OffensEval' shared task (Zampieri et al., 2019b), which builds on a hierarchical annotation model (Hierarchy of Multi-Class Classifiers).

Choice of features has been the crucial difference between the various approaches to abusive language detection. For the most part, word-level n-grams have been highly predictive, with other linguistic features such as part-of-speech tags (Xu et al., 2012; Davidson et al., 2017) and sentiment score (Van Hee et al., 2015; Davidson et al., 2017) providing slight improvements. Due to their ability to perform better in an online setting where spelling errors and adversarial behaviour are commonplace, character-level features have been endorsed (Mehdad and Tetreault, 2016), and also shown to often be superior to word-level information for this task (Meyer and Gambäck, 2019). Metadata about users have also been used as features: Waseem and Hovy (2016) claim gender information leads to improved performance, while Unsvåg and Gambäck (2018) report user-network data to be more important. Schmidt and Wiegland (2017) provides a comprehensive overview of many of the features used and their efficacy.

In terms of models, popular classical classification approaches include Logistic Regression and LSVM (Linear Support Vector Machines). Deep Neural networks such as Convolutional Neural Networks, CNN (Zhang et al., 2018; Gambäck and Sikdar, 2017) and variations of Recurrent Neural Networks, RNN (Pitsilis et al., 2018; Gao and Huang, 2017) have seen widespread success, regularly obtaining state-of-the-art results on various datasets. Lee et al. (2018) used the Founta et al. (2018) dataset to conduct a comparative study of the performance of many popular models. In the 'OffensEval' shared task (Zampieri et al., 2019b), the use of contextual embeddings such as BERT (Devlin et al., 2018) and ELMo (Peters et al., 2018) exhibited the best results.

[1] figure-eight.com
[2] mturk.com
[3] bit.ly/2HNfLaB

Generalisability of a model has also come under considerable scrutiny. Works such as Karan and Šnajder (2018) and Gröndahl et al. (2018) have shown that models trained on one dataset tend to perform well only when tested on the same dataset. Additionally, Gröndahl et al. (2018) showed how adversarial methods such as typos and word changes could bypass existing state-of-the-art abusive language detection systems. They also observed unimpressive results when using ULMFiT (Howard and Ruder, 2018) for abusive language detection, but argued that model architecture is less important than the type of data and the annotation scheme.

Karan and Šnajder (2018) experimented with cross-domain training and testing, and opted to use the same model (LSVM) with minimal features and to preprocess in favour of interpretability. They also reported positive improvements using Frustratingly Easy Domain Adaptation (FEDA; Daumé III, 2007) to augment smaller datasets with larger ones. Fortuna et al. (2018) concurred, stating that although models perform better on the data they are trained on, slightly improved performance can be obtained when adding more training data from other social media. Similarly, Waseem et al. (2018) attempted to address the problem of differences between datasets by building a robust multi-task learning model, which improves upon single-task performance by using auxiliary samples from select datasets. Their work revealed that such models could be competitive with the state-of-the-art single-task models with the additional benefit of allowing prediction on other datasets as well. This helps in negating hidden biases within datasets and promoting generalisability.

3 Datasets

The experiments in the next section will be based on four different datasets, annotated for hate speech and/or offensive language, as described below. The social media platform of choice, Twitter, was selected due to the availability of a multitude of easy to access datasets. The datasets are all in English and from Twitter, and largely chosen based on popularity and availability.

The first two datasets, from Waseem and Hovy (2016) and from Davidson et al. (2017) were chosen due to their widespread use as benchmarks for models. The third, from Founta et al. (2018) was selected because of its large size, while the fourth (Zampieri et al., 2019a) was included since it is using the contemporary hierarchical model. Some other large datasets were discarded since they are either not from Twitter (such as the Kaggle Toxicity classification of Wikipedia comments, Wulczyn et al., 2017) or not easily or openly available (e.g., Silva et al., 2016; Golbeck et al., 2017).

3.1 The Waseem and Hovy Dataset

In their work on the disambiguation of types of hate speech, Waseem and Hovy (2016) released a dataset of 16,914 tweets. They solicited their tweets using a lexicon of hate speech terms, and manually annotated them with three tags: `racism`, `sexism`, and `none`. Waseem and Hovy used an expert outside annotator for reviewing their annotations to mitigate any bias. The database is provided as a set of tweet IDs with tags, but many of the actual tweets have been removed over time, in particular those belonging to the racist class.[4] The first set of rows in Table 1 describes the dataset, including a comparison of the original Waseem and Hovy (2016) dataset to the one available for download using the Twitter API when the present experiments were initiated.

3.2 The Davidson et al. Dataset

Davidson et al. (2017) made publicly available a Twitter dataset with three labels: `hate_speech`, `offensive_language`, and `neither`. Similar to Waseem and Hovy (2016), they used a lexicon of hate speech terms derived from `Hatebase.org` and queried Twitter using these terms to collect potentially hateful tweets. Each tweet was annotated by at least three CrowdFlower workers and the tags were assigned based on the majority decisions. The final dataset available online contains 24,783 tweets. Table 1 provides some statistics of the dataset, which henceforth will be referred to as the Davidson et al. dataset.

Note the very large fraction of abusive tweets in the dataset. A possible explanation for this was given by Waseem et al. (2018), who noted that 2,161 tweets in Davidson et al.'s dataset written in African American Vernacular English had been annotated as offensive or hateful when including the n-word, although the actual usage was to mark group inclusion and informality. While Waseem et al. discuss that these errors were due to the

[4]Note that this discrepancy means that comparisons to work by others on this dataset are not straight-forward.

Dataset	Total	Normal	Hatespeech			Offensive / Abusive					Spam
				racism	sexism						
Waseem and Hovy

							UNT	TIN (targeted)			
								IND	GRP	OTH	
Zampieri et al.	14,100	9,460	N/A			4,640	551	2,507	1,152	430	N/A

Table 1: Overview of the datasets by Davidson et al., Founta et al., Waseem and Hovy, and Zampieri et al.

scarcity of African Americans among the annotators, they could also be attributed to lack of meta-information about the tweet authors: had the annotators known that those tweets were written by African Americans, they would probably have induced that the n-word was not used offensively.

3.3 The Founta et al. Dataset

Founta et al. (2018) released a large Twitter dataset with four labels: `hateful`, `abusive`, `normal`, and `spam`. The main part of their work revolved around a methodology to collect and annotate data over crowdsourcing platforms. They collected tweets from the Live Twitter stream and filtered them using sentiment score (searching for tweets with strong negative polarity) and a lexicon of offensive words from `Hatebase.org` and `noswearing.com/dictionary`.

Table 1 also introduces the Founta et al. dataset, which with a total of $99,996$ tweets is by far the largest in the present study, but also contains a sizable fraction of spam tweets (a category which is not included in the other datasets).

3.4 OLID

The Offensive Language Identification Dataset, OLID (Zampieri et al., 2019a) was used in SemEval-2019 Task 6: 'OffensEval' (Zampieri et al., 2019b). It consists of $14,100$ tweets annotated through a unique hierarchical model whose basic idea was proposed by Waseem et al. (2017b). For the shared task, the data was split into (non-stratified) training and test sets containing $13,240$ and 860 tweets, respectively.

As can be seen in last rows of Table 1, there are three annotation levels in OLID, each of which was directly reflected as a subtask in OffensEval:

A. Whether the tweet can be classified as being offensive (`OFF`) or non-offensive (`NOT`).

B. Tweets labelled as `OFF` are further classified as either `UNT` (untargeted insult/abuse) or `TIN` (targeted insult/abuse).

C. Tweets labelled as `TIN` are sub-divided as `IND` (insults targeted at an individual), `GRP` (insults targeted at a minority group) or `OTH` (insults targeted at an issue or organisation).

4 Preliminary Feature and Model Study

The first set of experiments aimed to test the efficacy of BERT (Devlin et al., 2018) when tackling the Abusive Language Detection task. For this, BERT's performance was compared to three other popular classifiers: Linear SVM, an LSTM (Long Short-Term Memory) Recurrent Neural Network (Hochreiter and Schmidhuber, 1997), and ELMo (Peters et al., 2018). The methodology and models are briefly explained here.

To shed some light on the models themselves rather than the features, no extra surface-level features or linguistic features were utilised in the classification. Also preprocessing was minimal, with lower-casing of tweets being the only standard. However, fine-tuning was carried out on the models' hyper-parameters, such as sequence length, drop out, and class weights. Test and training sets were created for each dataset by performing a stratified split of 20% vs 80%, with the larger part used for training the models. The training sets were further subdivided, keeping 1/8 shares of them as separate validation sets during development and fine-tuning of the hyper-parameters. However, the validation sets were conflated with the training sets for the final results as some of the datasets were already quite small and the models benefited from the extra data. Information on the models themselves are provided below.

Dataset	LSVM		LSTM		ELMo		BERT	
	Acc.	F_1	Acc.	F_1	Acc.	F_1	Acc.	F_1
Waseem and Hovy	.8911	.5696	.8498	.5312	.8614	.5394	**.9023**	**.5837**
Davidson et al.	.9014	.7278	.9143	.7419	.8909	.6802	**.9172**	**.7727**

OLID (Subtask A)	.7610	.7068	.7894	.7479	.7663	.7198	**.8004**	**.7738**

Table 2: Model test tesults (macro-F_1 and accuracy) for all datasets; the best performer is in bold.

4.1 Linear SVM

The Linear SVM (LSVM) was modelled and trained in the `Scikit-learn`[5] library (Pedregosa et al., 2011), utilising a TF-IDF vector representation for the tweets. The classes were artificially balanced and overfitting penalised using L2 regularisation. Interesting hyperparameters included the n-gram range and whether to use character or token n-grams. For example, the Davidson et al. dataset tended to perform better with token n-grams, while the Waseem and Hovy dataset worked better with character n-grams. The inclusion of unigrams was also pivotal to good classifier performance when using token n-grams.

4.2 LSTM Network

The tested Deep Learning Model was built on a fairly simple LSTM architecture using Keras[6] with a TensorFlow[7] back end. The 'Adam' optimiser (Kingma and Ba, 2014) was paired with categorical cross-entropy loss function for model training. Again no statistical or linguistic features were used and the only preprocessing involved lower-casing the tweets. The first layer used a 200 dimensional `GloVe embedding`,[8] pre-trained on 2 billion tweets (Pennington et al., 2014), with embedding weights fixed throughout the training. The Embedding Layer was followed by an LSTM layer of 200 units. The final layer was a dense layer with softmax activation and layer size dependent on the number of classes in the dataset being tested. The most significant hyperparameters were found to be dropout and class weights.

4.3 ELMo

The third model tested used ELMo for feature extraction and was implemented in the TensorFlow hub module[9] with 1024 dimensional ELMo embeddings. This input was passed through an LSTM layer of dimension 256 and then a dense layer with a softmax activation function. The size of the last dense layer was again equal to the number of labels that should be classified. The 'Adam' optimiser and categorical cross-entropy loss function were used during training. ELMo's standalone performance was found to not be as impressive as hoped, with the batch size and usage of dropout significantly affecting classification rates.

4.4 BERT

$\texttt{BERT}_{\texttt{base, uncased}}$ was used as the underlying pre-trained model, in a fine-tuning only approach with no statistical or linguistic features. The model built on the `run_classifier` API provided on the BERT GitHub page[10] and the BERT tokeniser, which simply lower-cases sentences and removes illegal characters. $\texttt{BERT}_{\texttt{base,uncased}}$ trains a total of 110 million parameters, and contains 12 transformer blocks and 12 self-attention heads with hidden layer dimension 768. The most successful parameter settings utilised larger maximum sequence lengths, but smaller batch sizes and lower learning rates. The best models used a learning rate of e^{-5} and batch size 32 with varying maximum sequence lengths between 60 and 70. Other parameters worth mentioning are the number of epochs and the Linear Warm-up Proportion.

4.5 Results

The experimental results are recorded in Table 2, with most improvements and decrements in performance across models being minimal. BERT exhibits the best results for all datasets used in the experiments (with a significance level of 0.05). Surprisingly, ELMo was neither competitive with BERT nor with the GLoVE-embedding LSTM recurrent neural network (when tested with the same statistical significance level).

5 Cross-Dataset Training and Testing

In the second round of experiments, the best models built for individual dataset were used to test generalisability across the other datasets. For all datasets, these were BERT models, but with varying hyper-parameter settings. Karan and Šnajder (2018) used a simpler Linear SVM model for all the datasets for the sake of interpretability, while the aim here, in contrast, was to see how well the best models (that may have learnt some dataset-specific biases) performed on other datasets. This was done to investigate how well state-of-the-art systems perform in a real-life scenario, i.e., when exposed to data from other domains, with the hypothesis that a model trained on one dataset that exhibits comparatively reasonable results on other datasets can be expected to generalise well.

For these experiments, the models were tested on the test set which had been generated for the preliminary model study described in Section 4. As there exists a large number of heterogeneous annotation schemes between datasets, the same approach as Karan and Šnajder (2018) was taken, separating the tags in each dataset according to positive (abusive) and negative (benign) labels. This separation is represented in Table 3, which also gives the percentage of positive samples in each dataset. As can be seen, three of the datasets contain slightly less than 1/3 abusive instances. The Davidson et al. dataset stands out, by containing 3/4 offensive instances. As discussed in Section 3.2, this can probably be attributed to how those tweets were selected and annotated.

The results of cross-dataset testing are presented in Table 4. Considerable performance drops can be observed when going from a large training dataset to a small test set (i.e., Founta et al.'s results when tested on the Waseem and Hovy dataset) and vice versa. This is in line with a similar conclusion by Karan and Šnajder (2018).

It is surprising to see how well a model trained on Founta et al.'s dataset performs when tested on OLID (Zampieri et al., 2019a) and vice versa. However, this can be expected to be the case where there is a good agreement between the datasets, i.e., there is a large amount of similar data shared between them. To this effect, the Founta et al. dataset was searched with terms used by Zampieri et al. when collecting data for OLID, giving around $6,600$ hits. For comparison, OLID gets around $12,200$ hits with the same set of terms.

The most interesting observation is that datasets with larger percentages of positive samples tend to generalise better than datasets with fewer positive samples, in particular when tested against dissimilar datasets. For example, we see that the models trained on the Davidson et al. dataset, which contains a majority of offensive tags, perform well when tested on the Founta et al. dataset, which contains a majority of non-offensive tags. (The differences are all statistically significant when the test set is Waseem and Hovy.) Similar trends were observed by Karan and Šnajder (2018) when employing the Kolhatkar et al. (2018) and TRAC-1 (Kumar et al., 2018a) datasets, that have 62.7% and 56.6% positive samples, respectively, and exhibited better results in cross-dataset testing than datasets with lower positive sample ratios.

	Subtask A		Subtask B		Subtask C	
	BERT	Top	BERT	Top	BERT	Top

Acc.	.8546	.8628	.9000	.9250	.7136	.7277
Rank	2	1	9	1	6	1

Table 5: BERT test set results (macro-F_1 and accuracy) compared to top OffensEval shared task performers.

6 Synthesising Subtasks Using the Hierarchical Model

The OLID dataset was used to perform cross-dataset training and testing similar to the experiments of the previous section. However, since OLID uses a hierarchical annotation model (differing from the annotation schemes of the other datasets), this task was approached from a different angle. A model trained on the three subtasks of the OLID dataset (described at the end of Section 3.4) was tested for the task of tagging the in-domain Twitter datasets. This makes it possible to not only see how well OLID-trained models generalise to other data, but to identify the overlap between the different subtasks that the other datasets tackle by observing what percentage of documents under each subtask share common OLID tags.

For the OLID classifiers, a BERT model was used without any extra statistical features and with minimal preprocessing (only lower-casing of tweets). The classifiers were then fine-tuned to the different subtasks, again showing a positive correlation between sequence length and classifier performance. For the results to be comparable to those obtained in the OffensEval 2019 shared task, the same test set was used as in that task. Model performances are reported in Table 5, along with what rank the model would have obtained if it had been submitted to OffensEval 2019, showing that the models are competitive when compared to the top shared task submissions.

The tested model was trained for a total of 3 epochs with a batch size of 16 and learning rate e^{-5}. The maximum sequence length was set to 70 for subtasks A and C, but to 60 for subtask B, where over-fitting was observed on sequence length 70. Also in subtask C the model showed significant signs of over-fitting, with the BERT approach only achieving an F_1 score of 0.52. In this case, a technique was borrowed from the top subtask C submission to OffensEval (Radivchev and Nikolov, 2019), namely to use lower decision boundaries for the `OTH` (0.2) and `GRP` (0.3) tags, instead of the typical decision boundary probability of 0.5. As can be seen in the table, this addition led to huge improvements ($F_1 = 0.62$), compared to the models using the typical decision boundary ($F_1 = 0.52$), although the achieved scores still were not close to the top submission.

Returning to the tagging/synthesis experiments, the entire datasets were used. The results are presented in Table 6. Here we see quite a bit of overlap between the offensive and hate speech tags with the majority tag being `(OFF, TIN, IND)` by a landslide. Clearly, these results can become trivial if the differences boil down to whether the model generalises well to the other datasets used here. This is why only in-domain (Twitter datasets) are considered here and the results also are discussed while taking this into account.

In the Davidson et al. dataset, the non-abusive tag, `neither` had a much lower percentage of its tweets annotated under `NOT` (69.37%) by the OLID classifier when compared to other datasets. This observation may be attributed to the data collection techniques used by Davidson et al., who filtered tweets based on a hate speech lexicon before annotating them, as well as to profanities occurring within the `neither` tag, causing a dip in the amount of explicitly non-offensive tweets.

A similar issue is seen, but to a lesser extent, in the `neither` tag of the Waseem and Hovy dataset, which also was extended by using a sample of hateful tweets. Another interesting observation with that dataset is that the majority class for the `sexism` tag in Subtask A was `NOT`. This complies with observations by both Waseem and Hovy and Davidson et al. (2017) that the human coders considered sexist terms as offensive rather than hateful. However, in terms of our classifier, this may only be due to the implicit nature of most sexist insults and a lack of sexist samples within the OLID dataset. Founta et al.'s dataset shows a high number of `hateful` tweets classified as `NOT`, which may be due to the implicit nature of sexism or sarcasm in the tweets involved.

Dataset	Tag	Subtask A		Subtask B		Subtask C		
		OFF	NOT	UNT	TIN	IND	GRP	OTH
Waseem and Hovy	racism	**52.94**	47.06	0.00	**100**	**64.70**	23.52	11.76
	sexism	42.96	**57.04**	8.28	**91.72**	**54.06**	30.27	15.67
	neither	20.22	**79.78**	28.27	**71.73**	**67.11**	25.95	6.94
Davidson et al.	hate_speech	**84.13**	15.87	3.35	**96.65**	**63.22**	24.61	12.17
	offensive_language	**86.89**	13.11	7.45	**92.55**	**71.89**	20.39	7.72
	neither	30.63	**69.37**	20.44	**79.56**	**63.29**	5.48	31.23
Founta et al.	hateful	**78.11**	21.89	5.92	**94.08**	**52.35**	27.37	20.28
	abusive	**97.34**	2.66	26.04	**73.96**	**75.56**	10.42	14.02
	normal	9.23	**90.77**	24.82	**75.18**	**60.24**	35.84	3.92
	spam	8.72	**91.28**	43.59	**56.41**	**50.98**	1.71	47.31
Zampieri et al.	*(actual annotation fraction)*	*32.91*	*67.09*	*11.88*	*88.12*	*61.31*	*28.17*	*10.52*

Table 6: Results of using a BERT model trained on OLID to tag other the datasets, for each OffensEval subtask. The values are percentages of tweets in each class (rows) annotated with the corresponding OLID tag (columns). Note that in the version of the Waseem and Hovy dataset used here, the racism tag only had 17 samples.

Some blanket statements that can be made given these results are that hate speech is highly targeted, mainly at individuals, but with a significant share targeted at groups and other institutions/issues. Offensive language, on the other hand, tends to be highly targeted only at individuals. Furthermore, the dearth of data belonging to the UNT, GRP and OTH tags may have had a detrimental effect on the model leading to the lob-sided (OFF, TIN, IND) classification.

7 Discussion and Conclusion

The paper makes two major contributions: First, an evaluation of the general effectiveness of BERT in Abusive Language Classification tasks and its ability to obtain results comparable to — or better than — the state-of-the-art by only fine-tuning.

Second, experiments showing that datasets with larger percentages of positive samples generalise better than datasets with fewer positive samples when tested against a dissimilar dataset (at least within the same platform, e.g., Twitter), which indicates that a more balanced dataset is healthier for generalisation. This observation should be accounted for when attempting to build new datasets to tackle Abusive Language Detection, but this is far from the only problem faced when attempting to create such datasets.

Looking at the various available datasets in this field, it is obvious that it cannot be expected for a single dataset to encompass all facets of abuse online. For example, on scanning the OLID (Zampieri et al., 2019a) using a lexicon of sexist and racist terms from Hatebase.org only a measly 55 and 567 hits, respectively, were obtained. Armed with this information we cannot possibly expect a model trained on the OLID dataset to effectively detect racism and sexism online. In fact, most of the data in OLID seem to be political, indicating that it in contrast has a high potential to detect such phenomena.

The point made here is that datasets used in the Abusive Language Detection space must be more representative of all facets of abusive language, if we expect them to generalise to any subset of abuse. Also, there are very few datasets that provide a large number of samples that can be taken advantage of by huge neural networks (Lee et al., 2018). However, we do acknowledge the difficulty in collecting abusive samples as most discourse online is benign. To address these issues, all datasets must advertise the subset of the abusive language they represent. In addition, more work must be done to identify similarities and holes in the representation of datasets. Merging of datasets may also prove to be a promising solution to the non-generalisability problem. Waseem et al. (2018)'s multi-task learning model can be a solid starting point for such endeavours.

A more ambitious solution could be the development of pre-trained embeddings (at the word and/or character level) for Abusive Language Detection, although the procurement of enough broad spanning data to produce a high-quality embedding could again be quite a challenging task.

In terms of whether the hierarchical annotation model helps in reducing redundancy and overlap in Abusive Language Detection subtasks, the answer is both yes and no:

- yes, the hierarchical annotation model does reveal the overlap in the subtasks of abusive language detection; but,

- no, it could hardly be a replacement for the existing multi-class annotation schema.

This is because there is still value in identifying whether a sample is racist / sexist / cyberbullying over just recognising whether the abuse is explicit or not, and in identifying the target of abuse.

However, the hierarchical model in its current form still cannot differentiate between various subsets of abusive language. Future hierarchical models could address this either by adding more levels to further differentiate the subsets or by creating additional levels to identify subsets more explicitly. For example, after the first level of the OLID (Zampieri et al., 2019a) annotation schema, it could branch out into a layer that classifies samples as hate speech, bullying / trolling or as non-abusive use of offensive language. The hate speech tag could then be expanded into another level classifying hate speech as being, e.g., racism, sexism, or other. This way of moving from coarse-grained tags to increasingly finer-grained ones might be a workable approach to tackling hierarchical annotation.

Other issues such as the adversarial methods used to bypass detection methods (Gröndahl et al., 2018) also plague this problem space. Character-based features alleviate this complication to some degree, but more work needs to be done to solve this. Research in this domain has also largely constrained itself to text, while real-world scenarios are quite different — there is a huge section of abuse online that rely on other forms of communication such as images, videos and gifs.

An overall conclusion is that the data is more important than the model when tackling Abusive Language Detection. Schmidt and Wiegland (2017) expressed the need for a benchmark dataset for abusive language tasks, but it would be unwise to say any current dataset fills this role. Future work must focus more on how models generalise to the real world by modifying the testing procedure. A model's performance on the dataset it was trained on cannot be indicative of how well it would perform in a real-life application, and a dataset's quality must be measured on how broad spanning and how representative it is of abusive language as a whole.

Acknowledgments

Thanks to all the researchers who have made their datasets available, specially Waseem and Hovy, Davidson et al., Founta et al., and Zampieri et al., the organisers of SemEval-2019 Task 6: OffensEval ('Identifying and Categorizing Offensive Language in Social Media').

Special thanks to the anonymous reviewers whose comments helped to improve the paper.

Abstract

Authorship attribution is an active research area which has been actively studied for many decades. Nevertheless, the majority of approaches consider problem sizes of a few candidate authors only, making them difficult to apply to recent scenarios incorporating thousands of authors emerging due to the manifold means to digitally share text. In this study, we focus on such large scale problems and propose to effectively reduce the number of candidate authors before applying common attribution techniques. By utilizing document embeddings, we show on a novel, comprehensive dataset collection that the set of candidate authors can be reduced with high accuracy. Moreover, we show that common authorship attribution methods substantially benefit from a preliminary reduction if thousands of authors are involved.

1 Introduction

Correctly determining the author of an anonymous text has been researched for several decades. Undoubtedly the most groundbreaking work in this area has been conducted in 1964 by Mosteller and Wallace, who attempted to automatically assign the authors of the Federalist Papers by utilizing a simple, but yet efficient statistical approach operating on function words (Mosteller and Wallace, 1964). By showing that writers can indeed be distinguished by their writing style, many approaches have been published in the following years, proposing enhancements by incorporating a variety of so-called stylometric features, methods and learning techniques (Stamatatos, 2009). By categorizing the problem of authorship attribution as a special form of text categorization (Sebastiani, 2002), also the respective methods in terms of different machine learning algorithms are effectively in use. With the advent of deep learning, also several approaches have been proposed recently which utilize comprehensive neural networks. Nevertheless, a recent comparison of all submitted approaches to the cross-domain authorship attribution task at PAN[1] indicates that deep learning is currently not able to surpass traditional methods (Kestemont et al., 2018).

Regardless of the features and methods used, the efficacy of an approach can only be measured by using appropriate datasets. Thereby, the majority of existing approaches focus only on a small number of candidate authors (up to 20, most of the times ten or less, e.g., (Stamatatos, 2009; Juola, 2012)). Only a few studies have examined the performance of authorship attribution approaches on larger amounts of possible authors, e.g., 114 (Madigan et al., 2005), 145 (Luyckx and Daelemans, 2008), 808 (Hitschler et al., 2017) or 1,000 (Shrestha et al., 2017) candidates. To the best of our knowledge, only three studies dive into the multiple thousands of authors: 10,000 (Koppel et al., 2006, 2011) and even 100,000 (Narayanan et al., 2012). While both studies agree that authorship attribution at large scale is substantially more difficult, they still show the potential of performing identification with acceptable accuracy. To be precise, both approaches report good performances only in scenarios where either an *"I don't know"* answer is also accepted (Koppel et al., 2011) or the attribution is not precise, i.e., the statement that the correct author is among the top k ones is sufficient (Narayanan et al., 2012).

Motivated by previous findings, which showed that direct authorship attribution is not feasible in a large scale scenario, we contribute to this field by proposing a two-step approach in this study. Specifically, we propose at first to reduce the number of candidate authors while keeping the correct

author in the reduced set with reasonable accuracy. Incorporating the promising results reported by using embedding representations ((Posadas-Durán et al., 2017)), we also find that a vector space based on document embeddings (Le and Mikolov, 2014) in combination with cosine similarity yields the best results for reducing candidate authors in the large scale. As authorship attribution generally heavily depends on the datasets used (e.g., the text type or the number of training and test documents (Luyckx and Daelemans, 2011; Potthast et al., 2016)) and the datasets used in the mentioned studies are not available,[2] we created a collection of 179 individual, novel datasets using a large question-and-answer (Q&A) network on which we extensively test our models. Using these datasets, we finally also show that a preliminary reduction of candidates substantially improves the overall accuracy of finding the correct author in large settings.

At a glance, our contributions are as follows: (1) We evaluate document embeddings in combination with cosine similarity and show that they outperform n-grams (which have proven to be among the most discriminating features, e.g., Stamatatos, 2013; Kestemont et al., 2018) with respect to the task of reducing the number of candidate authors in large scenarios. Thereby we show that neither n-grams used with similarity measures nor support vector machines are able to keep up with document embeddings. (2) We show that eliminating candidate authors using our approach in large settings—prior to performing direct attribution—substantially improves the accuracy of commonly used attribution methods. (3) We created a novel dataset collection based on a large Q&A network, consisting of 179 sub-datasets, each of which features six up to nearly 20,000 authors. To ensure reproducibility and to encourage further research, we make the dataset publicly available to the research community.

The remainder of this paper is organized as follows: At first, Section 2 summarizes related work and subsequently Section 3 presents the dataset. The proposed approach to reduce candidates using document embeddings and its evaluation is presented in Section 4, while Section 5 shows its impact on direct authorship attribution. Finally, Section 6 concludes and discusses future work.

[2]The dataset used by (Koppel et al., 2011) is partly available (see Section 4.2)

2 Related Work

Features and Methods

In the last decades many different features have been proposed for stylometry problems, which can basically be categorized into lexical, syntactic, structural and other specialized features (Stamatatos, 2009; Stein et al., 2011). For the specific task of authorship attribution, lexical metrics are predominant. Thereby, features are utilized on the character- and word-level, including character/word frequencies (Zheng et al., 2006), average word- and sentence lengths (Grieve, 2007), function word frequencies (Argamon et al., 2003; Zhao and Zobel, 2005), bag-of-words (BOW, Agun and Yilmazel, 2017) or especially character/word n-grams (Sapkota et al., 2015; Stamatatos, 2013; Schwartz et al., 2013 and variants thereof (Stamatatos, 2017). Moreover, derived features such as different readability measures (Tweedie and Baayen, 1998) or compression ratios (Marton et al., 2005) have also been investigated.

Syntactic features include the analysis of (n-grams of) Part-of-Speech (POS) tags (Zhao and Zobel, 2007) or the analysis of the parse tree of sentences (Luyckx and Daelemans, 2008; Tschuggnall and Specht, 2014), whereas structural features analyze indicators like the average paragraph length or the use of indentation (Zheng et al., 2006). In addition, various additional metrics have been proposed, e.g., the analysis of spelling and grammatical errors present in a text (Koppel and Schler, 2003).

From a methodical view, a wide range of machine learning techniques is in use, including Bayesian models, logistic regression, support vector machines (SVM) or decision trees. In most cases, the studies apply multiple classifiers and compare their results (e.g., see the surveys of Stamatatos, 2009; Juola and Stamatatos, 2013; Potthast et al., 2016; Kestemont et al., 2018). Recently, deep learning techniques have also been applied to authorship attribution problems. Thereby, various approaches have been proposed which use convolutional neural networks (CNN, Rhodes, 2015; Shrestha et al., 2017). With respect to input features, embeddings on different levels are heavily utilized, e.g., on words (*word2vec*, Mikolov et al., 2013), documents (*doc2vec*, Le and Mikolov, 2014), or n-grams of characters (Shrestha et al., 2017) or POS-tags (Hitschler et al., 2017). In addition, studies have reported that

embeddings are also highly efficient when fed into common machine learning techniques like SVMs or logistic regression (Agun and Yilmazel, 2017; Posadas-Durán et al., 2017).

In general, it has been shown that especially character n-grams and variants thereof are among the most discriminating features, which perform very well with common machine learning techniques such as out-of-the-box SVMs (e.g., Stamatatos, 2013; Kestemont et al., 2018), ensembles (e.g., Custódio and Paraboni, 2018) as well as with recent deep learning methods (e.g., Shrestha et al., 2017; Rhodes, 2015). Due to this success of n-grams, we chose to rely on them as a reference as is shown in Sections 4 and 5.

Large-Scale Authorship Attribution

As mentioned earlier, the majority of authorship attribution approaches target a relatively small number of candidate authors (up to at most 20). The few studies considering more than a hundred authors utilize various lexical features such as character n-grams together with syntactic features, and achieve accuracies ranging from 50-80% (Madigan et al., 2005; Luyckx and Daelemans, 2008). For about 800 authors, Hitschler et al. (2017) achieve 13% accuracy with a CNN, and Shrestha et al. (2017) also utilize a CNN to attribute the correct author out of 1,000 candidates with an accuracy of 36%.

Koppel et al. (2006, 2011) conducted two experiments on blogs with 10,000 authors. First, they achieve about 35% by using inverse-document-frequencies of stylistic features, represented in a vector space and compared using cosine similarity. In a second study, aiming for precision rather than recall (i.e., to rather output *don't know* than to guess), they use *space-free character 4-grams* with cosine similarity, and enhance their approach by iteratively evaluating randomized subsets of features. By doing so, they report a precision of 93% for the cases an answer is given.

Finally, the most comprehensive study with respect to number of candidate authors has been conducted by Narayanan et al. (2012), who evaluate different features with several machine learning techniques on a dataset consisting of 100,000 authors of blogs. In their study, the main focus is laid on security concerns, i.e., that the correct author can be identified in an attack. The authors show that a combination of a simple nearest neighbor approach with a regularized least squares classifier is able to detect the correct author of a blog in 20% of the cases and that the correct author is in the top-20 ranked candidates in 35% of the cases. Moreover and along the lines of Luyckx and Daelemans (2011) or Eder (2010), it is shown that the size of available training/test texts substantially influences the performance.

As the studies of (Koppel et al., 2011) and (Narayanan et al., 2012) are the only ones targeting authors in the large scale, we will also use these studies as references throughout this paper (in terms of their methodology and reported results). Nevertheless, a direct comparison is difficult as they either target different aims and/or the underlying datasets are not or only partly available. In contrast to these studies, we propose a novel two-step method in this paper and provide comprehensive large scale studies alongside, which can easily be reproduced in both methods as well as data used.

3 The SE-179 Dataset Collection

For the task of authorship attribution, a suitable dataset has to consist of realistic documents where the authorship of each document can undoubtedly be attributed to a single author. In the case of single-domain or single-topic analyses, it has to additionally be assured that all candidate authors write about the same topics—such that they cannot be exposed by simply looking at specific topic-related content words. Along the lines of Kestemont et al. (2018), who showed that data from Q&A forums can successfully be employed to analyze the writing style, we also used the same Q&A platform, namely *StackExchange*[3], to create our dataset.

The StackExchange network consists of several sites where people answer questions related to specific topics (*Stackoverflow* being the most popular site). In contrast to Kestemont et al. (2018) where only selected posts of selected StackExchange sites were crawled, we use the provided data dump[4] containing all questions and answers of all sites. Because the posts for each site are related to a single topic (e.g., photography), it allows us to create individual datasets from each site. Thereby the procedure for creating a dataset from a site was as follows:

[3] https://stackexchange.com

[4] provided directly by StackExchange at https://archive.org/details/stackexchange

(1.) We collected all questions and answers by all users participating in the site. (2.) We removed all posts that were edited by a person different from the original author (in the StackExchange network, basically everyone can edit anyone's posts). (3.) We cleaned each post, i.e., we removed code snippets, block quotes, bullet lists, embedded images and replaced links with `$URL$`. We then dismissed all posts containing less than ten tokens after cleaning. (4.) We combined all remaining posts of each user into a single document and removed all users with less than 500 tokens. Subsequently, we divided each document into a training and a test document. Thereby we assured that each training and test document contains at least 500 tokens, and in case this was not possible (because there were less than 1,000 tokens available), we only kept the training document to increase the number of candidates. I.e., there exist several training documents where there exists no corresponding test document. Note that it is a common procedure to fix training and test documents in order to ensure reproducibility (Stamatatos et al., 2018).

Consequently, we created a balanced, single-topic dataset from each site, containing different numbers of authors depending on the size of the community of the respective site. Table 1a shows the statistics of the resulting 179 datasets[5], including the average tokens per document (avg t/d) as well as the ratio between number of training to test documents (ttr). We consequently call the overall dataset collection *SE-179*. With respect to languages throughout the collection, the predominant one is English, but also individual problems in different languages are present[6].

For our study, the datasets containing many authors as listed in Table 1b are of high interest, nevertheless we conducted our experiments also on all other datasets as is detailed in Section 4.2. By doing so we can avoid potential biases towards specific datasets. As we are concerned about reproducibility, we make the SE-179 collection publicly available and encourage other researchers to utilize it according to their needs.[7]

[5]We didn't process the *Stackoverflow* site due to computational limitations with respect to its size.

[6]I.e., one for each Chinese, Esperanto, French, German, Italian, Japanese, Korean, Polish, Portuguese, Russian, Spanish and Ukrainian.

4 Reducing Candidate Authors

In this section, we outline our approach of effectively reducing the number of candidate authors by utilizing document embeddings. After describing the applied technique in Section 4.1 as well as the reference implementations used, we show the results in Section 4.2.

4.1 Methods

Document Embeddings

Based on the promising results reported by Posadas-Durán et al. (2017), we also utilize document embeddings with doc2vec (Le and Mikolov, 2014). Considering the two possible representation techniques provided by doc2vec, i.e., distributed memory (DM) and distributed bag of words (DBOW), we evaluated the three basic models (i) DM using concatenation (DM/concat), (ii) DM using average (DM/avg), (iii) DBOW as well as the two combinations (iv) DBOW+DM/concat and (v) DBOW+DM/avg. For each model, we evaluated vector sizes (dimensions) of $d = \{100, 200, 300\}$ (or the double in case of the combined models) and relied on the default/optimal settings found by Posadas-Durán et al. (2017) for the specific model parameters. With respect to the textual input, we at first tokenize the text and then experiment with the following settings to compute the embeddings:

– *type*: we either provide the text as is (*unigram*) or we compute *bigrams* of the words

– *stem*: decides whether stemming should be applied or not

– *windowing*: if a window length (w_l) is set, we traverse the document using a sliding window containing w_l tokens and thereby create new "documents" for each author. The window step w_s defines the number of tokens the window is shifted after each iteration. Additionally, we compute models from the original documents without windowing.

For the final reduction of candidate authors according to a given test document, the procedure is as follows: (1.) According to the previously described settings, we learn models from all available training documents of all authors. During this step, all documents are assigned a vector of dimension d (the model dimension), which form an according vector space. In case windowing is used, each author is represented by several vectors (one per window). (2.) For the given test document, we apply the same preprocessing steps (i.e., input type, stemming and windowing) and make use of the functionality provided by doc2vec to estimate a vector for a document that was not seen during learning. (3.) Similar to Koppel et al. (2011) we then compare the test document's vector with all document vectors in the vector space by computing the cosine similarity. Ordering by this similarity and using the top-k authors finally allows reducing the set of candidates to an arbitrary extent. In case windowing is used, i.e., when there are multiple documents by each author, we use the average of the similarities of all the author's document vectors.

Reference Implementations

To compare the proposed approach, we reimplemented the approach described by Koppel et al. (2011). Specifically, in this approach so-called *space-free* character 4-grams are computed for each document and their normalized frequencies form the basis for a vector space. By repeatedly (k_1 times) selecting k_2% of the feature set randomly, cosine similarity is used to compare the documents. In our reimplementation we used the optimal values as reported, i.e., $k_1 = 100$ and $k_2 = 40\%$. As an additional reference, we used regular n-grams instead of the space-free variants.

authors	**model**	d	stem	w_l	w_s	type
≤ 10	DM/avg	200	yes	–	–	unigram
11–100	DM/avg	100	yes	–	–	unigram
101–250	DM/concat	100	yes	300	50	unigram
251–500	DM/concat	100	yes	300	50	unigram
501–1,000	DM/concat	100	yes	300	50	unigram
1,001–5,000	DM/concat	200	yes	300	50	unigram
5,001–10,000	DM/concat	100	yes	–	–	unigram
$> 10{,}000$	DM/concat	100	yes	–	–	unigram

Table 2: Best doc2vec models with respect to number of authors.

4.2 Estimating Best Reduction Models

Contrary to Narayanan et al. (2012) we find it more suitable to not test whether the correct author is in the top-k results, but to evaluate how often s/he is in the result set after reducing by percentage (e.g., eliminating 90% of the candidates). This makes especially sense as we are dealing with 179 different datasets of different sizes, where a comparison of the top-k results with a fixed k is not meaningful (e.g., it makes a huge difference if the correct author is in the top-5 in a dataset containing 20 authors or in one containing 16,000 authors). Thus, we experimented with the reduction rates 10-90%, 95%, and 99%, and measured the hit rate, i.e., the percentage of how often the correct author is still in the reduced candidate set.

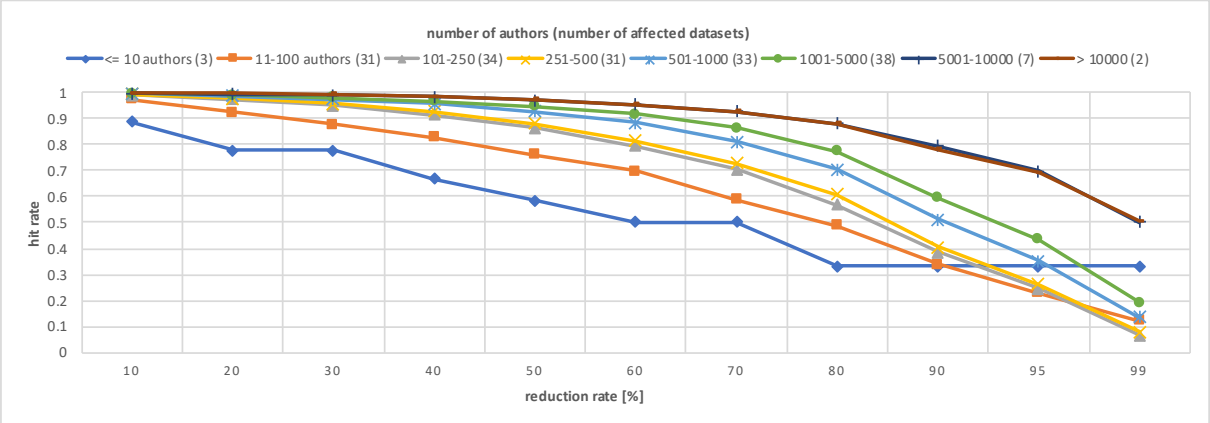
In a first preliminary step, we aimed to find the best models with respect to reduction rate and candidate author size[8]. We evaluated on all 179 datasets using the respective training documents for learning and the test documents for testing. For the larger datasets, we tested on 1,000 randomly selected test documents (as has been done by Koppel et al. (2011)).

After conducting the experiment, we found that the reduction rate doesn't make any difference with respect to the model type and that the best performing models only depend on the number of authors. Table 2 shows the best settings for different number of authors, computed by using the average of all corresponding datasets and regardless of the reduction rate.[9] It can be seen that stemmed unigrams work best in all cases and that windowing is not the preferred option when looking at large (and small) candidate sizes.

Using the best models found (depending on the number of candidate authors) we evaluated their

[8] E.g., what is the best doc2vec-model for reducing an 8,000 author dataset by 70%?

[9] Note that we cannot provide single hit rates for each configuration, as they significantly depend on the reduction rate.



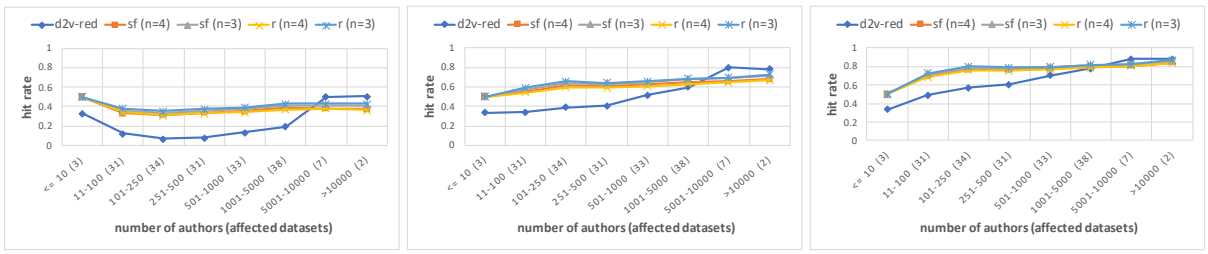


Figure 1: Hit rates for the doc2vec reduction models averaged over all datasets with respect to reduction rate and candidate author size.

(a) reduction rate = 99%

(b) reduction rate = 90%

(c) reduction rate = 80%

Figure 2: Comparison of the doc2vec reduction (d2v-red) with the method proposed by Koppel et al. (2011) using space-free (sf) and regular (r) n-grams. The y-axis shows the average hit rates over all datasets for different reduction rates, grouped by number of candidate authors.

performance with respect to the reduction rate. That is, we reduced the number of candidates by the respective percentage and measured—in terms of hit rate—if the correct author is still in the remaining set. As expected and can be seen in Figure 1, the performance decreases as the reduction rate increases. In general, the more candidate authors, the better the model is able to filter out irrelevant ones: E.g., the datasets having more than 5,000 authors could be reduced by 50% with a hit rate of 0.97, and by 80% with a hit rate of 0.88. When reducing these datasets by 99%, a hit rate of approximately 0.5 remains.

In a further experiment, we compared the reduction results to the reference systems described in Section 4.1, i.e., with regular and space-free n-grams as proposed by Koppel et al. (2011), Figure 2 exemplarily shows the average results over all datasets, grouped by the number of candidate authors for the reduction rates 99%, 90% and 80%, respectively. Regardless of the individual reduction rate, the doc2vec model is inferior to the other models for datasets having less than 5,000 authors, but can significantly[10] exceed them when more authors are involved. For example, when reducing candidates by 90% in a 5,000+ candidate author setting, it is able to keep the correct author with a hit rate of 0.69 in average, whereas the best other model (regular 3-grams) achieves a hit rate of 0.60. Although the superiority of our doc2vec model decreases with lower reduction rates, it is still better than the other models for all reduction rates in scenarios having more than 5,000 candidate authors, as is shown in Table 3.

5 Attribution on Reduced Candidates

In the previous section, we have shown that the number of candidate authors in large authorship attribution problems can effectively be reduced by compiling a document embedding model based on word unigrams. As a follow-up, we wanted to assess the influence of this reduction technique for state-of-the-art authorship attribution methods. The basic idea is to apply a two-step attribution by

[10] We computed a McNemar's test (Dietterich, 1998) and interpreted $p < 0.05$ as significant.

red.	d2v-red	sf (n=4)	sf (n=3)	r (n=4)	r (n=3)

Table 3: Comparison of the proposed doc2vec reduction (d2v-red) with the method proposed by Koppel et al. (2011) using space-free (sf) and regular (r) n-grams. The table shows the average hit rates for the respective reduction rates (red.) over all 9 datasets containing more than 5,000 authors.

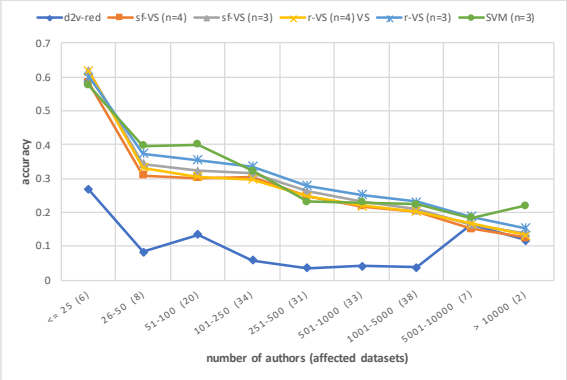

Figure 3: Accuracies for direct authorship attribution averaged over different candidate author sizes. *sf-VS* and *r-VS* represent space-free and regular n-grams, respectively, represented in a vector space as proposed by Koppel et al. (2011), and *SVM* refers to the reference implementation provided by PAN-2018.

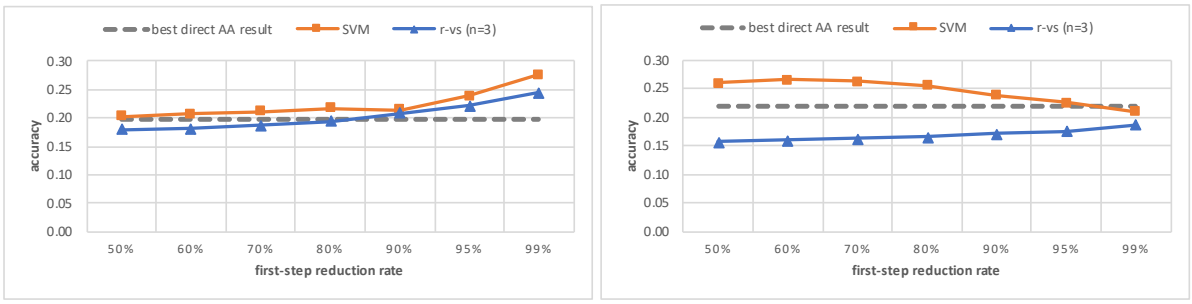
transforming large scale problems to normal-scale problems: (1.) reduce the number of candidate authors, (2.) apply regular authorship attribution approaches for the remaining candidates.

5.1 Direct Attribution Baseline

In a first step, we created a baseline by computing the accuracies achieved for direct authorship attribution, i.e., for finding the correct author without any reduction. For this, we utilized the proposed reduction technique, but reduced to exactly one author instead of a set of authors. Similar to Section 4.1, we again utilized the approach of Koppel et al. (2011) with space-free and regular character 3-/4-grams in combination with a vector space and cosine similarity. As an additional reference for comparison, we made use of the reference implementation provided for the author identification task at the PAN 2018 event (Kestemont et al., 2018). It computes character 3-grams and makes classifications using a standard SVM, yet achieving competitive results by applying grid search (Murauer et al., 2018). The results averaged over candidate author sizes are presented in Figure 3, revealing that doc2vec is very imprecise for direct authorship attribution in non-large cases. The other approaches generally perform similarly, except for the largest datasets where the SVM achieved the best results (0.21 for the datasets with more than 10,000 authors).



5.2 Two-Step Attribution

To measure the influence of the reduction proposed in Section 4, we conducted an experiment on the largest datasets by at first reducing the number of candidates, and subsequently performing regular authorship attribution. Considering the best results of direct attribution as presented previously, we evaluated the regular 3-gram vector space approach and the SVM implementation of PAN[11]. For each approach, we at first reduced the authors by the respective reduction rate, applied the two approaches and compared it to the best result achieved by direct attribution.

Figure 4 depicts the results for the 5,000-10,000 author datasets and for those having more than 10,000 authors, respectively. It can be seen that in general the accuracy–especially that of the SVM–can be improved, nevertheless, the best first-step reduction rate depends on the problem size: For datasets up to 10,000 candidates, the best option is to reduce the number of authors by 99% before performing attribution. On the contrary, the best accuracy for problems with more than 10,000 candidates could be achieved by using a reduction rate of 60%.

As stated initially in the paper, the evaluation results of authorship attribution techniques is highly dependent on the dataset (Luyckx and Daelemans, 2011; Potthast et al., 2016), and while our datasets within the SE-179 collection are highly heterogeneous with respect to topics and author sizes and also languages, they still belong to the genre of question-answering platforms. We therefore aimed to evaluate the dataset used by Koppel et al. (2011) to gain additional insight into the perfor-

[11]Note that for each test document a corresponding SVM has to be trained on the remaining candidate authors after reduction.

(a) 5k-10k authors datasets

mance on a different genre, i.e., blogs. Unfortunately, the data is only available in a raw form, i.e., we had to reconstruct the dataset as to the best of our knowledge incorporating the facts given by the authors. Consequently, we ended up with blog entries from 10,000 authors, each containing about 2,000 words, whereby the first 1,500 words were used for training and the last 500 for testing.

Considering the superiority of the SVM with character 3-grams in the previous experiment, we compared the performance of the SVM on all datasets of the SE-179 collection with more than 5,000 authors with the performance on the recreated blog dataset. Figure 5 shows the relative improvements of our proposed two-step attribution compared to the best direct attribution results, which are very similar for both the SE-179 datasets and the blog dataset, i.e., 0.202 and 0.204, respectively. As can be seen, a preliminary reduction of candidates substantially improves the performance, especially for the blog dataset for which the accuracy could be increased by more than 10%.

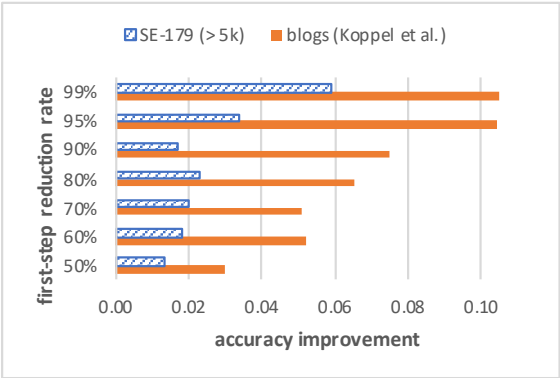

Figure 5: Relative performance improvements of the PAN-2018-SVM baseline implementation on SE-179 datasets with more than 5,000 authors and the reproduced blogs dataset (Koppel et al., 2011). The chart shows the improvements in accuracy that could be gained by applying preliminary candidate reduction.

6 Conclusion and Future Work

In this paper, we tackled the problem of large scale authorship attribution incorporating thousands of authors by first filtering candidate authors before the actual classification step. Extensive evaluations on a novel, publicly available dataset collection reveal that document embeddings in combination with cosine similarity are able to effectively reduce the number of candidate authors for large scale problems. We also outlined that a preliminary reduction increases the overall attribution accuracy in such cases.

As for future work, several open issues should be addressed. In this study, we relied on related work that suggests document embeddings, nevertheless other embedding techniques like *word2vec* (Mikolov et al., 2013), *fastText* (Joulin et al., 2016) or *GloVe* (Pennington et al., 2014) could be evaluated. Moreover, for the computation of similarities between document vectors, we relied on cosine similarity, whereas several other metrics should be evaluated. In the case of authorship attribution, we similarly utilized a common, established technique (SVM). As the reduction of problem sizes additionally enables the utilization of resource-intensive algorithms, more experiments are needed in that direction, especially using deep learning techniques. Finally, it would be worth investigating how this approach performs on cross-domain/-topic scenarios and other text genres like short messages or other social media contents.

Variational Semi-supervised Aspect-term Sentiment Analysis via Transformer

Abstract

Aspect-term sentiment analysis (ATSA) is a long-standing challenge in natural language processing. It requires fine-grained semantical reasoning about a target entity appeared in the text. As manual annotation over the aspects is laborious and time-consuming, the amount of labeled data is limited for supervised learning. This paper proposes a semi-supervised method for the ATSA problem by using the Variational Autoencoder based on Transformer. The model learns the latent distribution via variational inference. By disentangling the latent representation into the aspect-specific sentiment and the lexical context, our method induces the underlying sentiment prediction for the unlabeled data, which then benefits the ATSA classifier. Our method is classifier-agnostic, i.e., the classifier is an independent module and various supervised models can be integrated. Experimental results are obtained on the SemEval 2014 task 4 and show that our method is effective with different five specific classifiers and outperforms these models by a significant margin.

1 Introduction

Aspect based sentiment analysis (ABSA) has two sub-tasks, namely aspect-term sentiment analysis (ATSA) and aspect-category sentiment analysis (ACSA). ACSA is to infer the sentiment polarity with regard to the predefined categories, e.g., the aspect $food, price, ambience$. On the other hand, ATSA aims at classifying the sentiment polarity of a given aspect word or phrase in the text. For example, given a review about a restaurant "*the* $[pizza]_{aspect}$ *is the best if you like thin crusted pizza, however, the* $[service]_{aspect}$ *is awful.*", the sentiment implications with regard to "*pizza*" and "*service*" are contrary. For the aspect "*pizza*", the sentiment polarity is "*positive*" while "*negative*" for the aspect "*service*". In contrast to document-level sentiment analysis, ATSA requires more fine-grained reasoning about the textual context. The task is worthy of investigation as it can obtain the attitude with regard to a specific entity which we are interested in. The task is widely applicated in analyzing the comments, such as opinion generation. Recently, many attempts (Tang et al., 2016b; Pan and Wang, 2018; Liu et al., 2018; Xue and Li, 2018; Li et al., 2018a) focus on supervised learning and pay much attention to the interaction between the aspect and the context. However, the amount of labeled data is quite limited as the annotation about the aspects is laborious. Currently available data sets, e.g. SemEval, only has around 2K unique sentences and 3K sentence-aspect pairs, which is insufficient to fully exploit the power of the deep models. Fortunately, a large amount of unlabeled data is available for free and can be accessed easily from the websites. It will be of great significance if numerous unlabeled samples can be utilized to further facilitate the supervised ATSA classifier. Therefore, the semi-supervised ATSA is a promising research topic.

In ATSA, achieving the sentiment of the aspect-term is semantically complicated and it is non-trivial for a model to capture sentimental similarity of the aspects, which causes the difficulties for semi-supervised learning. In this paper, we proposed a classifier-agnostic framework which named Aspect-term Semi-supervised Variational Autoencoder (Kingma and Welling, 2014) based on Transformer (ASVAET). The variational autoencoder offers the flexibility to customize the model structure. In other words, the proposed framework is compatible with other supervised neural networks to boost their performance. Our proposed model learns the latent representation

of the input data and disentangles the representations into two independent parts, i.e., the aspect-term sentiment and the representation of the lexical context. By regarding the aspect sentiment polarity of the unlabeled data as the discrete latent variable, the model implicitly induces the sentiment polarity via the variational inference. Specifically, the representation of the lexical context is extracted by the encoder and the aspect-term sentiment polarity is inferred from the specific ATSA classifier. The decoder takes these two representations as inputs and reconstructs the original sentence by two unidirectional language models. In contrast to the conventional auto-regressive models, the latent representations have their specific meanings and are obtained from the encoder and the classifier to the input examples. Therefore, it is also possible to condition the sentence generation on the sentiment and lexical information w.r.t. a certain target entity. In addition, by separating the representation of the input sentence, the classifier becomes an independent module in our framework, which endows the method with the ability to integrate different classifiers. The method is presented in detail in Sec. 3.

Experimental results are obtained on the two classical datasets from SemEval 2014 task 4 (Pontiki et al., 2014). Five recent available models are implemented as the classifier in ASVAET. Our method is able to utilize the unlabeled data and consistently improve the performance against the supervised models. Compared with other semi-supervised methods, i.e., in-domain word embedding pre-training and self-training, the proposed method also demonstrates better performance. We also evaluate the effectiveness of labeled data and sharing embeddings, and show that the structure can provide the separation between lexical context and sentiment polarity in the latent space.

2 Related Work

Sentiment analysis is a traditional research hotspot in the NLP field (Wang and Manning, 2012). Rather than obtaining the sentimental inclination of the entire text, ATSA instead aims to extract the sentimental expression w.r.t. a target entity. With the release of online completions, abundant methods were proposed to explore the limits of current models. Tang et al. (Tang et al., 2016a) proposed to make use of bidirectional Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) to encode the sentence from the left and right to the aspect-term. This model primarily verifies the effectiveness of deep models for ABSA Tang et al. (Tang et al., 2016b) then put forward a neural reasoning model in analogy to the memory network to perform the reasoning in many steps. There are also many other works dedicating to solve this task (Pan and Wang, 2018; Liu et al., 2018; Zhang and Liu, 2017).

Another related topic is semi-supervised learning for the text classification. Recently, Data augmentation methods (Xie et al., 2019; Berthelot et al., 2019) achieve a greate success on low-resource datasets. Moreover, A simple but efficient method is to use pre-trained modules, e.g., initializing the word embedding or bottom layers with pre-training. Word embedding technique has been wildly used in NLP models, e.g., Glove (Pennington et al., 2014) and ELMo (Peters et al., 2018). Recently, Bidirectional Encoder Representations from Transformer (BERT) (Devlin et al., 2018) replaces the embedding layer to context-dependent layer with the pre-trained bidirectional language model to capture the contextual representation. BERT is complementary to the encoder of the proposed method. To keep our framework neat, these pre-training investigations are not conducted in this paper.

VAE-based semi-supervised methods, on the other hand, are able to cooperate with various kinds of classifiers. VAE has been applied in many semi-supervised NLP tasks, ranging from text classification (Xu et al., 2017), relation extraction (Marcheggiani and Titov, 2016) to sequence tagging (Chen et al., 2018). Different from text classification where sentiment polarity is related to an entire sentence, ATSA just interested in related information of a given aspect-term. To circumvent this problem, a novel structure is proposed.

3 Method Description

In this section, the problem definition is provided and then the model framework is presented in detail.

The ATSA task aims to classify a data sample with input sentence $\mathbf{x} = \{x_1, ..., x_n\}$ and corresponding aspect [1] $\mathbf{a} = \{a_1, ..., a_m\}$, where $\mathbf{a}$ is a subsequence of $\mathbf{x}$, into a sentiment polarity y, where $y \in \{P, O, N\}$. P, O, N denotes

[1] If an input sentence has n aspect-terms, then n data samples are generated.

"positive", "neutral", "negative". For the semi-supervised ATSA, we consider the following scenario. Given a dataset consisting of labeled samples $\mathbf{S}_l$ and unlabeled samples $\mathbf{S}_u$, where the $\mathbf{S}_l = \{(\mathbf{x}_l^{(i)}, \mathbf{a}_l^{(i)}, y_l^{(i)})\}_{i=1}^{N_l}$ and $\mathbf{S}_u = \{(\mathbf{x}_u^{(i)}, \mathbf{a}_u^{(i)}\}_{i=1}^{N_l}$, the goal is to utilize $\mathbf{S}_u$ to improve the classification performance over the supervised model using $\mathbf{S}_l$ only.

The architecture is depicted in Fig. 1. The method consists of three main components, i.e., the classifier, the encoder, and the decoder. The classifier can be any differentiable supervised ATSA model, which takes $\mathbf{x}$ and $\mathbf{a}$ as input, and outputs the prediction about y. The encoder transform the data into a latent space that is independent of the label y. And the decoder combines the outputs from the classifier and the encoder to reconstruct the input sentence. For the labeled data, the classifier and the autoencoder are trained with the given label y. For the unlabeled data, the y is regarded as the latent discrete variable and it is induced by maximizing the generative probability. As the classifier can be implemented by various models, the description of the classifier will be omitted. We present a autoencoder structure based on Transformer (Vaswani et al., 2017). In the following, the objective functions are clarified, followed by the model description.

3.1 Variational Inference

Using generative models is a common approach for semi-supervised learning, which tries to extract the information from the unlabeled data by modeling the data distribution. In VAE, the data distribution is modeled by optimizing the evidence lower bound (ELBO) of data log-likelihood, which leads to two objectives for labeled data and unlabeled data respectively. For the labeled data, VAE maximizes the ELBO of $p(\mathbf{x}, y|\mathbf{a})$. For the unlabeled data, it optimizes the ELBO of $p(\mathbf{x}|\mathbf{a})$, where the y is latent and integrated. Specifically, the dependency between variables is illustrated in Fig. 2. The ELBO of $\log p(\mathbf{x}, y|\mathbf{a})$ can be given as follows:

$$\begin{aligned}\log p_\theta(\mathbf{x}, y|\mathbf{a}) \geq\ & \mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x},\mathbf{a},y)}[\log p_\theta(\mathbf{x}|y,\mathbf{a},\mathbf{z})] \\ & - D_{KL}(q_\phi(\mathbf{z}|\mathbf{x},\mathbf{a},y)||p_\theta(\mathbf{z})) \\ & + \log p_\theta(y) \\ =\ & \mathcal{L}(\mathbf{x},\mathbf{a},y)\,,\end{aligned} \tag{1}$$

where $\mathbf{z}$ is the latent variable which represents lexical information over the sentence and D_{KL} is the KullbackLeibler divergence.

In terms of the unlabeled data, the ELBO of $\log p(\mathbf{x}|\mathbf{a})$ can be extended from Eq. 1.

$$\begin{aligned}\log p_\theta(\mathbf{x}|\mathbf{a}) \geq & \sum_y q_\phi(y|\mathbf{x},\mathbf{a})(\mathcal{L}(\mathbf{x},\mathbf{a},y)) \\ & + \mathcal{H}(q_\phi(y|\mathbf{x},\mathbf{a})) \\ = & \mathcal{U}(\mathbf{x},\mathbf{a})\,,\end{aligned} \tag{2}$$

where $\mathcal{H}$ is the entropy function and $q_\phi(y|\mathbf{x},\mathbf{a})$ is the classification function.

And $q_\phi(y|\mathbf{x},\mathbf{a})$ can also be trained in the supervised manner using the labeled data. Combining the above objectives, the overall objective for the entire data set is:

$$\begin{aligned}J = & \sum_{(\mathbf{x},\mathbf{a},y)\in S_l} -\mathcal{L}(\mathbf{x},\mathbf{a},y) + \sum_{\mathbf{x}\in S_u} -\mathcal{U}(\mathbf{x},\mathbf{a}) \\ & + \gamma \sum_{(\mathbf{x},\mathbf{a},y)\in S_l} -\log q_\phi(y|\mathbf{x},\mathbf{a})\,,\end{aligned} \tag{3}$$

where γ is a hyper-parameter which controls the weight of the additional classification loss.

To implement this objective, three components are required to model the $q_\phi(y|\mathbf{x},\mathbf{a})$, $q_\phi(\mathbf{z}|\mathbf{x},\mathbf{a},y)$ and $p_\theta(\mathbf{x}|y,\mathbf{a},\mathbf{z})$ respectively.

3.2 Classifier

Various currently available models can be used as the classifier. For the unlabeled data, the classifier is used to predict the distribution of label y for the decoder, i.e., $y \sim q_\phi(y|\mathbf{x},\mathbf{a})$. The distribution $q_\phi(y|\mathbf{x},\mathbf{a})$ will be tuned during maximizing the objective in Eq. 2. In this work, five classifiers are implemented in ASVAET and they are also used as the supervised baselines for the comparison.

3.3 Transformer Encoder

The encoder plays the role of $q_\phi(\mathbf{z}|\mathbf{x},\mathbf{a},y)$. This module attempts to extract the lexical feature that is independent of the label y when given data sample $(\mathbf{x},\mathbf{a})$. In this way, the $\mathbf{z}$ and $\mathbf{y}$ jointly form the representative vector for the input data.

In our implementation, we use a bidirectional encoder to construct sentences embeddings. It is referred as the Transformer encoder that is actually a sub-graph of the Transformer architecture (Vaswani et al., 2017), the architecture is shown in the left part of the Fig. 2. The encoder employs residual connections around each of the multi-head attention sub-layers, followed by

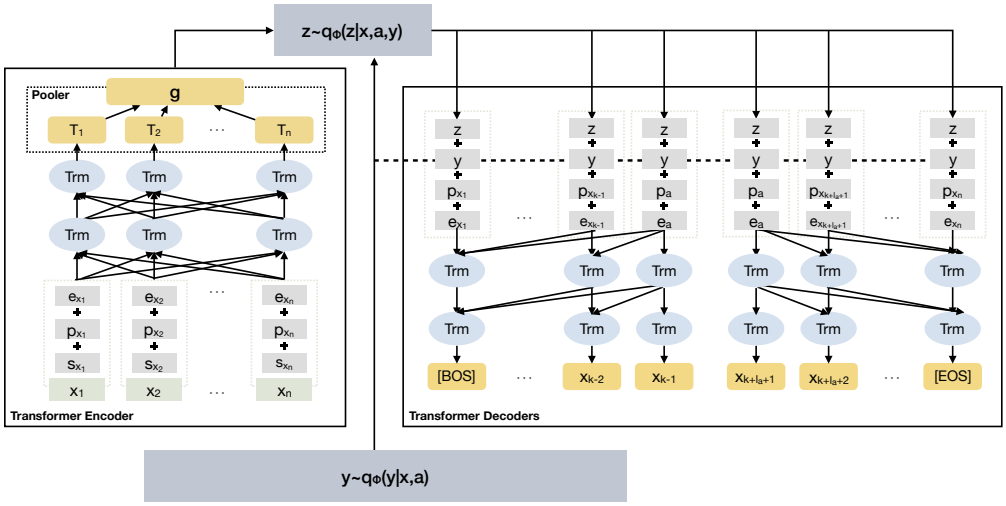

Figure 1: This is the sketch of our model with bidirectional encoder and decoder. Assuming the aspect-term starts at the k-th position in $\mathbf{x}$. **Bottom**: When using unlabeled data, the distribution of $y \sim q_\phi(y|\mathbf{x}, \mathbf{a})$ is provided by the classifier. **Left**: The sequence is encoded by a Transformer block, which receives the summation of three embeddings, i.e., segment (used to distinguish aspect words) $\mathbf{s}_{x_n}$, position $\mathbf{p}_{x_n}$ and word $\mathbf{e}_{x_n}$. The encoding and the label y are used to parameterize the posterior $q_\phi(z|\mathbf{x}, \mathbf{a}, y)$. **Right**: A sample $\mathbf{z}$ from the posterior $q_\phi(\mathbf{z}|\mathbf{x}, \mathbf{a}, y)$ and label y are passed to the generative network which estimates the probability $p_\theta(\mathbf{x}|y, \mathbf{a}, \mathbf{z})$ by two unidirectional Transformer decoders. The number of aspect tokens is l_a.

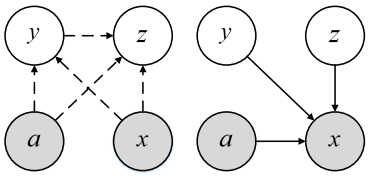

Figure 2: Illustration of ASVAET as a directed graph. **Left**: Dashed lines are used to denote variational approximation $q_\phi(y|\mathbf{x}, \mathbf{a})q_\phi(\mathbf{z}|\mathbf{x}, \mathbf{a}, y)$. **Right**: Solid lines are used to denote generative model $p_\theta(\mathbf{x}|y, \mathbf{a}, \mathbf{z})$.

layer normalization. To capture the aspect-term, we treat the aspect-term and its context differently by segment embeddings. To further emphasize the position of the conditional aspect, the position tag is also included for each token. The position tag indicates the distance from the token to the aspect. And then the position tag is transformed into a vector as defined in (Vaswani et al., 2017), which is added with the word embedding and segment embedding as the input of the Transformer encoder. Let $\mathbf{g}$ denote the output of the Transformer encoder after pooling which simply averaging the hidden states of the aspect-terms (the number of tokens is equal or greater than one) of the last layer, $\mathbf{y}$ is the indicator vector of the polarity. Then the distribution of $\mathbf{z}$ can be given as:

$$\mathbf{z} \sim \mathcal{N}(\mu(\mathbf{x}, y), diag(\sigma^2(\mathbf{x}, y))) ,$$
$$\mu(\mathbf{x}, y) = \tanh(\mathbf{W}_\mu[\mathbf{g} : \mathbf{y}] + \mathbf{b}_\mu) ,$$
$$\sigma(\mathbf{x}, y) = \tanh(\mathbf{W}_\sigma[\mathbf{g} : \mathbf{y}] + \mathbf{b}_\sigma) .$$

The sequences are divided into two parts by using segment embedding, the encoder can be aware of the position and the content of the aspect-term $\mathbf{a}$ by multi-head attention operation in the Transformer encoder. The information from two sides are aggregated into the aspect-term $\mathbf{a}$, and therefore the resulting $\mathbf{z}$ can gather the information related to the aspect.

3.4 Transformer Decoders

The decoder is also a sub-graph of Transformer architechture (Vaswani et al., 2017) which focus on reconstructing original text. The main difference from the Transformer encoder is that the Transformer decoder is unidirectional by modifying the self-attention sub-layer to prevent positions from paying attention to subsequent positions. The textual sequence is well-known to be semantically complex and it is non-trivial for a Transformer decoder to capture the high-level semantics. Here we investigate two questions. How to implement $p_\theta(\mathbf{x}|y, \mathbf{a}, \mathbf{z})$ without losing the information of $\mathbf{a}$ and how to capture the semantic polarity by a sequential model. For the first question, denoting

that $\mathbf{x}$ is composed of three parts $(\mathbf{x}_l, \mathbf{a}, \mathbf{x}_r)$, we use two Transformer decoders to model the left and right content. For the second question, we let each token is generated conditioned on the summation of the variables $\mathbf{z}$ and embedding $\mathbf{y}$.

One way to achieve $p_\theta(\mathbf{x}|y, \mathbf{a}, \mathbf{z})$ is to separate the sequence into two parts, reversing the process in the two unidirectional decoder. For each decoder, the input state is represented by the summation of the four input i.e., the polarity indicator vector $\mathbf{y}$ from the classifier or the labeled dataset, the context vector $\mathbf{z}$ from the encoder, the input token embedding $\mathbf{e}_{x_t}$ and the position embedding $\mathbf{p}_{x_t}$:

$$
\begin{aligned}
\overleftarrow{\mathbf{h}}_t^{trm} &= \overleftarrow{f_{trm}}(\mathbf{e}_{[x_t:a]}, \mathbf{p}_{x_t}, \mathbf{y}, \mathbf{z}), \quad x_t \in [\mathbf{x}_l : \mathbf{a}] \\
p(x_{t-1}|\cdot) &= \text{softmax}(\mathbf{W}_p \overleftarrow{\mathbf{h}}_t^{trm} + b_p)\,, \\
\log p_\theta(\mathbf{x}_l|\mathbf{a}, y, \mathbf{z}) &= \sum_{x_t} \log p(x_t|\cdot), \quad x_t \in \mathbf{x}_l\,, \\
\overrightarrow{\mathbf{h}}_t^{trm} &= \overrightarrow{f_{trm}}(\mathbf{e}_{[a:x_t]}, \mathbf{p}_{x_t}, \mathbf{y}, \mathbf{z}), \quad x_t \in [\mathbf{a} : \mathbf{x}_r] \\
p(x_{t+1}|\cdot) &= \text{softmax}(\mathbf{W}_p \overrightarrow{\mathbf{h}}_t^{trm} + b_p)\,, \\
\log p_\theta(\mathbf{x}_r|\mathbf{a}, y, \mathbf{z}) &= \sum_{x_t} \log p(x_t|\cdot), \quad x_t \in \mathbf{x_r}\,.
\end{aligned}
$$

It is equivalent to generate two sequences using two decoders. When decoding left part (or right part), the aspect will first get processed by the decoder and hence the decoder is aware of the aspect-terms. The position tag is also used in the decoder.

4 Experiments

4.1 Datasets and Preparation

The models are evaluated on two benchmarks: Restaurant (REST) and Laptop (LAPTOP) datasets from the SemEval ATSA challenge (Pontiki et al., 2014). The REST dataset contains the reviews in the restaurant domain, while the LAPTOP dataset contains the reviews of Laptop products. The statistics of these two datasets are listed in Table 1. When processing these two datasets, we follow the same procedures as in another work (Lam et al., 2018). The dataset has a few samples that are labeled as "conflict" and these samples are removed. All tokens in the samples are lowercased without other preprocess, e.g., removing the stop words, symbols or digits.

In terms of the unlabeled data, we obtained samples in the same domain for the REST and LAPTOP datasets. For the REST, the unlabeled samples are obtained from a sentiment analysis competition in Kaggle [2]. The competition consists of 82K training samples and 34K test samples. For the LAPTOP, the unlabeled samples are obtained from the "Six Categories of Amazon Product Reviews" [3], which has 412K samples. The reviews about the laptops are used among six product categories.

		# Positive	# Negative	# Neutral
REST	Train	2159	800	632
	Test	730	195	196
LAPTOP	Train	980	858	454
	Test	340	128	171

Table 1: The statistics of the datasets.

		Avg. Length	Std. Length
REST	Labeled	20.06	10.38
	Unlabeled	22.70	12.38
LAPTOP	Labeled	21.95	11.80
	Unlabeled	29.89	17.33

Table 2: The statistics of the reviews.

The NLTK sentence tokenizer is utilized to extract the sentences from the raw comments. And each sentence is regarded as a sample in our model for both REST and LAPTOP. To obtain the aspects in the unlabeled samples, an open-sourced aspect extractor [4] is pre-trained using labeled data. The resulting test F1 score is 88.42 for the REST and 80.12 for the LAPTOP. Then the unlabeled data is processed by the pre-trained aspect extractor to obtain the aspects. The sentences that have no aspect are removed. And the sentences are filtered with maximal sentence length 80. The statistic of the resulting sentences is given in Table. 2.

4.2 Model Configuration & Classifiers

In the experiments, the model is fixed with a set of universal hyper-parameters. The number of units in the encoder and the decoder is 100 and the latent variable is of size 50 and the number of layers of both Transformer blocks is 2, the number of self-attention heads is 8. The KL weight klw should be carefully tuned to prevent the model from trapping in a local optimum, where $\mathbf{z}$ carries no useful information. In this work, the KL weight is set to be 1e-4. In term of word embedding, the pre-trained GloVe (Pennington et al., 2014) is used as the in-

Table 3: Experimental results (%). For each classifier, we performed five experiments, i.e., the supervised classifier, the supervised classifier with pre-trained embedding using unlabeled data and our model with the classifier. The results are obtained after 5 runs, and we report the mean and the standard deviation of the test accuracy, and the Macro-averaged F1 score. Better results are in bold. ♮ denotes that the results are extracted from the original paper.

put of the encoder and the decoder [5] and the out-of-vocabulary words are excluded. And it is fixed during the training. The γ is set to be 10 across the experiments.

We implemented and verified four kinds of mainstream ATSA classifiers integrated into our model, i.e., TC-LSTM (Tang et al., 2016a), MemNet (Tang et al., 2016b), BILSTM-ATT-G (Zhang and Liu, 2017), IAN (Ma et al., 2017) and TNet (Li et al., 2018b).

- **TC-LSTM**: Two LSTMs are used to model the left and right context of the target separately, then the concatenation of two representations is used to predict the label.

- **MemNet**: It uses the attention mechanism over the word embedding over multiple rounds to aggregate the information in the sentence, the vector of the final round is used for the prediction.

- **IAN**: IAN adopts two LSTMs to derive the representations of the context and the target phrase interactively and the concatenation is fed to the softmax layer.

- **BILSTM-ATT-G**: It models left and right contexts using two attention-based LSTMs and makes use of a special gate layer to combine these two representations. The resulting vector is used for the prediction.

- **TNet-AS**: Without using an attention module, TNet adopts a convolutional layer to get salient features from the transformed word representations originated from a bi-directional LSTM layer. Among current supervised models, TNet is currently one of the in-domain state-of-the-art methods and the TNet-AS is one of the two variants of TNet.

The configuration of hyper-parameters and the training settings are the same as in the original papers. Various classifiers are tested here to demonstrate the robustness of our method and show that the performance can be consistently improved for different classifiers.

4.3 Main Results

Table 3 shows the experimental results on the REST and LAPTOP datasets. Two evaluation metrics are used here, i.e., classification accuracy and Macro-averaged F1 score. The latter is more sensitive when the dataset is class-imbalance. In this table, the semi-supervised results are obtained with 10K unlabeled data. We didn't observe further improvement with more unlabeled data. The mean and the standard deviation are reported over

[5] http://nlp.stanford.edu/data/glove.8B.300d.zip

5 runs. For each classifier *clf*, we conducted the following experiments:

- *clf*: The classifier is trained using labeled data only.
- *clf* (EMB): We use CBOW (Mikolov et al., 2013) to train the word embedding vectors using both labeled and unlabeled data. And the resulting vectors, instead of pre-trained GloVe vectors, are used to initialize the embedding matrix of the classifier. This is the embedding-level semi-supervised learning as the embedding layer is trained using in-domain data.
- *clf* (ST): The self-training (ST) method is a typical semi-supervised learning method. We performed the self-training method over each classifier. At each epoch, we select the 1K samples with the best confidence and give them pseudo labels using the prediction. Then the classifier is re-trained with the new labeled data. The procedure loops until all the unlabeled samples are labeled.
- *clf* (ASVAET): The proposed method that uses *clf* as the classifier. Note again that the classifier is an independent module in the proposed model, and the same configuration is used as in the supervised learning.

Besides, we also include the results of several supervised models in the first block, i.e., CNN-ASP (Lam et al., 2018), AE-LSTM, ATAE-LSTM (Wang et al., 2016), GCAE (Li and Xue, 2018), from the original paper.

From the Table 3, the ASVAET is able to improve supervised performance consistently for all classifiers. For the MemNet, the test accuracy can be improved by about 2% by the TSSVAE, and so as the Macro-averaged F1. The TNet-AS outperforms the other three models.

Compared with the other two semi-supervised methods, the ASVAET also shows better results. The ASVAET outperforms the compared semi-supervised methods evidently. The adoption of in-domain pre-trained word vectors is beneficial for the performance compared with the Glove vectors.

4.4 Ablation Studies

4.4.1 Effect of Labeled Data

Here we investigated whether the ASVAET works with less labeled data. Without loss of generality, the MemNet is used as the basic classifier. We sampled different amount of labeled data to verify the improvement by using ASVAET. The test accuracy curve w.r.t. the amount of labeled data used is shown in Fig. 3. With fewer labeled samples, the test accuracy decreases, however, the improvement becomes more evident. When using 500 labeled samples, the improvement is about 3.2%. With full 3591 labeled samples, 1.5% gain can be obtained. This illustrates that our method can improve the accuracy with limited data.

Accuracy	w/o sharing	w/ sharing
TC-LSTM (ASVAET)	**78.34**	77.65
MemNet (ASVAET)	**80.58**	78.82
IAN (ASVAET)	**80.23**	79.22
BILSTM-ATT-G (ASVAET)	**81.11**	78.36
TNet-AS (ASVAET)	**81.77**	79.53

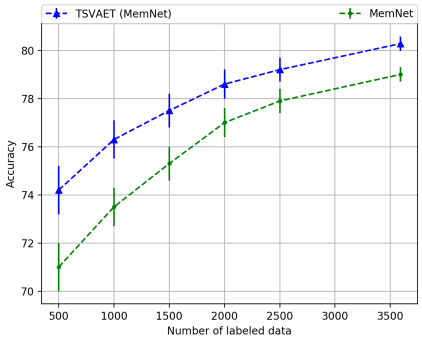

Figure 3: The test accuracy w.r.t. the number of labeled samples on the REST dataset with MemNet classifier.

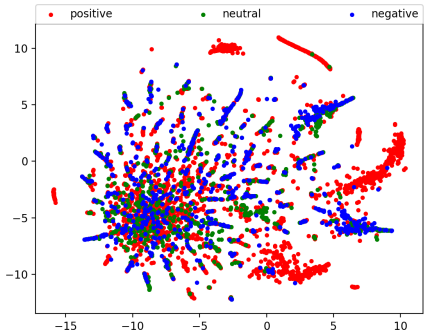

Figure 4: The distribution of the REST dataset in latent space $\mathbf{z}$ using t-SNE.

4.4.2 Effect of Sharing Embeddings

In previous works, the word embedding is shared among all the components. In other words, the word embedding is also tuned in learning to reconstruct the data. It is questionable whether the improvement is obtained by using VAE or multi-

Positive
... the best *food* i 've ever had !!! ...
... the *lox* is very tasty ...
... the *rice* is a great value ...
Negative
... the worst *food* i 've ever had !!! ...
... the *lox* is a bit of boring ...

... lox with a glass of chilli sauce ...
... the *rice* with a couple of olives salad ...

Table 5: Nice sentences that are generated by controlling the sentiment polarity y using the decoder.

task learning (text generation and classification). In the aforementioned experiments, the embedding layer is not shared between the classifier and autoencoder. This implementation guarantees that the improvement does not come from learning to generate. To verify if sharing embedding will benefit, we also conducted experiments with sharing embedding, as illustrated in Table. 4. The results indicate that the joint training for the embedding layer is negative for improving the performance in this task. The gradient from the autoencoder may collide with the gradients from the classifier and therefore, interferes with the optimization direction.

4.5 Analysis of the Latent Space

Transformer encodes the data into two representations, i.e., y and $\mathbf{z}$. These two latent variable represented sentiment polarity and lexical context individually from the input text. We expect the y and $\mathbf{z}$ are fully disentangled and represent different meanings. The scatters of latent variable $\mathbf{z}$ (cf. Fig. 4) helps us have a better understanding. As shown in the figure, the distributions of three different polarities are very similar, which indicates that the lexical context reprensetation $\mathbf{z}$ is independent of the polarity y.

The generation ability of the decoder is also investigated. Several sentences are generated and selected in the Table 5. By controlling the sentiment polarity y with the same $\mathbf{z}$, the decoder can generate sentences with different sentiment in a similar format. This indicates that the decoder is trained successfully to perceive the y and model the relationship between the y and $\mathbf{x}$.

5 Conclusion

A VAE-based framework has been proposed for the ATSA task. In this work, the encoder and decoder are constructed from the Transformers. Both analytical and experimental work has been carried out to show the effectiveness of the ASVAET. The method is verified with various kinds of classifiers. For all tested classifiers, the improvement is obtained when equipped with ASVAET, which demonstrates its universality.

In this paper, the aspect-term is assumed to be known and there is an error accumulation problem when using the pre-trained aspect extractor. According to this, in future work, it is also interesting to show if it is possible to learn the aspect and sentiment polarity jointly for the unlabeled data. It will be of great importance if detailed knowledge can be extracted from the unlabeled data, which will shed light on other related tasks.

Abstract

Aspect-based sentiment analysis (ABSA) is to predict the sentiment polarity towards a particular aspect in a sentence. Recently, this task has been widely addressed by the neural attention mechanism, which computes attention weights to softly select words for generating aspect-specific sentence representations. The attention is expected to concentrate on opinion words for accurate sentiment prediction. However, attention is prone to be distracted by noisy or misleading words, or opinion words from other aspects. In this paper, we propose an alternative hard-selection approach, which determines the start and end positions of the opinion snippet, and selects the words between these two positions for sentiment prediction. Specifically, we learn deep associations between the sentence and aspect, and the long-term dependencies within the sentence by leveraging the pre-trained BERT model. We further detect the opinion snippet by self-critical reinforcement learning. Especially, experimental results demonstrate the effectiveness of our method and prove that our hard-selection approach outperforms soft-selection approaches when handling multi-aspect sentences.

1 Introduction

Aspect-based sentiment analysis (Pang and Lee, 2008; Liu, 2012) is a fine-grained sentiment analysis task which has gained much attention from research and industries. It aims at predicting the sentiment polarity of a particular aspect of the text. With the rapid development of deep learning, this task has been widely addressed by attention-based neural networks (Wang et al., 2016; Ma et al., 2017; Cheng et al., 2017; Tay et al., 2018; Wang et al., 2018a). To name a few, Wang et al. (2016) learn to attend on different parts of the sentence given different aspects, then generates aspect-specific sentence representations for sentiment prediction. Tay et al. (2018) learn to attend on correct words based on associative relationships between sentence words and a given aspect. These attention-based methods have brought the ABSA task remarkable performance improvement.

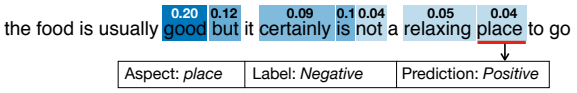

Figure 1: Example of attention visualization. The attention weights of the aspect *place* are from the model ATAE-LSTM (Wang et al., 2016), a typical attention mechanism used for soft-selection.

Previous attention-based methods can be categorized as **soft-selection** approaches since the attention weights scatter across the whole sentence and every word is taken into consideration with different weights. This usually results in attention distraction (Li et al., 2018b), i.e., attending on noisy or misleading words, or opinion words from other aspects. Take Figure 1 as an example, for the aspect *place* in the sentence *"the food is usually good but it certainly is not a relaxing place to go"*, we visualize the attention weights from the model ATAE-LSTM (Wang et al., 2016). As we can see, the words *"good"* and *"but"* are dominant in attention weights. However, *"good"* is used to describe the aspect *food* rather than *place*, *"but"* is not so related to *place* either. The true opinion snippet *"certainly is not a relaxing place"* receives low attention weights, leading to the wrong prediction towards the aspect *place*.

Therefore, we propose an alternative **hard-selection** approach by determining two positions

in the sentence and selecting words between these two positions as the opinion expression of a given aspect. This is also based on the observation that opinion words of a given aspect are usually distributed consecutively as a snippet (Wang and Lu, 2018). As a consecutive whole, the opinion snippet may gain enough attention weights, avoid being distracted by other noisy or misleading words, or distant opinion words from other aspects. We then predict the sentiment polarity of the given aspect based on the average of the extracted opinion snippet. The explicit selection of the opinion snippet also brings us another advantage that it can serve as justifications of our sentiment predictions, making our model more interpretable.

To accurately determine the two positions of the opinion snippet of a particular aspect, we first model the deep associations between the sentence and aspect, and the long-term dependencies within the sentence by BERT (Devlin et al., 2018), which is a pre-trained language model and achieves exciting results in many natural language tasks. Second, with the contextual representations from BERT, the two positions are sequentially determined by self-critical reinforcement learning. The reason for using reinforcement learning is that we do not have the ground-truth positions of the opinion snippet, but only the polarity of the corresponding aspect. Then the extracted opinion snippet is used for sentiment classification. The details are described in the model section.

The main contributions of our paper are as follows:

- We propose a hard-selection approach to address the ABSA task. Specifically, our method determines two positions in the sentence to detect the opinion snippet towards a particular aspect, and then uses the framed content for sentiment classification. Our approach can alleviate the attention distraction problem in previous soft-selection approaches.

- We model deep associations between the sentence and aspect, and the long-term dependencies within the sentence by BERT. We then learn to detect the opinion snippet by self-critical reinforcement learning.

- The experimental results demonstrate the effectiveness of our method and also our approach significantly outperforms soft-selection approaches on handling multi-aspect sentences.

2 Related Work

Traditional machine learning methods for aspect-based sentiment analysis focus on extracting a set of features to train sentiment classifiers (Ding et al., 2009; Boiy and Moens, 2009; Jiang et al., 2011), which usually are labor intensive. With the development of deep learning technologies, neural attention mechanism (Bahdanau et al., 2014) has been widely adopted to address this task (Tang et al., 2015; Wang et al., 2016; Tang et al., 2016; Ma et al., 2017; Chen et al., 2017; Cheng et al., 2017; Li et al., 2018a; Wang et al., 2018a; Tay et al., 2018; Hazarika et al., 2018; Majumder et al., 2018; Fan et al., 2018; Wang et al., 2018b). Wang et al. (2016) propose attention-based LSTM networks which attend on different parts of the sentence for different aspects. Ma et al. (2017) utilize the interactive attention to capture the deep associations between the sentence and the aspect. Hierarchical models (Cheng et al., 2017; Li et al., 2018a; Wang et al., 2018a) are also employed to capture multiple levels of emotional expression for more accurate prediction, as the complexity of sentence structure and semantic diversity. Tay et al. (2018) learn to attend based on associative relationships between sentence words and aspect.

All these methods use normalized attention weights to softly select words for generating aspect-specific sentence representations, while the attention weights scatter across the whole sentence and can easily result in attention distraction. Wang and Lu (2018) propose a hard-selection method to learn segmentation attention which can effectively capture the structural dependencies between the target and the sentiment expressions with a linear-chain conditional random field (CRF) layer. However, it can only address aspect-term level sentiment prediction which requires annotations for aspect terms. Compared with it, our method can handle both aspect-term level and aspect-category level sentiment prediction by detecting the opinion snippet.

3 Model

We first formulate the problem. Given a sentence $S = \{w_1, w_2, ..., w_N\}$ and an aspect $A = \{a_1, a_2, ..., a_M\}$, the ABSA task is to predict the

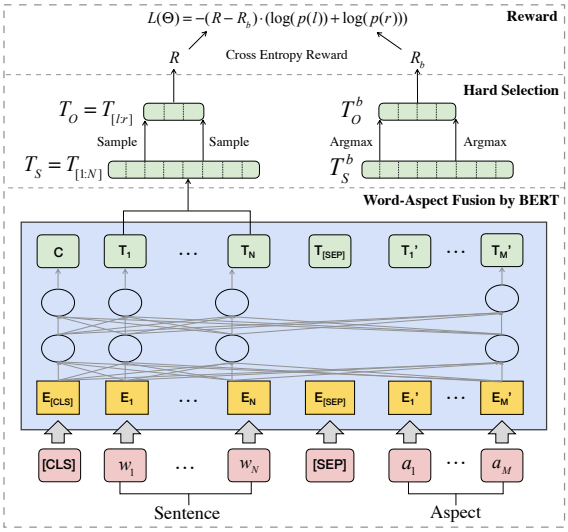

Figure 2: Network Architecture. We leverage BERT to model the relationships between sentence words and a particular aspect. The sentence and aspect are packed together into a single sequence and fed into BERT, in which E represents the input embedding, and T_i represents the contextual representation of token i. With the contextual representations from BERT, the start and end positions are sequentially sampled and then the framed content is used for sentiment prediction. Reinforcement learning is adopted for solving the non-differentiable problem of sampling.

sentiment of A. In our setting, the aspect can be either aspect terms or an aspect category. As aspect terms, A is a snippet of words in S, i.e., a sub-sequence of the sentence, while as an aspect category, A represents a semantic category with $M = 1$, containing just an abstract token.

In this paper, we propose a hard-selection approach to solve the ABSA task. Specifically, we first learn to detect the corresponding opinion snippet $O = \{w_l, w_{l+1}..., w_r\}$, where $1 \leq l \leq r \leq N$, and then use O to predict the sentiment of the given aspect. The network architecture is shown in Figure 2.

3.1 Word-Aspect Fusion

Accurately modeling the relationships between sentence words and an aspect is the key to the success of the ABSA task. Many methods have been developed to model word-aspect relationships. Wang et al. (2016) simply concatenate the aspect embedding with the input word embeddings and sentence hidden representations for computing aspect-specific attention weights. Ma et al. (2017) learn the aspect and sentence interactively by using two attention networks. Tay et al. (2018) adopt circular convolution of vectors for performing the word-aspect fusion.

In this paper, we employ BERT (Devlin et al., 2018) to model the deep associations between the sentence words and the aspect. BERT is a powerful pre-trained model which has achieved remarkable results in many NLP tasks. The architecture of BERT is a multi-layer bidirectional Transformer Encoder (Vaswani et al., 2017), which uses the self-attention mechanism to capture complex interaction and dependency between terms within a sequence. To leverage BERT to model the relationships between the sentence and the aspect, we pack the sentence and aspect together into a single sequence and then feed it into BERT, as shown in Figure 2. With this sentence-aspect concatenation, both the word-aspect associations and word-word dependencies are modeled interactively and simultaneously. With the contextual token representations $T_S = T_{[1:N]} \in \mathbb{R}^{N \times H}$ of the sentence, where N is the sentence length and H is the hidden size, we can then determine the start and end positions of the opinion snippet in the sentence.

3.2 Soft-Selection Approach

To fairly compare the performance of soft-selection approaches with hard-selection approaches, we use the same word-aspect fusion results T_S from BERT. We implement the attention mechanism by adopting the approach similar to the work (Lin et al., 2017).

$$\begin{aligned} \boldsymbol{\alpha} &= softmax(\boldsymbol{v_1} tanh(W_1 {T_S}^{\mathrm{T}})) \\ \boldsymbol{g} &= \boldsymbol{\alpha} T_S \end{aligned} \tag{1}$$

where $\boldsymbol{v_1} \in \mathbb{R}^H$ and $W_1 \in \mathbb{R}^{H \times H}$ are the parameters. The normalized attention weights $\boldsymbol{\alpha}$ are used to softly select words from the whole sentence and generate the final aspect-specific sentence representation $\boldsymbol{g}$. Then we make sentiment prediction as follows:

$$\hat{\boldsymbol{y}} = softmax(W_2 \boldsymbol{g} + \boldsymbol{b}) \tag{2}$$

where $W_2 \in \mathbb{R}^{C \times H}$ and $\boldsymbol{b} \in \mathbb{R}^C$ are the weight matrix and bias vector respectively. $\hat{\boldsymbol{y}}$ is the probability distribution on C polarities. The polarity with highest probability is selected as the prediction.

3.3 Hard-Selection Approach

Our proposed hard-selection approach determines the start and end positions of the opinion snippet

and selects the words between these two positions for sentiment prediction. Since we do not have the ground-truth opinion snippet, but only the polarity of the corresponding aspect, we adopt reinforcement learning (Williams, 1992) to train our model. To make sure that the end position comes after the start position, we determine the start and end sequentially as a sequence training problem (Rennie et al., 2017). The parameters of the network, Θ, define a policy p_θ and output an action that is the prediction of the position. For simplicity, we only generate two actions for determining the start and end positions respectively. After determining the start position, the "state" is updated and then the end is conditioned on the start.

Specifically, we define a start vector $\boldsymbol{s} \in \mathbb{R}^H$ and an end vector $\boldsymbol{e} \in \mathbb{R}^H$. Similar to the prior work (Devlin et al., 2018), the probability of a word being the start of the opinion snippet is computed as a dot product between its contextual token representation and $\boldsymbol{s}$ followed by a softmax over all of the words of the sentence.

$$\boldsymbol{\beta_l} = softmax(T_S \boldsymbol{s}) \tag{3}$$

We then sample the start position l based on the multinomial distribution $\boldsymbol{\beta_l}$. To guarantee the end comes after the start, the end is sampled only in the right part of the sentence after the start. Therefore, the state is updated by slicing operation ${T_S}^r = T_S[l:]$. Same as the start position, the end position r is also sampled based on the distribution $\boldsymbol{\beta_r}$:

$$\boldsymbol{\beta_r} = softmax(T_S^r \boldsymbol{e}) \tag{4}$$

Then we have the opinion snippet $T_O = T_S[l:r]$ to predict the sentiment polarity of the given aspect in the sentence. The probabilities of the start position at l and the end position at r are $p(l) = \boldsymbol{\beta_l}[l]$ and $p(r) = \boldsymbol{\beta_r}[r]$ respectively.

3.3.1 Reward

After we get the opinion snippet T_O by the sampling of the start and end positions, we compute the final representation $\boldsymbol{g_o}$ by the average of the opinion snippet, $\boldsymbol{g_o} = avg(T_O)$. Then, equation 2 with different weights is applied for computing the sentiment prediction $\hat{\boldsymbol{y_o}}$. The cross-entropy loss function is employed for computing the reward.

$$R = -\sum_c y^c \log \hat{\boldsymbol{y_o}}^{\boldsymbol{c}} \tag{5}$$

where c is the index of the polarity class and y is the ground truth.

3.3.2 Self-Critical Training

In this paper, we use reinforcement learning to learn the start and end positions. The goal of training is to minimize the negative expected reward as shown below.

$$L(\Theta) = -R \cdot p(l) \cdot p(r) \tag{6}$$

where Θ is all the parameters in our architecture, which includes the base method BERT, the position selection parameters $\{\boldsymbol{s}, \boldsymbol{e}\}$, and the parameters for sentiment prediction and then for reward calculation. Therefore, the *state* in our method is the combination of the sentence and the aspect. For each state, the *action* space is every position of the sentence.

To reduce the variance of the gradient estimation, the reward is associated with a reference reward or baseline R_b (Rennie et al., 2017). With the likelihood ratio trick, the objective function can be transformed as.

$$L(\Theta) = -(R - R_b) \cdot (log(p(l)) + log(p(r))) \tag{7}$$

The baseline R_b is computed based on the snippet determined by the baseline policy, which selects the start and end positions greedily by the $argmax$ operation on the $softmax$ results. As shown in Figure 2, the reward R is calculated by sampling the snippet, while the baseline R_b is computed by greedily selecting the snippet. Note that in the test stage, the snippet is determined by $argmax$ for inference.

4 Experiments

In this section, we compare our hard-selection model with various baselines. To assess the ability of alleviating the attention distraction, we further conduct experiments on a simulated multi-aspect dataset in which each sentence contains multiple aspects.

4.1 Datasets

We use the same datasets as the work by Tay et al. (2018), which are already processed to token lists and released in Github[1]. The datasets are from SemEval 2014 task 4 (Pontiki et al., 2014), and SemEval 2015 task 12 (Pontiki et al., 2015), respectively. For aspect term level sentiment classification task (denoted by T), we apply the Laptops and

Restaurants datasets from SemEval 2014. For aspect category level sentiment prediction (denoted by C), we utilize the Restaurants dataset from SemEval 2014 and a composed dataset from both SemEval 2014 and SemEval 2015. The statistics of the datasets are shown in Table 1.

4.2 Implementation Details

Our proposed models are implemented in PyTorch[2]. We utilize the bert-base-uncased model, which contains 12 layers and the number of all parameters is 100M. The dimension H is 768. The BERT model is initialized from the pre-trained model, other parameters are initialized by sampling from normal distribution $\mathcal{N}(0, 0.02)$. In our experiments, the batch size is 32. The reported results are the testing scores that fine-tuning 7 epochs with learning rate 5e-5.

4.3 Compared Models

- **LSTM**: it uses the average of all hidden states as the sentence representation for sentiment prediction. In this model, aspect information is not used.

- **TD-LSTM** (Tang et al., 2015): it employs two LSTMs and both of their outputs are applied to predict the sentiment polarity.

- **AT-LSTM** (Wang et al., 2016): it utilizes the attention mechanism to produce an aspect-specific sentence representation. This method is a kind of soft-selection approach.

- **ATAE-LSTM** (Wang et al., 2016): it also uses the attention mechanism. The difference with AT-LSTM is that it concatenates the aspect embedding to each word embedding as the input to LSTM.

- **AF-LSTM(CORR)** (Tay et al., 2018): it adopts circular correlation to capture the deep fusion between sentence words and the aspect, which can learn rich, higher-order relationships between words and the aspect.

- **AF-LSTM(CONV)** (Tay et al., 2018): compared with AF-LSTM(CORR), this method applies circular convolution of vectors for performing word-aspect fusion to learn relationships between sentence words and the aspect.

- **BERT-Original**: it makes sentiment prediction by directly using the final hidden vector C from BERT with the sentence-aspect pair as input.

4.4 Our Models

- **BERT-Soft**: as described in Section 3.2, the contextual token representations from BERT are processed by self attention mechanism (Lin et al., 2017) and the attention-weighted sentence representation is utilized for sentiment classification.

- **BERT-Hard**: as described in Section 3.3, it takes the same input as BERT-Soft. It is called a hard-selection approach since it employs reinforcement learning techniques to explicitly select the opinion snippet corresponding to a particular aspect for sentiment prediction.

4.5 Experimental Results

In this section, we evaluate the performance of our models by comparing them with various baseline models. Experimental results are illustrated in Table 2, in which *3-way* represents 3-class sentiment classification (*positive*, *negative* and *neutral*) and *Binary* denotes binary sentiment prediction (*positive* and *negative*). The best score of each column is marked in bold.

Table 2: Experimental results (accuracy %) on all the datasets. Models in the first part are baseline methods. The results in the first part (except BERT-Original) are obtained from the prior work (Tay et al., 2018). Avg column presents macro-averaged results across all the datasets.

Firstly, we observe that BERT-Original, BERT-Soft, and BERT-Hard outperform all soft attention baselines (in the first part of Table 2), which demonstrates the effectiveness of fine-tuning the pre-trained model on the aspect-based sentiment classification task. Particularly, BERT-Original outperforms AF-LSTM(CONV) by 2.63%∼9.57%, BERT-Soft outperforms AF-LSTM(CONV) by 2.01%∼9.60% and BERT-Hard improves AF-LSTM(CONV) by 3.38%∼11.23% in terms of accuracy. Considering the average score across eight settings, BERT-Original outperforms AF-LSTM(CONV) by 6.46%, BERT-Soft outperforms AF-LSTM(CONV) by 6.47% and BERT-Hard outperforms AF-LSTM(CONV) by 7.19% respectively.

Secondly, we compare the performance of three BERT-related methods. The performance of BERT-Original and BERT-Soft are similar by comparing their average scores. The reason may be that the original BERT has already modeled the deep relationships between the sentence and the aspect. BERT-Original can be thought of as a kind of soft-selection approach as BERT-Soft. We also observe that the snippet selection by reinforcement learning improves the performance over soft-selection approaches in almost all settings. However, the improvement of BERT-Hard over BERT-Soft is marginal. The average score of BERT-Hard is better than BERT-Soft by 0.68%. The improvement percentages are between 0.36% and 1.49%, while on the Laptop dataset, the performance of BERT-Hard is slightly weaker than BERT-Soft. The main reason is that the datasets only contain a small portion of multi-aspect sentences with different polarities. The distraction of attention will not impact the sentiment prediction much in single-aspect sentences or multi-aspect sentences with the same polarities.

4.6 Experimental Results on Multi-Aspect Sentences

On the one hand, the attention distraction issue becomes worse in multi-aspect sentences. In addition to noisy and misleading words, the attention is also prone to be distracted by opinion words from other aspects of the sentence. On the other hand, the attention distraction impacts the performance of sentiment prediction more in multi-aspect sentences than in single-aspect sentences. Hence, we evaluate the performance of our models on a test dataset with only multi-aspect sentences.

A multi-aspect sentence can be categorized by two dimensions: the *Number* of aspects and the *Polarity* dimension which indicates whether the sentiment polarities of all aspects are the same or not. In the dimension of *Number*, we categorize the multi-aspect sentences as *2-3* and *More*. *2-3* refers to the sentences with two or three aspects while *More* refers to the sentences with more than three aspects. The statistics in the original dataset shows that there are much more sentences with *2-3* aspects than those with *More* aspects. In the dimension *Polarity*, the multi-aspect sentences can be categorized into *Same* and *Diff*. *Same* indicates that all aspects in the sentence have the same sentiment polarity. *Diff* indicates that the aspects have

Type	*Same*			*Diff*			Total
	2-3	*More*	Total	*2-3*	*More*	Total	
Number	1665	352	2017	655	327	982	2999

Table 3: Distribution of the multi-aspect test set. Around 67% of the multi-aspect sentences belong to the *Same* category.

different polarities.

Multi-aspect test set. To evaluate the performance of our models on multi-aspect sentences, we construct a new multi-aspect test set by selecting all multi-aspect sentences from the original training, development, and test sets of the Restaurants term-level task. The details are shown in Table 3.

Multi-aspect training set. Since we use all multi-aspect sentences for testing, we need to generate some "virtual" multi-aspect sentences for training. The simulated multi-aspect training set includes the original single-aspect sentences and the newly constructed multi-aspect sentences, which are generated by concatenating multiple single-aspect sentences with different aspects. We keep the balance of each subtype in the new training set (see Table 4). The number of *Neutral* sentences is the least among three sentiment polarities in all single-aspect sentences. We randomly select the same number of *Positive* and *Negative* sentences. Then we construct multi-aspect sentences by combining single-aspect sentences in different combinations of polarities. The naming for different combinations is simple. For example, *2P-1N* indicates that the sentence has two positive aspects and one negative aspect, and *P-N-Nu* means that the three aspects in the sentence are positive, negative, and neutral respectively. For simplicity, we only construct 2-asp and 3-asp sentences which are also the majority in the original dataset.

Type	*Same*	*Diff*			Total
		2-3	*More*	Total	
BERT-Original	73.33	57.10	60.86	58.35	68.42
BERT-Soft	75.31	57.25	57.19	57.23	69.39
BERT-Hard	**76.90**	**60.15**	**64.53**	**61.61**	**71.89**

Table 5: Experimental results (accuracy %) on multi-aspect sentences. The performance of the 3-way classification on the multi-aspect test set is reported.

Results and Discussions. The results on different types of multi-aspect sentences are shown in Table 5. The performance of BERT-Hard is better than BERT-Original and BERT-Soft over all types of multi-aspect sentences. BERT-Hard outperforms BERT-Soft by 2.11% when the aspects have the same sentiment polarities. For multi-aspect sentences with different polarities, the improvements are more significant. BERT-Hard outperforms BERT-Soft by 7.65% in total of *Diff*. The improvements are 5.07% and 12.83% for the types *2-3* and *More* respectively, which demonstrates the ability of our model on handling sentences with *More* aspects. Particularly, BERT-Soft has the poorest performance on the subset *Diff* among the three methods, which proves that soft attention is more likely to cause attention distraction.

Intuitively, when multiple aspects in the sentence have the same sentiment polarities, even the attention is distracted to other opinion words of other aspects, it can still predict correctly to some extent. In such sentences, the impact of the attention distraction is not obvious and difficult to detect. However, when the aspects have different sentiment polarities, the attention distraction will lead to catastrophic error prediction, which will obviously decrease the classification accuracy. As shown in Table 5, the accuracy of *Diff* is much worse than *Same* for all three methods. It means that the type of *Diff* is difficult to handle. Even though, the significant improvement proves that our hard-selection method can alleviate the attention distraction to a certain extent. For soft-selection methods, the attention distraction is inevitable due to their way in calculating the attention weights for every single word. The noisy or irrelevant words could seize more attention weights than the ground truth opinion words. Our method considers the opinion snippet as a

Aspect	Label	Method	Multi-Aspect Sentence	Prediction
appetizers	*Neutral*	BERT-Soft	the appetizers are ok, but the service is slow (0.24, 0.18, 0.06)	*Negative* ✗
		BERT-Hard	the appetizers are ok, but the service is slow (1)	*Neutral* ✓
service	*Negative*	BERT-Soft	the appetizers are ok, but the service is slow (0.12, 0.12, 0.12, 0.12, 0.15)	*Negative* ✓
		BERT-Hard	the appetizers are ok, but the service is slow (1)	*Negative* ✓

Figure 3: Visualization. The attention weights are visualized for BERT-Soft, and the selected opinion snippets are marked for BERT-Hard. The correctness of the predicted results is also marked.

consecutive whole, which is more resistant to attention distraction.

4.7 Visualization

In this section, we visualize the attention weights for BERT-Soft and opinion snippets for BERT-Hard. As demonstrated in Figure 3, the multi-aspect sentence *"the appetizers are OK, but the service is slow"* belongs to the category *Diff*. Firstly, the attention weights of BERT-Soft scatter among the whole sentence and could attend to irrelevant words. For the aspect *service*, BERT-Soft attends to the word *"ok"* with relatively high score though it does not describe the aspect *service*. This problem also exists for the aspect *appetizers*. Furthermore, the attention distraction could cause error prediction. For the aspect *appetizers*, *"but"* and *"slow"* gain high attention scores and cause the wrong sentiment prediction *Negative*.

Secondly, our proposed method BERT-Hard can detect the opinion snippet for a given aspect. As illustrated in Figure 3, the opinion snippets are selected by BERT-Hard accurately. In the sentence *"the appetizers are ok, but the service is slow"*, BERT-Hard can exactly locate the opinion snippets *"ok"* and *"slow"* for the aspect *appetizers* and *service* respectively.

At last, we enumerate some opinion snippets detected by BERT-Hard in Table 6. Our method can precisely detect snippets even for latent opinion expression and alleviate the influence of noisy words. For instance, *"cannot be beat for the quality"* is hard to predict using soft attention because the sentiment polarity is transformed by the negative word *"cannot"*. Our method can select the whole snippet without bias to any word and in this way the attention distraction can be alleviated. We also list some inaccurate snippets in Table 7. Some meaningless words around the true snippet are included, such as *"are"*, *"and"* and *"at"*. These words do not affect the final prediction. A possible explanation to these inaccurate words is that the true snippets are unlabeled and our method predicts them only by the supervisory signal from sentiment labels.

Positive Snippets	Negative Snippets
very good prompt attentive	not great bland
beautifully presented	can not eat this well
extremely tasty	unbearable conversation
as interesting as possible	no idea how to use
cool and soothing	would never go there
impressed by	not above ordinary
cannot be beat for the quality	not good

Table 6: Examples of accurate opinion snippets detected by BERT-Hard.

Inaccurate Snippets	
are very large and	and even greater food
are not terrible	tasty treat at
everyone who works	the money and said

Table 7: Examples of inaccurate opinion snippets detected by BERT-Hard.

5 Conclusion

In this paper, we propose a **hard-selection** approach for aspect-based sentiment analysis, which determines the start and end positions of the opinion snippet for a given input aspect. The deep associations between the sentence and aspect, and the long-term dependencies within the sentence are taken into consideration by leveraging the pre-trained BERT model. With the hard selection of the opinion snippet, our approach can alleviate the attention distraction problem of traditional attention-based soft-selection methods. Experimental results demonstrate the effectiveness of our method. Especially, our hard-selection approach outperforms soft-selection approaches significantly when handling multi-aspect sentences with different sentiment polarities.

Abstract

In this article we present an extended version of PolEmo – a corpus of consumer reviews from 4 domains: medicine, hotels, products and school. Current version (PolEmo 2.0) contains 8,216 reviews having 57,466 sentences. Each text and sentence was manually annotated with sentiment in 2+1 scheme, which gives a total of 197,046 annotations. We obtained a high value of Positive Specific Agreement, which is 0.91 for texts and 0.88 for sentences. PolEmo 2.0 is publicly available under a Creative Commons copyright license. We explored recent deep learning approaches for the recognition of sentiment, such as Bidirectional Long Short-Term Memory (BiLSTM) and Bidirectional Encoder Representations from Transformers (BERT).

1 Introduction

In recent years, we have observed a growing interest in methods of effective sentiment analysis, especially in subjective, opinion-forming online texts. This trend is perfectly illustrated by Figure 1, which compares the popularity of two terms: *customer feedback* and *sentiment analysis*. A very dynamic growth has been observed since 2010, which correlates with the increase in the number of scientific research in this area. Many studies focus on the perception of emotion and sentiment in text messages and, for example, their impact on election results (Ramteke et al., 2016), prediction of future events (Zhang and Skiena, 2010) and security issues around the world (Subramaniyaswamy et al., 2017; Al-Rowaily et al., 2015). Automatic sentiment analysis systems have proven to be effective in analyzing many different types of text data such as emails, blogs, news, tweets and books (Medhat et al., 2014). The introduction of advanced computational techniques (machine learning, deep learning) in natural language processing has resulted in a significant increase in sentiment analysis techniques (Zhang et al., 2018). This increase for some languages is effectively limited by the lack of good quality resources for this task, especially in the form of manually annotated corpora (Balahur and Turchi, 2012; Dashtipour et al., 2016).

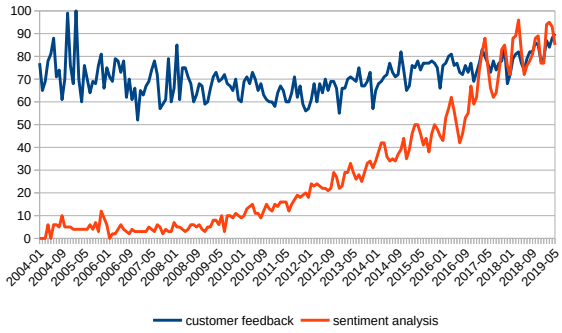

Figure 1: Google Trends (https://trends.google.com) data showing interest in time for search terms "customer feedback" and "sentiment analysis". On the vertical axis 100 means biggest search term popularity.

Analysis of the existing language resources in the area of sentiment analysis shows that they largely concern the English language (Dashtipour et al., 2016). However, there is a clear growing interest in other languages, often much more complex than English (e.g. Slavic languages in the area of loose syntax and rich inflection) and new resources become available for them, e.g., Slovene (Bučar et al., 2018), Czech (Habernal and Brychcín, 2013) or Russian (Rogers et al., 2018). Due to a small number of available corpora manually annotated with sentiment for the Polish language, we decided that the construction of the PolEmo resource will be a valuable contribution to the collection of publicly available resources for sentiment analysis and may in the future provide a basis for the creation of shared tasks, in which the recognition of sentiment for the Polish language

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 980–991
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

will also be included. Both for the construction of the corpus and for further research, we used the experience from the work on the manual annotation of the Polish WordNet – plWordNet 4.0 Emo (Janz et al., 2017; Kocoń et al., 2018a,b) – as a result of which the sentiment metadata of more than 55,000 lexical units were described.

The main objectives of the article are to present:

- The current state of resources related to the analysis of sentiment for the Polish language;
- The method of selecting data for the PolEmo 2.0 corpus, the annotation method, the annotation results and the analysis of annotation errors;
- The results of research related to the automatic analysis of sentiment, with particular emphasis on the importance of the *text domain* in this topic.

The key contribution of these studies includes:

- Detailed description of the procedure of building PolEmo 2.0: manually annotated corpus of consumer reviews from 4 domains (medicine, school, hotels, products) at 2 levels of sentiment granularity (document, sentence);
- Detailed analysis of manual annotation with regard to frequently occurring errors;
- Development of methods based on deep learning (BiLSTM, BERT), adapted to PolEmo 2.0 corpus, also using sentiment lexicon generated from plWordNet 4.0 Emo;
- Performing tests on sets prepared for the analysis of the quality of methods (1) evaluated on texts within a given domain, (2) evaluated on texts from various domains (3) trained on texts that do not include a given domain and tested on a given domain;
- Comparison of deep learning methods with classic methods (Logistic Regression), especially in the context of the ability to generalize the problem of recognizing sentiment and providing semantic representation, which is as independent of the domain as possible;
- Making PolEmo 2.0 corpus available under an open license.

2 Related Work

There are several well-known resources annotated with sentiment for English, e.g.: MPQA 3.0 (Deng and Wiebe, 2015), the Stanford Sentiment Treebank (Socher et al., 2013), Amazon Product Data (He and McAuley, 2016), Pros And Cons Dataset (Ganapathibhotla and Liu, 2008), corpora developed within the Semantic Evaluation workshops (Nakov et al., 2016; Pontiki et al., 2016), SentiWordNet (Baccianella et al., 2010) or Opinion Lexicon (Hu and Liu, 2004). There are also different approches and tools used for multilingual sentiment analysis (Lo et al., 2017) which are based on transformations on the existing resources. In this section we are focusing on the resources prepared directly for Polish.

2.1 Polish Sentiment Corpora

There are corpora for the Polish language that can be used for automatic sentiment analysis. One of them is a corpus prepared for the sentiment recognition shared task within *PolEval2017*[1] workshop (Wawer and Ogrodniczuk, 2017). The corpus contains 1550 sentences annotated at the level of phrases determined by the dependency parser. The sentences came from consumer reviews and covered 3 domains: *perfume*, *clothing* and *other*. Each node of the dependency tree received one of the three sentiment annotations: -1 (negative), 0 (neutral), 1 (positive). Most of the systems participating in the PolEval2017 competition used Tree LSTM adapted to dependency trees, including the best system, which reached an accuracy of 79% on this data.

Another resource is *HateSpeech*[2] corpus containing 2,000 posts crawled from public Polish web. These texts were annotated for hate speech. The annotator team reached an agreement score of Krippendorff's $\alpha = 0.6$ (Krippendorff, 2018). The SVM model trained on a subset of 1500 texts (containing equal amounts of hate speech and non-hate speech) obtained the precision of 0.8 (Troszyński and Wawer, 2017).

Other interesting resource is the *Polish Corpus of Suicide Notes* (PCSN) (Zaśko-Zielińska, 2013). The PCSN is one of very few such resources in the world. It includes 1,244 genuine SNs that have been scanned and manually transcribed. Each SN

[1] http://2017.poleval.pl/index.php/tasks/

[2] http://zil.ipipan.waw.pl/HateSpeech

was linguistically annotated on several levels, including selected semantic and pragmatic phenomena (Zaśko-Zielińska, 2013). The annotation is stored in a TEI-based format (Marcińczuk et al., 2011) with corrected version in a separate layer. PCSN includes also a subcorpus of 334 counterfeited SNs (elicited). They were created by volunteers who were asked to imitate a real SN for imaginary person whose characteristic had been provided at the beginning of the experiment. Most volunteers were told that the notes written by them would be used *to deceive* the computer program. Due to the sensitive nature of the texts and legal obligations of the author, the corpus is not publicly available. In the experiment described in article (Piasecki et al., 2017) we have collected 3,200 texts from the Internet as examples of non-letters. Using SVM with a rich set of features we obtained 90,06% (F1-score) in the task of distinguishing between genuine SNs, counterfeited SNs and non-letters.

2.2 Polish Sentiment Lexicons

One of the largest Polish sentiment lexical resources in terms of number of annotations is *plWordNet 4.0 Emo*[3] (Janz et al., 2017; Kocoń et al., 2018a). This dataset is available under the WordNet 3.0 license. It was built within CLARIN-PL[4] project (Piasecki, 2014). The manual annotation is done at the level of lexical units (Zaśko-Zielińska et al., 2015). Available values for polarity are: *strong negative, weak negative, neutral, weak positive, strong positive, ambiguous*. One annotator could assign only one of these values for a single lexical unit. There are more than 83,000 annotations covering more than 54,000 lexical units and 41,000 synsets (Kocoń et al., 2018b). About 22,000 of the polarity annotations are different than neutral and these annotations cover 13,000 lexical units and 9,000 synsets (22% of all synsets containing annotated units). plWordNet 4.0 Emo is used in the research presented in this article as a knowledge base for the sentiment recognition task.

Another lexicon is the *Nencki Affective Word List (NAWL)*[5] (Wierzba et al., 2015; Riegel et al., 2015). It is a database of Polish words suitable for studying various aspects of language and emotions. 2902 Polish words from the NAWL were presented to 265 subjects, who were instructed to rate them according to the intensity of each of the five basic emotions: happiness, anger, sadness, fear and disgust. The total number of ratings was 385,575.

The next resource is called the *Polish Sentiment Dictionary*[6] (Wawer, 2012; Wawer and Rogozinska, 2012). It contains 3,704 words with sentiment scores computed using supervised methods presented in (Wawer and Rogozinska, 2012).

Recently, a new resource has appeared in the Sentimenti project, containing a large database of annotated lexical units and annotated texts. Details are described in Section 2.3.

2.3 Sentimenti Project

This year, the first results of the Sentimenti[7] project (Kocoń et al., 2019a) were published, which were aimed at creating methods of analyzing texts written on the Internet in terms of emotions aroused by the recipients of the analysed content. A large database has been created, in which 30,000 lexical units from plWordNet database (Piasecki et al., 2014) and 7,000 texts were annotated. Most of the texts were consumer reviews from the domain of hotels and medicine. The elements were annotated by 20,000 unique Polish respondents in the Computer Assisted Web Interview survey and more than 50 marks were obtained for each element. Within each mark, polarisation of the element, stimulation and basic emotions aroused by the recipients are determined. The total number of manual annotations is 3,742,611 for texts and 19,141,041 for lexical units The first results concerning the automatic recognition of polarity and emotions for this set are presented in (Kocoń et al., 2019a) and propagation of this annotation with the use of Heterogeneous Structured Synset Embeddings is presented in (Kocoń et al., 2019b). Due to the commercial nature of the Sentimenti project, it is planned to publish only 20% of the project data available soon. The data will be published at the main project's site[7].

The Sentimenti project has interested both the scientific community and business. Within the CLARIN-PL project, we decided that in addition to a large annotated plWordNet lexicon, there

[3] http://plwordnet.pwr.edu.pl
[4] https://clarin-pl.eu
[5] https://exp.lobi.nencki.gov.pl/nawl-analysis
[6] http://zil.ipipan.waw.pl/SlownikWydzwieku
[7] https://sentimenti.com/

should also be a large corpus annotated with sentiment, available under an open license. In the next part we present the works related to the preparation of PolEmo.

3 PolEmo Sentiment Corpus

3.1 Motivation

Linguistic research on sentiment recognition involves two approaches: (1) *bottom-up* from the perspective of analysing the occurrence of emotional words and (2) *top-down* from the perspective of the entire document. The first attempt is usually a consequence of the creation of the sentiment lexicon, e.g. manual annotation of the WordNet (Baccianella et al., 2010). The second results from the analysis of the specific text content in which we see that the sentiment of a word or phrase changes under the influence of the surrounding context (Taboada et al., 2008). This change may vary depending on the domain of the text.

A discourse perspective in sentiment analysis is an attempt to address limitations of *bottom-up* methods (e.g. problems with negation, focusing on adjectives). It used findings of Rhetorical Structure Theory (Mann and Thompson, 1988). The attempt bears in mind local and global orientation in the text, discourse structure or topicality (Taboada et al., 2008). It allows the researcher to extract the most important sentences from the text in the perspective of the entire discourse context: nucleus satellite method (Wang et al., 2012). The relevance of the sentences is evaluated in relation to the main topic and the analysis omits some less important parts of the text.

There are interesting articles focused at domain-oriented sentiment analysis (Kanayama and Nasukawa, 2006), where a system is trained on labeled reviews from one source domain but is meant to be deployed on another (Glorot et al., 2011). The latter article describes the research carried out on the Amazon Product Data (He and McAuley, 2016). The ratings were assigned to reviews by authors of the reviews. Moreover, the ratings were applied to the entire text. Our idea was to obtain such a set of reviews that would be rated by the recipients and not by the authors of the content. The annotation should take into account not only the level of the entire review, but also the level of the individual sentences of the review. Additionally, this dataset was supposed to be a multi-domain one, to evaluate potential knowledge transfer across domains.

ID	Name	Source	Author	Subject
H	hotels	tripadvisor.com	visitor	hotel
M	medicine	znanylekarz.pl	patient	doctor
S	school	polwro.pl	student	teacher
P	products	ceneo.pl	buyer	product

Table 1: Each review is described in its domain **ID** and domain **Name** with the given **Source** of the review, **Author**'s type and the general **Subject** of the review.

3.2 Dataset

In the initial part of the work, presented in article (Kocoń et al., 2019), we have chosen online customer reviews from four domains, presented in Table 1. At the beginning of our work we had only 1000 texts for each of the following domains: *school, products, medicine*. In the case of *product* reviews, we also had metadata from the reviewer, how many stars he assigned to a specific review (from 1 to 5, where 5 means the most positive review). We used this information to select the reviews for the corpus, where 200 reviews from each star category were added.

On the basis of a preliminary analysis of several dozen examples of opinions, we have come to the conclusion that neutral examples are very difficult to find in the case of reviews. In the meantime, the corpus was extended by 8000 texts from the category Medicine and 17000 texts from the category Hotels, also with a uniform distribution in relation to the star categories available in the source data (also 1 to 5). In order to capture the phenomenon of neutral text, we decided to add 2000 new texts to each of the last two fields (medicine, hotels). These texts were fragments of articles from information portals on hotel industry[8] and health[9].

In Section 3.3 we present how the genre structure of a customer review affects the text sentiment polarity. It is an enhancement of the discourse perspective in sentiment analysis.

3.3 Pilot Annotation

Our CLARIN-PL pilot study on sentiment analysis of customer reviews was conducted in 2018. The initial part of the analysis included 3,000 reviews. Each text was manually annotated by two annotators: a psychologist and a linguist,

[8] http://ehotelarstwo.com
[9] http://naukawpolsce.pap.pl/zdrowie

who worked according to the general guidelines. The annotation tool used for this task was Inforex[10] (Marcińczuk et al., 2012; Marcińczuk and Oleksy, 2019) – a web-based system for text corpora management, annotation and analysis, available as an open source project. In the pilot project, we decided to deal with the sentiment annotation of the entire text. There was also an attempt to manually extract descriptions of particular aspects of the review. In both annotation cases we used the same tag system that is used in plWordNet Emo for lexical units: [+m] (strong positive), [+s] (weak positive), [-m] (strong negative), [-s] (weak negative), [amb] (ambiguous). We assumed that reviews are always characterised by a certain polarity, which is why we did not use the [0] (neutral) tag in the pilot annotation.

In the process of annotation we focused mainly on the strategic places of the text. In the consumer review these are opening and closing sentences, i.e. a text frame. The opening sentences consist of the general opinion of the author about the subject of the review, and the closing sentences contain the author's recommendation for the review recipients. The annotators have developed their first overall rating based on these two segments. In the text, review authors changed their opinions only subtly. Regardless of the modification of the main opinion in the text, we did not use the [amb] tag when the frame of the text was clearly positive or negative. Polarity of the text frame was influenced not only by the lexical content, but also by non-verbal elements: emoticons or multiplication of punctuation marks, e.g. exclamation marks.

The annotators were also recommended to distinguish those parts of the text that are placed in one sentence, but relate to different aspects (e.g. the teacher's appearance or teaching skills). This task turned out to be very difficult, specially in specifying, even with the help of guidelines, how to mark precisely in the text the boundaries of a given aspect. The Positive Specific Agreement (Hripcsak and Rothschild, 2005) between the annotators in the task of annotating the boundaries of aspects was below 0.15. The concept of annotation was radically changed and presented in Section 3.4.

[10] https://github.com/CLARIN-PL/Inforex

3.4 PolEmo Annotation Guidelines

In the main stage of the project we decided to annotate the sentiment for the whole text (a *meta* level) and the *sentence* level. We assumed that this strategy allows to establish the acceptable value of PSA, because the division of the text into sentences was determined by the MACA[11] tool (Radziszewski and Śniatowski, 2011), so the task was limited only to annotating the sentiment of the sentence. We followed the rule that the *meta* annotation results partially from sentence annotations, however the frame polarity is the main factor for the final meta annotation. We have prepared the following annotation tags, regardless of whether the entire text or sentence is annotated:

- SP – entirely positive;
- WP – generally positive, but there are some negative aspects within the review;
- 0 – neutral;
- WN – generally negative, but there are some positive aspects within the review;
- SN – entirely negative;
- AMB – there are both positive and negative aspects in the text that are balanced in terms of relevance.

This time we used [0] tag (neutral) because in the main stage of the project we extended the corpus with neutral texts presented in Section 3.2. Also reviews that are not neutral often contain neutral sentences.

We tested the new guidelines on a subset of 50 documents, achieving a PSA of 80% for the meta level and 78% for the sentence level. In the second iteration of the annotation guidelines improvement, the values were 87% (meta) and 85% (sentence). In the last iteration of the improvement of the guidelines, the annotators reached a PSA of 90% (meta) and 87% (sentence).

3.5 PolEmo 2.0 Annotation Analysis

We decided to publish the first results of the research on the PolEmo 1.0 corpus when the number of annotated reviews reached 8462 and the number of annotated sentences was 35724 (Kocoń et al.,

[11] Morphological Analysis Converter and Aggregator: http://nlp.pwr.edu.pl/redmine/projects/libpltagger/wiki

2019). Due to the fact that in PolEmo 2.0 there are only those annotated elements that received 2 annotations from linguists and were agreed by the super-annotator, this time we provide 8216 reviews and 57466 sentences. In Section 5 we present Table 7 with the final distribution of annotations and Table 6 with the number of elements in each domain (evaluation data splits). In this section we focus on annotation agreement and annotation errors.

L	D	SN	WN	0	WP	SP	AMB	A
T	H	91.91	36.29	99.41	39.38	91.61	40.11	79.73

	P	94.06	23.33	100.0	47.62	85.95	33.68	78.76
	S	87.50	20.00	00.00	36.07	92.52	54.19	77.03
	A	92.87	32.20	99.18	37.10	93.48	41.86	83.41
S	H	93.78	00.00	88.40	00.20	93.05	33.94	85.39
	M	90.43	28.75	91.84	26.58	93.43	39.04	88.83
	P	91.27	01.20	48.42	06.90	90.84	30.50	76.82
	S	79.21	00.00	26.56	02.76	81.39	33.73	60.78
	A	91.93	11.94	87.21	07.24	92.12	33.86	84.56

Table 2: Positive Specific Agreement for annotations obtained at the level (L) of text (T) and sentence (S) for each domain (D): hotels (H), medicine (M), products (P), school (S) and all (A).

Table 2 presents PSA values obtained at the level of text and sentence for all domains. The overall PSA value for texts is 83.41% and for sentences is 84.56%. It is worth noting that for the domains to which we have not added neutral texts (products, school), there are practically no neutral annotations at the text level (see Table 7). The highest values are obtained for the most obvious categories (SP, SN and 0), regardless of the level of text description. For the remaining categories PSA value is lower than 40.00% in most cases.

D	A/ WP	SN/ WN	SP/ WP	A/ WN	A/ SN	A/ SP	R R	A/WP/ WN
H	28.55	22.07	18.33	17.08	07.86	03.12	02.99	47.63
M	18.66	26.24	14.29	17.49	12.24	04.37	06.71	37.32
P	28.16	24.27	13.59	19.42	10.68	02.91	00.97	48.54
S	36.21	07.76	28.45	10.34	06.03	08.62	02.59	49.14
A	26.69	22.07	17.82	16.79	09.02	03.89	03.74	45.23

Table 3: Distribution (%) of disagreements between annotators at the text level. A – AMB tag, A/WP – one annotator assigned [AMB], other – [WP]. R is the rest of rare occurring combinations. A/WP/WN is the sum of A/WP, A/WN and WN/WP.

Table 3 presents the distribution of disagreements between annotators at the text level. The most common disagreement is within the pair of tags [AMB/WP]. Nearly half of the disagreements are related to any pair of AMB, WP and WN tags. This suggests that annotators, despite the guidelines, have difficulty in judging the relevance of aspects regardless of the domain, or it is a very subjective task.

Table 4: Distribution (%) of disagreements between annotators at the sentence level. A – AMB tag, A/WP – one annotator assigned [AMB], other – [WP]. R is the rest of rare occurring combinations. A/WP/WN is the sum of A/WP, A/WN and WN/WP.

Table 4 presents the distribution of disagreements between annotators at the sentence level. The most common disagreement is within the pair of tags [SN/0]. This time the cases of disagreements between A/WP/WN tags are less than 20%. Most of the errors are related to the neutral sentence marking. The analysis of specific cases and a discussion with linguists showed that in the task of annotating sentences it is difficult to isolate a sentence from the context and sometimes the annotation of the next sentence was a consequence of the sentiment of the previous sentence.

We have found that it is difficult to decide on the relevance of the aspects and without creating a hierarchy of relevance of aspects for a given domain it will be hard to achieve better agreement for WP/WN/AMB tags. Due to the fact that mistakes are often within these tags, we have combined them into one AMB tag. PolEmo 2.0 will also be available for the original tags, but research (Kocoń et al., 2019) has shown that machine learning methods achieve F-score for WP/WN/AMB classes no higher than PSA. The evaluation data in this research has WP/WN/AMB tags merged into one AMB tag. Table 5 presents PSA values after the merging step. The total PSA increased from 83% to 91% for texts and from 85% to 88% for sentences.

4 Multi-Level Sentiment Recognition

Recently deep neural networks show relatively good performance among all available methods of processing such information (Glorot et al., 2011). Possibility of retrieving data from different sources like social networks (Pak and Paroubek, 2010), publicly available discussion boards or

Table 5: Positive Specific Agreement for annotations with WP/WN/AMB merged into one AMB tag, obtained at the level (L) of text (T) and sentence (S) for each domain (D): hotels (H), medicine (M), products (P), school (S) and all (A).

marketing platforms connected with proper annotations on training data set can provide not only simple positive, negative or neutral classification but lead to accurate fine-grained sentiment prediction (Guzman and Maalej, 2014).

We selected the same classifiers for the recognition tasks as in (Kocoń et al., 2019): (1) Logistic Regression as a fastText recognition model (Joulin et al., 2017) with KGR10 word embeddings (Kocoń and Gawor, 2018) providing a baseline for text classification; (2) BiLSTM (Zhou et al., 2016) in two variants: KGR10 embeddings as features only and KGR10 embeddings extended with general polarity information from sentiment dictionary described in (Kocoń et al., 2019); (3) BERT (Devlin et al., 2018) with additional sequence classification layer.

We changed the architecture of BiLSTM and BERT architecture. In case of BiLSTM, instead of fixed input length we changed the model to work with text of any length. The input tensor shape is (None, 300) for *embedding-only* variant (BiLSTM) and (None, 306) for *embedding+dictionary* variant (BiLSTMd). We changed the shape of the second gaussian noise layer to (None, 300)/(None, 306), respectively. Next layers remain the same, i.e. (1) BiLSTM layer with 1024 hidden units, (2) dropout layer (ratio 0.2). Last dense layer changed due to the reduction of sentiment labels from 6 to 4 by label merging process described in Section 3.5. For BERT we used the same architecture as in (Kocoń et al., 2019) for the whole texts, but we changed it for sentences. We reduced the maximum sequence length from 512 to 64 (covers more than 99% of sentences) and we increased batch size from 32 to 128.

5 Evaluation

As in article (Kocoń et al., 2019a; Kocoń et al., 2019), we prepared three variants of evaluation of the sentiment classification methods:

- *SD – Single Domain* – evaluation sets created using elements from the same domain;
- *DO – Domain Out* – train/dev sets created using elements from 3 domains, test set from the remaining domain. This variant allows to evaluate the ability of the classification method to capture the domain-independent sentiment features;
- *MD – Mixed Domains* – SD train/dev/test sets joined respectively. This variant allows to examine the ability of the classifier to generalise the task of sentiment analysis in all available domains.

We use *SDT*, *DOT*, and *MDT* abbreviations for *text* evaluation types and *SDS*, *DOS*, and *MDS* for *sentence* evaluation types. We use also prefixes of domains (*Hotels, Medicine, School, Products*) as suffixes for *SD** and *DO** variants, e.g. SDS-H is a Single Domain evaluation type performed on Sentences within *Hotels* domain, whereas DOT-M is a Domain-Out evaluation type performed on Texts trained on texts outside *Medicine* domain and tested on texts from that domain.

Table 6 shows the number of texts and sentences annotated by linguists for all evaluation types, with division into the number of elements within training, validation and test sets. The distribution of labels for each domain (both texts and sentences) is presented in Table 7.

6 Results

Table 8 presents the values of F1-score for each label, global F1-score, micro-AUC and macro-AUC for all evaluation types related to the texts. In case of evaluation for a single domain for each label, fastText (using Logistic Regression) outperformed other classifiers in 16 out of 28 distinguishable cases. The worst results are obtained for *ambiguous* cases, but in 9 out of 13 cases F1-score is higher than 0.5 and this result is much better, than obtained for intermediate labels (*weak* positive and *weak* negative) presented in work (Kocoń

Table 7: The distribution (%) of annotations in a given domain for the following sets: SDT – single domain texts (100%=8216), SDS – single domain sentences (100%=57466).

et al., 2019). BERT classifier performs much better (14 out of 28 cases) in domain-out knowledge transfer evaluation (DOT). For this evaluation type only 4 times fastText was better. These observations are consistent with the results of article (Kocoń et al., 2019a) for *valence* dimensions.

7 Conclusions

BERT's performance is below the expectations of this advanced method in case of the classification of the whole texts. Looking at both tables (8 and 9), BERT's results are the best in 64 out of 182 label-specific cases. BiLSTM outperformed other methods in 48 cases. Adding an external sentiment dictionary helped in 40 label-specific cases. Overall BiLSTM performance is better in 88 out of 182 cases. BERT dominance (when distinguishing between BiLSTM and BiLSTMd) is observed in DOT and all sentence cases. MDT case is the most promising in terms of the further use of the recognition method in applications such as brand monitoring or early crisis detection. The values of the general F1, micro AUC and macro AUC are the highest for BiLSTM variants (see Table 6).

We published PolEmo 2.0 in CLARIN-PL DSpace repository[12] under the Creative Commons 4.0 License. We also intend to test the contextualized embedding that we are currently building using the ELMo deep word representations method (Peters et al., 2018), with the use of the large KGR10 corpus presented in work (Kocoń et al., 2019a). We also want to train the basic BERT model with the use of KGR10 to investigate whether it will improve the quality of sentiment recognition. It is also very interesting to use the propagation of sentiment annotation in WordNet (Kocoń et al., 2018a,b), to increase the coverage of the sentiment dictionary and to potentially improve the recognition quality as well. This objective can be achieved by other complex methods such as OpenAI GPT-2 (Radford et al., 2019) and domain dictionaries construction methods utilising WordNet (Kocoń and Marcińczuk, 2016).

A Personalized Sentiment Model with Textual and Contextual Information

Siwen Guo **Sviatlana Höhn** **Christoph Schommer**

ILIAS Research Lab, CSC,
University of Luxembourg
{siwen.guo,sviatlana.hoehn,christoph.schommer}@uni.lu

Abstract

In this paper, we look beyond the traditional population-level sentiment modeling and consider the individuality in a person's expressions by discovering both textual and contextual information. In particular, we construct a hierarchical neural network that leverages valuable information from a person's past expressions, and offer a better understanding of the sentiment from the expresser's perspective. Additionally, we investigate how a person's sentiment changes over time so that recent incidents or opinions may have more effect on the person's current sentiment than the old ones. Psychological studies have also shown that individual variation exists in how easily people change their sentiments. In order to model such traits, we develop a modified attention mechanism with Hawkes process applied on top of a recurrent network for a user-specific design. Implemented with automatically labeled Twitter data, the proposed model has shown positive results employing different input formulations for representing the concerned information.

1 Introduction

Sentiment is one of the key factors affecting human behavior. Studying the way in which sentiment is perceived, evolved and expressed is an essential part in artificial intelligence. To analyze sentiment in text, researchers have made different assumptions on linguistic behaviors that are leveraged with approaches developed based on the nature of the text, the representation of the related information and the objectives. However, majority of the studies are conducted at the population-level which assumes that people follow a common understanding with regard to the use of language. Such approaches can be inaccurate in the cases where people use the same lexical choices to convey different messages or vice versa. Harris (2006) stated that 'no two alike' showing the inherent difference in human that motivates the research of personalized sentiment analysis. Grounded in the psychological works, we argue that it is significant to study the effect of individuality in the expressions and to investigate the possibility of providing a deeper understanding of the expressions from the writers' own perspectives. In this work, we concern the use of preferred lexical choices when expressing sentiment (Reiter and Sripada, 2002) and the level of consistency in retaining a sentiment (Janis and Field, 1956).

Besides the targeted text message itself, we exploit two types of contextual information for the purpose of realizing the psychological aspects: a person's expressions in the past and the time when the expressions were made. With the goal of discovering the effect of the contextual information, distinct formulation methods are proposed to integrate the information in the personalized sentiment model. The backboned model is a hierarchical neural network which follows a conventional embedding – recurrent – attention structure with each part rectified for the task. The embedding block is used to generate representations for the used information; the recurrent network fulfills the task of relating to the information from the past; the attention model is shaped with Hawkes process (Laub et al., 2015) in order to model the information decay for each expresser. Generally, recurrent networks consider the order of the elements in a sequence but omit the different gaps between them. Hawkes process is utilized to compensate this issue. Furthermore, a novel approach with a user – factor transformation is employed to merge the Hawkes process within the attention model and to construct user-specific processes. For evaluation, we take the data from a number of frequent users on social platforms where Twitter is used as an example. The data is domain-independent, and

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 992–1001
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

it is possible to obtain self-labeled texts that aligns with our goal of understanding the expressers' perspectives. Significant improvements are seen with certain input formulations, and different Hawkes processes applied for the users are visualized. In the end, we conclude that it is effective to introduce the contextual information to the model.

2 Related Work

Individualities are mostly considered in sentiment analysis when analyzing product-review texts (Gong et al., 2016; Chen et al., 2016b; Wu et al., 2018). A common issue that challenges the research of this area is data sparsity. It is infeasible to build or train an effective model for each user. Gong et al. (2016) address this issue by relating to a global model that captures 'social norms', and individualities are included by adapting from the global model via a series of linear transformations. While in the works that apply neural networks, the user information is embedded separately (Chen et al., 2016b) or added at the attention layer (Chen et al., 2016a; Wu et al., 2018) in order to make user-specific predictions at the output. In other works, the aspect of personalization is relaxed to provide user-group based predictions (Gong et al., 2017). The aforementioned approaches are modeled with domain-dependent text, while our concentration on the text associated with various topics makes the task more challenging. Wu and Huang (2016) focus on microblog posts as well and apply the same concept of using a global model and an individual model via multi-task learning as in Gong et al. (2016). In addition, users' social relations are leveraged to enhance the individual models. Similarly, followers' and followees' information is also used in Song et al. (2015) while a variant of latent factor model is utilized. Most of the studies leverage earlier posts from users in order to better understand the individuality; however the evolvement of the sentiment is largely neglected — the preferences of users are considered constant. In this work, we take the user dynamics into consideration, and incorporate user information both in the input and in the Hawkes process to deal with the data sparsity and to offer personalized analysis.

Technically, there are very few works that investigate the different gaps between the input nodes in a recurrent neural network. Neil et al. (2016) have proposed a phased LSTM that utilizes an additional time gate to control the passing of the information. However, the time gate is triggered by periodic oscillations while modeling sensory events, which makes such a design less flexible when the time gaps are highly various. As an alternative, we explicitly add the time gaps in the Hawkes process to offer a time-sensitive modeling.

In our previous works, we have evaluated the effectiveness of considering individual differences in sentiment analysis by employing a concept-based representation and the static or universal Hawkes process (Guo et al., 2018, 2019a). In this paper, we advance the development by adopting five input formulations with different combinations of granular levels, and propose a refined model with user-specific Hawkes process to constitute a step forward in capturing the nuances of user dynamics and providing insights in the personalized modeling.

3 Personalized Sentiment Model

Motivated by the diversity in individuality, we introduce a model that considers both textual and contextual information and applies hierarchical neural networks to facilitate the aspect of personalization in sentiment analysis. Particularly, we focus on analyzing the effect of contextual information and discover ways to embed such information in the prediction process.

3.1 Model Structure

The personalized sentiment model follows a conventional embedding – recurrent – attention structure as shown in Figure 1 with modifications applied at each block. First, a formulation method is applied in order to represent the current and a number of earlier posts of a user. The embedding

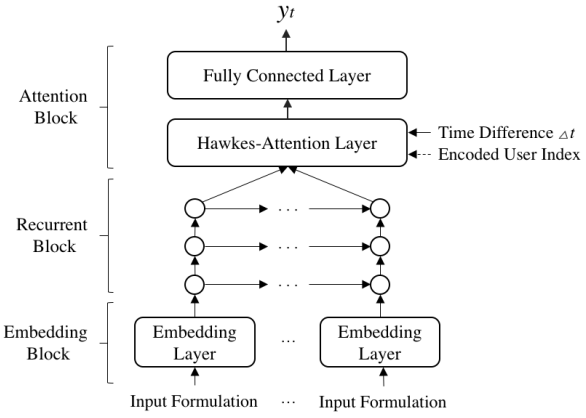

Figure 1: The structure of the sentiment model.

layer takes the formulated inputs and produces a vector for each time step at the recurrent layer. After that, the outputs of the recurrent layer together with the auxiliary time differences are fed to the attention block. Encoded user index is used in the Hawkes-attention layer when different settings of Hawkes process are considered for different users. A fully connected layer is applied afterwards to regularize the output of the Hawkes-attention layer. Finally, the output of the model y_t is generated which is the predicted sentiment label of the target text.

3.2 Textual and Contextual Information

In linguistic studies, the notion of 'context' varies from theory to theory that some in monologism see it as 'secondary complications', whereas in dialogist theory, it considers the reflexive relation between an expression and its setting or occasion essential (Linell, 2009). In this work, we target social text and regard context as an important factor in the setting of social platforms. Based on the characteristics of such text and the applicability in modeling, we categorize the information used in the sentiment model into two genres: **Textual Information** — the information that can be extracted directly from the *target* text, and **Contextual Information** — the information that is *not* present *in* the target text but is *associated* with the text according to the user index.

Textual Information

Text is the central part in sentiment analysis. Researchers in this area have proposed various approaches aiming to provide a deep text understanding given the complex nature of how people express their sentiments in text. Moreover, methods designed at the population-level for many other natural language processing tasks can also be used for sentiment analysis. Generally, such methods start at a pre-defined granular level and generate a representation for the text by capturing related information in each granule and the ones surrounding it. In the end, the text is represented explicitly (e.g., concepts as in Poria et al., 2014) and / or implicitly (e.g., embeddings as in Pennington et al., 2014 and Peters et al., 2018).

Contextual Information

Besides the *target* text itself, other types of information have been used to support the understanding of the sentiment as well.

Earlier Posts correspond to the texts produced by the same user in the past. The use of earlier posts leverages the assumption that a person may have similar lexical choices when expressing opinions about related topics while different individuals share different preferences in this regard. By analyzing the lexical choices and the topics or entities associated with them, the tendency of repeating such patterns in a user's text in the future can be beneficial to the prediction.

Timestamp corresponds to the creation time of the text. It has been shown that there exists a certain level of consistency in an individual's opinions and such consistency varies from one individual to another (Janis and Field, 1956). We study such a trait by taking the timestamp of each earlier post and applying Hawkes process to observe how the effect of the information on a user's behaviors or opinions decays over time. Note that here, we do not distinguish the inconsistency between the time when the expression was made and the time when the sentiment was felt.

3.3 Input Formulations

We employ different formulations for the input sequence based on the representation method. For all the formulations, timestamps are apart from other information and are used as an auxiliary input directly at the attention layer with Hawkes process. Additionally, user index is used as a feature in the input in order to handle the issue of data sparsity, and by doing that, the model is able to analyze textual and contextual relations targeting a specific user. The encoded user index is also used at the Hawkes-attention layer when considering individual differences in information decay.

Atomic Representation (AR)

In this formulation, four types of components are extracted: concepts, entities, negations and user index. Concepts are extracted based on Cambria et al. (2018) which contain conceptual and affective information, and can be seen as the 'signal terms' regarding lexical choices. Entities are extracted based on grammatical rules as the 'targets' of a user's lexical choice. Negations are extracted based on the lexicon by Reitan et al. (2015) for their ability to invert the orientation of a sentiment. User index is extracted for its role in personalization. After extracting the components, an embedding layer is applied to generate a representation vector for the text.

Representation with Pre-trained Word Embeddings (WE)

Pre-trained word vectors such as GloVe (Pennington et al., 2014) and Word2Vec (Mikolov et al., 2013), generate embeddings according to the co-occurrences of the words. The word embeddings are aggregated dimension-wise to produce a vector for each post. The user index is encoded by itself and then combined with the representation of the post at each time point of an input sequence.

Representation with Concepts and Words (CW)

Since the pre-trained word vectors do not consider the contexts of the target words, we combine the representations of both words and concepts in this formulation. The word embeddings are taken as the same as the one in the **WE** formulation. The concepts appeared in the text are encoded together with the associated user index so that the relation between the user and the use of concepts can be learned. Afterwards, the two types of representation of the same post are concatenated to generate an input sequence for the recurrent layer.

Representation with Deep Contextualization (DC)

Peters et al. (2018) proposed a deep contextualized representation (ELMo) that takes a finer granular level (characters) to generate embeddings for the text by leveraging a deep bidirectional language model. Prominent results are shown across a number of linguistic tasks using this representation. We apply ELMo for each post, and then combine the representation of the post and the encoded user index at each time point.

Representation with Combined Granular Levels (Combi)

This formulation combines three granular levels, namely character-level (**DC**), word-level and concept-level (**CW**). The representations are embedded separately and are concatenated afterwards as mentioned in Peters et al. (2018).

3.4 Recurrent Neural Network with Input Selection from Post History

We apply a deep recurrent neural network with long short-term memory (LSTM, Hochreiter and Schmidhuber, 1997) on the input sequences constructed with one of the input formulations. Each input sequence X_i consists of an entry of the current post at the end of the sequence (which contains textual information and the encoded user index) and a number of earlier posts by the same user (contextual information), i.e.,

$$X_i = [H_{i-n}, ..., H_{i-2}, H_{i-1}, F_a(x_i)] \quad (1)$$

where

$$H_j = \begin{cases} F_a(x_j) & \text{if } u(x_j) = u(x_i) \\ 0 & \text{else} \end{cases},$$

n is the number of earlier posts considered, F_a is the formulation chosen beforehand, and u is the user index of the post.

Additionally, a selection procedure followed Guo et al. (2019b), is performed for choosing the earlier post x_j of a target text x_i from user u. The use of this procedure is motivated by the large difference in user frequency (the number of posts of a user in a given corpus), as well as the observation of the case where the recent posts are unrelated to the current one while the related posts have appeared long before. The selection is done by calculating the similarity between the topics of each earlier post and the target text. Given a fixed number of time steps T in a recurrent network and a similarity threshold δ, the recent T earlier posts that have a similarity score larger or equal to δ are chosen. For the case where the number of chosen posts is smaller than T, other earlier posts are added in the sequence as complements prioritizing on the recent ones. After the selection, the posts in each sequence are ordered by time.

3.5 Hawkes-Attention Layer

A modified attention mechanism is applied on top of the recurrent neural network. Attention model has the ability to provide more flexibilities at the output layer (Bahdanau et al., 2015). The network can 'attend' to different histories based on the immediate situation. As in Yang et al. (2016), the model is defined as follows:

$$u_i = \tanh\left(W_t h_i + b_t\right) \quad (2)$$

$$\alpha_i = \frac{exp(u_i^\top u_t)}{\sum_i exp(u_i^\top u_t)} \quad (3)$$

$$\lambda_i = \alpha_i h_i \quad (4)$$

$$v = \sum_i \lambda_i \quad (5)$$

where h_i is the i-th output of the recurrent network, u_i is the hidden representation of h_i, and u_t is the 'context vector'. Here, we randomly initialize the context vector which is later jointly learned with other weights during the training phase. λ_i is the representation of the information learned at time step i. Lastly, v summarizes all the information of the posts from the corresponding sequence. However, conventional recurrent networks and attention models do not differentiate the relations between time steps regarding various time intervals. To model this difference, we shape the representation of the post λ_i with Hawkes process before summarizing them at the last step (Equation 5) in the attention mechanism.

Universal Hawkes Process

Hawkes process is known for modeling the excitation and decay of information over time. When using exponential decay as the excitation function, the Hawkes conditional intensity is (Laub et al., 2015):

$$\lambda^*(t) = \lambda + \sum_{t_i<t} \alpha e^{-\beta(t-t_i)} \tag{6}$$

where λ describes the positive background intensity, t is the current time and t_i is the time when the past event happened. α and β are the most important factors in the Hawkes process that the former corresponds to the amount of excitement the past event brought to the system while the latter corresponds to the decay rate of the excitement. Taking the same concept as in Guo et al. (2019a), we see a post in the past as an 'event' that can influence the decision in the future and such influence decays over time. Instead of treating all the past events equally, we use λ_i in Equation 4 as the background intensity and $\alpha = \epsilon\lambda'_i$ as the amount of excitement the post at time step i contributes to the current decision. Note that $\lambda'_i = max(\lambda_i, 0)$ for we do not consider negative effect from the past. With this modification, the information decay of a past event can also depend on the relativeness between the past and the current events, and ϵ can be seen as a scaler to balance the importance of adding the process. As a result, Equation 5 is replaced with the following:

$$v' = \sum_{i:\Delta t_i \geqslant 0} (\lambda_i + \epsilon\lambda'_i e^{-\beta\Delta t_i}) \tag{7}$$

where Δt_i indicates the time gap between the earlier post at time step i and the current post. The current post is included in the summarization when $\Delta t_i = 0$. ϵ and β are learned jointly with other learnable parameters during the training phase.

User-specific Hawkes Process

In order to build user-specific Hawkes process, we compute the values of ϵ and β in Equation 7 for each user by applying learned transformation vectors on the encoded user index. In this way, different behaviors concerning the information decay can be analyzed. That is, ϵ and β are calculated as

$$\epsilon = a_\epsilon^\top E(u) \tag{8}$$

$$\beta = a_\beta^\top E(u) \tag{9}$$

where E is the user-index encoder. The transformation vectors a_ϵ and a_β are learned during the training process, and other settings remain the same with the universal Hawkes process.

Similarly, Cao et al. (2017) also integrate a Hawkes process in a neural-based system. To avoid pre-defining a time decay function, the time range in an observation is split into a number of disjoint intervals, whereas user information is embedded in the input. Although this non-parametric method can be applied in our model, the selection of the number of intervals undermines the flexibility of the process. However, as in their work, a fully connected layer is applied afterwards which takes the exited (decayed) information representation v' as input and outputs the final prediction of the sentiment y_t.

4 Experiments

We investigate the effect of textual and contextual information in personalization and evaluate the performance of the model employing different input formulations.

4.1 Dataset

The Sentiment140[1] corpus is chosen in the experiments for complying the requirements that

1. there are sufficient frequent users,
2. the text is domain-independent,
3. the desired textual and contextual information is present,

[1] http://help.sentiment140.com/for-students, last seen on September 24, 2019

4. the corpus is annotated from the writers' perspectives.

The corpus is labeled automatically by emoticons as described in Go et al. (2009) and reflects a user-specific view in contrast to the corpus labeled by others such as the SemEval[2] corpus. However, the automatic labeling may also contain a certain level of noise caused by the variation in emoticon usage and the unreliability at the user end. The experimented dataset is created by taking the messages from the users who have posted at least 20 times before a pre-set timestamp. This results in 2369 users with overall 122,000 messages in which 79,009 are positive and 42,991 are negative. Furthermore, the dataset is split into a training set, a development set and a test set according to two pre-set time points to ensure that the prediction is only made based on the messages in the past. Other details of the dataset can be found in the appendix.

4.2 Experimental Settings

The experiments are conducted using Keras[3] with TensorFlow[4] backend. The concepts used in the **AR** and **CW** formulations are based on SenticNet 5[5]. In **WE** and **CW**, 100 dimensional Twitter word vectors are taken from GloVe[6]. The ELMo word representations in the **DC** input formulation are supported by TensorFlow Hub[7], which are later re-trained with other weights in the model. The inputs with **AR**, **WE** and **DC** are encoded into different lengths based on the number of elements in each formulation, however they are suppressed at the embedding layer that generates a vector of length 100 at each time step in order to make fair comparisons. In **CW** and **Combi**, the input vectors fed to the recurrent layer are longer (164 and 264 respectively) because of the concatenation of representations. The dimension of user embeddings is set to 32. There are three recurrent layers at the recurrent block that each contains 100 units, and the number of time steps T is set to 20. For the selection procedure, the same setting is used as in Guo et al. (2019b), where Manhattan distance is used as the ground measurement for calculating topic similarities and the similarity threshold δ is set empirically at 0.8. At the attention block, the time unit is hour, and the values of ϵ and β are initialized at 0.01 and 0.001 respectively when using the universal Hawkes process; the initial values for the vectors a_ϵ and a_β when using user-specific processes are also vectors of 0.01 and 0.001 respectively, and the length of the vectors has to be the same with the dimension of user embeddings, which is 32. The dimension of the fully connected layer applied before the output is set to the same as the number of units in the recurrent layer. We report the overall accuracy of the model as well as the F_1 scores for the positive and negative classes. Detailed settings of the model, sample codes for the Hawkes process, and trained models with the **Combi** formulation can be found in the supplementary material.

4.3 Results

Table 1 shows the performance of the model in different settings. The best result is given by the **Combi** formulation with user-specific Hawkes process. Comparing to the result we have reported previously in Guo et al. (2019a) with an accuracy of 76.13, the best performance with this model has reached 80.38 using the same test set.

Results with Different Input Formulations

Across different input formulations, improvements can be seen comparing the models using the universal - and the user-specific Hawkes process. Although the increase when applying the **AR** formulation is not significant, the improvement of other formulations are significant (t test with $p < 0.05$). The lack of improvements with the **AR** formulation when learning user-specific behaviors can be caused by the sparser representation compared to the other formulations. A matching from each post to a list of concepts and negations is performed which omits information that is not present in the given list. The list of concepts provided by SenticNet 5 is more restricted than the word vectors by GloVe, and is far less flexible than the character-based representation. In addition, due to the highly unstructured nature of social texts, the preprocessing of the posts plays a significant role in the **AR** formulation, which also affects the per-

Input Formulation	Universal Hawkes Process			User-specific Hawkes Process		
	Pos. F1	Neg. F1	Accuracy	Pos. F1	Neg. F1	Accuracy
AR	75.12	76.87	76.04	74.94	77.48	76.28
WE	76.06	77.06	76.58	76.61	78.41	77.55
CW	76.43	77.71	77.10	76.90	79.10	78.06
DC	76.60	79.71	78.27	77.10	80.36	78.86
Combi	77.78	80.67	79.34	78.06	82.25	80.38

Table 1: Performance of the sentiment model when applying the universal - and the user-specific Hawkes process with different input formulations.

formance substantially.

We can also observe improvements when using finer granular levels which are more sensitive and representative towards user variations. Note that using the character-based **DC** formulation alone offers better performance than using the combination of word - and concept-level representations; however the ELMo representation has a more complex structure, a higher dimensional output, and it takes longer time to re-train the weights in the network. In conclusion, the best solution for constructing representation for the inputs is to leverage the combined granular levels from character to word, and to concept (**Combi**). With such a representation, the system is able to analyze user-specific behaviors regarding the lexical usage and the consistency of sentiment.

Results for Various Lengths of History

Figure 2 shows the performance of the models while using the **CW** formulation. The models are tested for T from 1 where no earlier posts are considered, to 20 after which no significant improvement can be observed due to the number of related posts a user normally publishes.

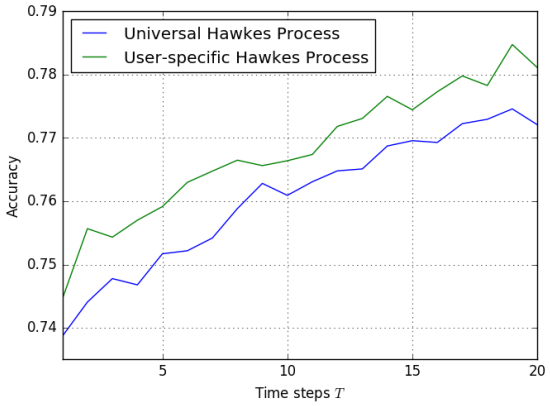

Figure 2: Comparison of the universal - and the user-specific Hawkes process-based models while using different time steps.

For the case when the user history is not incorporated in the model ($T = 1, \Delta t = 0$), we can deduce that $v' = \lambda + \epsilon\lambda'$, which leads to an accuracy of 73.87 with the universal ϵ and 74.46 with the user-specific ϵ (Equation 8).

We can observe an increase in both models when rising the number of time steps T. The increase indicates that the personalization is effective and earlier posts are valid contextual information. By using the selection procedure, the models with a smaller number of T (except for when $T = 1$) take into account more related posts in the past. The increase grows slightly faster towards smaller numbers of T, which is also caused by the limitation of user frequencies in the experimented corpus. We believe that given a sufficient number of frequent users, the performance of the proposed models can be further improved.

Results for Various User Frequencies

The performance of the models when applying for users with different frequencies can be seen in Figure 3. The x-axis corresponds to the lower bound of the user frequency. We take the lower bound for the illustration because there are different numbers of users for each frequency, and many frequencies have no users to assign to. With both models, significant growths for each input formulation can be observed while increasing the lower bound of the frequency. Note that although the **Combi** formulation gives the overall best performance, we can see from the figure that it does not give the best results in all the cases. For instance, when the user frequency is around 80, the **WE** formulation has the best accuracy in both models. However, such an observation is also restricted by the number of frequent users in general — with only 372 posts in the test set when the user frequency is at least 100, the performance is highly dependent on the remaining 3 users. Another observation is that the

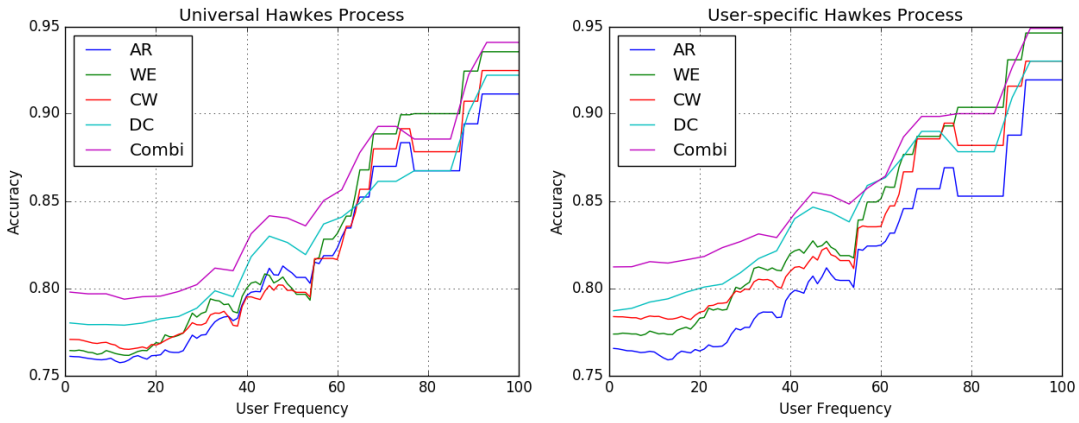

Figure 3: Performance of the universal - and the user-specific Hawkes process-based models for users with different frequencies when applying different formulations.

WE formulation performs better than the **CW** formulation in higher user frequencies, but it has a lower overall performance because there are more users who have published less than 30 posts than the ones who have more.

4.4 Visualization of User-specific Hawkes-Attention

In order to examine the user-specific Hawkes process, we visualize the intermediate calculations for the values of ϵ and β for 10 random users (Figure 4). Each cell in the figure corresponds to the value of $a_{\epsilon i} * E_i(u)$ in Equation 8 (top figure) or $a_{\beta_i} * E_i(u)$ in Equation 9 (bottom figure) at dimension i for the respective user.

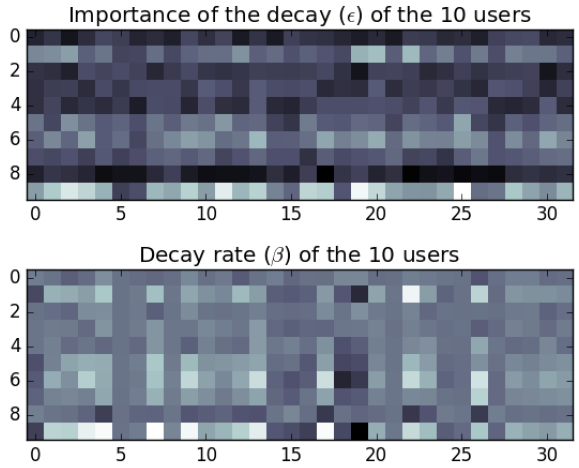

Figure 4: The vectors of ϵ and β in the user-specific Hawkes process of the random 10 users.

The effect of the learned transformation vectors on the 10 users is illustrated. It can be seen that the last user in the figure (the one at the bottom line) has the greatest values for ϵ and β, which means that the decay factor has a great impact on the prediction for this user than the others but the influence from the past decays comparably fast — the user is affected a lot by recent events. In contrast, among the 10 users, the second last user is the least influenced by the past which is visualized in darker colors. From this figure, we can see that the different decaying processes are indeed learned for different users with the vector transformation. One may argue that the behavior of the Hawkes process also depends on the time period of the experimented dataset; however, if an earlier post (outside of the training period) is highly relevant to the current one, the large value of λ_i can still prevail regardless the value of ϵ.

5 Conclusion

This paper presents a personalized sentiment model that captures the individualities in expressing sentiment and analyzes the evolvement of sentiment over time. Particularly, we categorize the information used for the modeling into textual and contextual information, and evaluate the effectiveness of using the contextual information to boost the performance of the model. A novel attention mechanism with user-specific Hawkes process is employed for this purpose. Technically, it also provides an alternative for studying various time gaps in temporal sequences with neural networks. Different input formulations are applied in which the combined granular representation performs the best. Based on our findings, we can conclude that the individual variation indeed affects the analy-

sis, and the contextual information, as an essential part in human interactions, positively contributes to the performance.

Because the informal text we have used deviates from the language standard, the representation of input text plays a significant role in improving the performance. In the future work, we will exploit phonetic representation which can provide another source of information for such text. The posts can be transcribed into phonetic sequences, for instance, by using the International Phonetic Alphabet, in order to handle certain misspellings and to study the trend of using letters with similar pronunciations as substitutions. Moreover, other types of contextual information should be explored as well to enhance the understanding of individual behaviors on social platforms. As an example, social relations can be used to identify abnormalities in the change of sentiment, especially in the case that a user is exceptionally stimulated by other users or special events which causes untypical behaviors. The personalized model can also be helpful in other scenarios, such as to offer deep understanding for user-tailored conversations or companionship.

Abstract

Text classification plays a crucial role for understanding natural language in a wide range of applications. Most existing approaches mainly focus on long text classification (e.g., blogs, documents, paragraphs). However, they cannot easily be applied to short text because of its sparsity and lack of context. In this paper, we propose a new model called cluster-gated convolutional neural network (CGCNN), which jointly explores word-level clustering and text classification in an end-to-end manner. Specifically, the proposed model firstly uses a bi-directional long short-term memory to learn word representations. Then, it leverages a soft clustering method to explore their semantic relation with the cluster centers, and takes linear transformation on text representations. It develops a cluster-dependent gated convolutional layer to further control the cluster-dependent feature flows. Experimental results on five commonly used datasets show that our model outperforms state-of-the-art models.

1 Introduction

With the rapid development of social media, e-commerce and on-line communication, the Internet has been generating an increasing amount of short texts, including texts, search snippets, user reviews for products, etc., which poses an urgent demand for understanding them. Short text classification, assigning predefined categories to texts, is a fundamental technique in natural language processing, and plays an important role in a wide range of applications, such as sentiment analysis, web searching, and ads matching.

In prior research, much progress has been made on text classification, including traditional approaches based on human-designed features (Lazaridou et al., 2013; Zhang et al., 2015a) and neural networks based on deep architectures (Lai et al., 2015; Yang et al., 2016). However, such methods prefer to deal with documents and paragraphs, and still have limitations for short texts. Each short text does not have enough words, which may result in data sparsity and lack of contexts (Wang et al., 2017).

Some researchers incorporated knowledge bases into traditional approaches (Feng et al., 2013; Wang et al., 2014) or neural networks (Wang et al., 2017) to overcome these challenges. Extra resources can provide abundant semantic information for short text classification, but the performance of such methods is strongly dependent on the quality of knowledge bases and constructing a large-scale knowledge base is time-consuming and labor-intensive. Another strategy is to explore latent topics (Chen et al., 2011; Ren et al., 2016) or clustering features (Ma et al., 2015; Revanasiddappa and Harish, 2018) for texts and input them into some classifiers as features. Such methods can reduce high dimensionality and terms' sparse distribution problems. Their shortness is to use pre-trained topics or clusters as features, which might be hard to explore the potential association between clustering and classification.

To address the limitations, we construct a joint architecture to embed a soft clustering method into the classification task, because joint architectures can leverage mutual information for each other and have been useful in many studies for understanding natural language (Luo et al., 2015; Shao et al., 2017; Schmitt et al., 2018). In addition, convolutional neural network and the gated mechanisms have been proven effectiveness in sentence-level language modeling (Dauphin et al., 2016; Gehring et al., 2017), and cluster centers of words contain semantic closeness of similar ones, which motivate

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 1002–1011
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

us to utilize them to auto-extract and highlight the cluster-related features for classification.

Based on the above analysis, we propose a joint model called cluster-gated convolutional neural network (CGCNN), coupling clustering and classification methods, to construct an end-to-end deep architecture. It integrates a soft clustering method into a gated convolutional neural network, which can explore the semantic relation of word-level context and the global corpus. And it can also guide the gating mechanism unit to control cluster-dependent feature flows. Specifically, it firstly uses a bi-directional long short-term memory model (BiLSTM) to learn word representations and capture local context in text. Then, it performs a soft clustering method on word representations for the probability of each word assigning to each cluster, which can build a bridge between word and the global corpus. And we develop a linear transformation to calculate cluster-dependent text representations. Based on the gating mechanism, we uses the cluster centers to further highlight the cluster-dependent convolutional features for the corresponding cluster. At last, we perform max-over-time pooling and concatenation operations to combine the selected features for classification.

The main contributions of this study are summarized as follows:

- We develop a joint model that combines clustering and classification methods in an end-to-end manner. The model leverages the semantic relation of words and the global corpus by learning from a soft clustering method to assist the classification task.

- To the best of our knowledge, our model is the first to incorporate a clustering method into the gating mechanism for convolutional neural network, which can help to control related features with clusters.

- We conduct extensive experiments on five real-world datasets to verify the effectiveness of our model. The experiment results show that the proposed method outperforms state-of-the-art methods.

2 Related Work

In this section, we review the related work from the following two aspects: text classification and short text classification.

2.1 Text Classification

Traditional text classification methods generally rely on manual features, such as bag-of-words, short n-grams, POS tagging. Most recent studies design more complex features for specific applications. For example, Lazaridou et al. (2013) considered discourse connectives (such as "*but*", "*and*") in the Bayesian model for sentiment classification. Post and Bergsma (2013) used multiple explicit and implicit syntactic features (e.g., unigrams, bigrams, and grammar tree patterns) for text classification. Zhang et al. (2015a) integrated word embeddings learned by word2vec into support vector machine model.

Recently, deep learning methods have been proven to be effective in text classification. Kim (2014) proposed a convolutional neural network (CNN) architecture that utilized multiple parallel convolutional layers with varying filter window sizes and concatenated the selected important features into a dense softmax layer for sentence classification. Lai et al. (2015) applied a recurrent structure to learn contextual information of each word and employed a max-pooling layer to capture the important features in texts. Another state-of-the-art method is hierarchical attention networks for document classification (Yang et al., 2016). Based on documents' hierarchical structure, it performed attention mechanisms on word-level and sentence-level representations extracted by BiLSTMs.

Such methods have good performance for long texts, especially for documents or paragraphs, but they are inferior when directly applied for short text classification task. Short texts tend to span over a wide range of words, resulting in data sparsity and lack of enough contexts (Chen et al., 2011; Wang et al., 2017).

2.2 Short Text Classification

According to our review, there generally exist two strategies for short text classification.

The first strategy is to leverage an external knowledge base to expand the context of short texts. For example, Feng et al. (2013) calculated the correlation between each short text and domain knowledge for classification. Wang et al. (2014) leveraged a large-scale taxonomy knowledge base to learn the concepts of words and ranked the similarities between short texts and concepts. Wang et al. (2017) associated each short text with its relevant concepts in the knowledge base. They

combined the words and relevant concepts of the short text to generate its embedding. A high-quality knowledge base is vital for their performance, but its construction is time-consuming and labor-intensive, or even worse, it may be unavailable for some domains (Li et al., 2016).

The second strategy is to explore latent topics or clustering features for classification. For example, Chen et al. (2011) derived multi-granularity topics through latent Dirichlet allocation (LDA) as features for traditional classifiers. Ren et al. (2016) used LDA to extract topics and extended existing recursive autoencoder to effectively incorporate topic information. Ma et al. (2015) used Gaussian models to describe the distribution of words embeddings and classified new short texts using the Bayesian rule to get the posterior probability. Revanasiddappa and Harish (2018) developed a fuzzy c-means clustering method and built the match degree between cluster and categories. Such methods can reduce high dimensionality and terms' sparse distribution problems. But their pipeline architecture (i.e., using clustering or topic models to derive clusters or topics, and then integrating them into classifiers as features), might be hard to leverage the mutual dependency of clustering and classification methods.

3 Method

In this paper, we propose a joint model called cluster-gated convolutional neural network (CGCNN), coupling a soft clustering method and a gated CNN for classification. In this section, we mainly introduce the overall architecture of our model, and define the objective function for training.

3.1 Overall Architecture of the Model

Figure 1 presents the CGCNN structure, composing of five major components: (1) a word encoder layer based on BiLSTM to learn word representations in each short text, (2) a clustering layer that calculates words' distributions and performs a linear transformation to get cluster-dependent text representations, (3) a cluster-gated convolutional layer that integrates cluster centers into a gated CNN for further controlling cluster-related feature flows, (4) a max-pooling layer to select most important features and concatenate them as the final text features, and (5) a fully connected layer with softmax function for classification. We update all the parameters in these five components simultaneously, which is introduced in the next subsection.

Word Encoder. Suppose each short text has a maximum of T words, and the t-th word can be

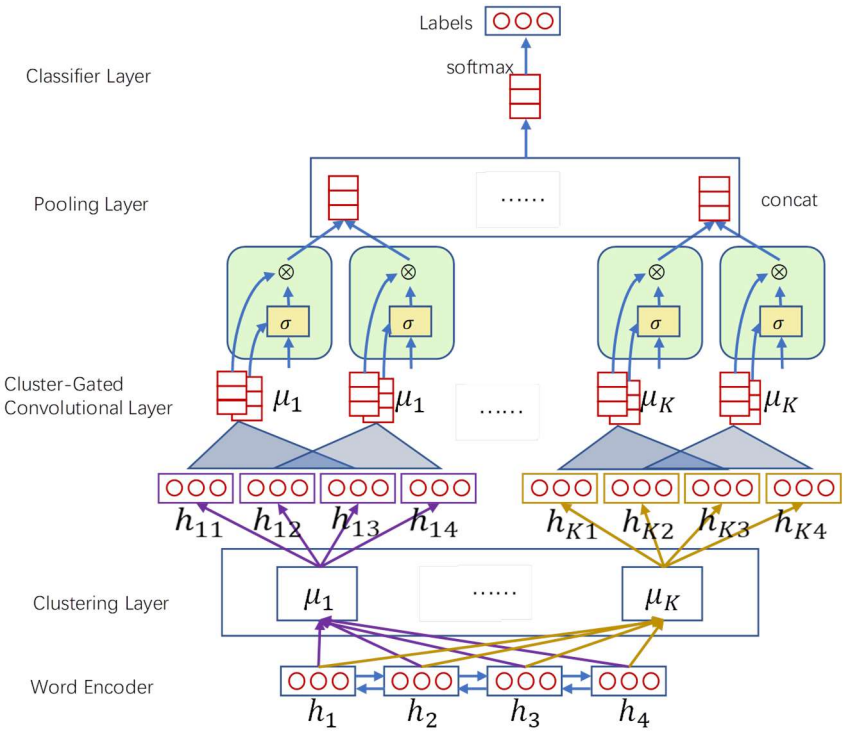

Figure 1: Cluster-gated convolutional neural network.

denoted as w_t, $t \in [1,T]$. We can embed the short text to vectors through an embedding matrix W_e. To capture the local context in text, we employ a BiLSTM to derive the forward representation f_t and backward representation b_t. We concatenate them as word representation, i.e., $h_t = [f_t, b_t]$. Specifically, the input text is represented as a matrix $X = [h_1, h_2, \dots, h_T]$. In some cases with weak sequential text, we will directly use word embedding as the corresponding word representation h_t, i.e., $h_t = W_e w_t$. This will be further discussed in the experiment section.

Clustering Layer. Cluster centers contain semantic closeness of similar words, which is used to selectively control related word flows in the next layer. Here we employ a soft clustering method (Maaten and Hinton, 2008; Xie et al., 2016) to explore words' cluster centers. And then we build a projection function $f_\theta: (h_t, \mu_k) \rightarrow h_{kt}$ to get cluster-dependent text representations, where μ_k refers to the *k*-th cluster center, and h_{kt} refers to the *t*-th representation dependent on the *k*-th cluster center. We set the number of clusters as *K*, i.e., $k \in [1,K]$. The soft clustering method uses the student's *t*-distribution as a kernel to calculate the similarity between word representation h_t and cluster center μ_k, as formula (1).

$$q_{t,k} = \frac{(1+ \| h_t - \mu_k \|^2)^{-1}}{\sum_{k'} (1+ \| h_t - \mu_{k'} \|^2)^{-1}} \quad (1)$$

where $q_{t,k}$ is the probability of *t*-th word belonging to *k*-th cluster. A higher value of $q_{t,k}$ indicates the word is more closed to the cluster.

With the help of the probability, we build a linear function to get the cluster-dependent text representations, as formula (2). It can reduce the role of words unrelated with the cluster, and ensures the sum of all cluster-dependent word representations at position *t* to the corresponding word representation h_t, as formula (3).

$$f_\theta : h_{k,t} = h_t q_{t,k} \quad (2)$$

$$\sum_k h_{k,t} = \sum_k h_t q_{t,k} = h_t \sum_k q_{t,k} = h_t \quad (3)$$

In this way, we can transfer the matrix of a short text to *K* cluster-dependent matrices, as formula (4).

$$X_k = [h_{k,1}, h_{k,2}, ..., h_{k,T}], k \in [1,K] \quad (4)$$

Cluster-Gated Convolutional Layer. The gating mechanism can control information flows in the network, which have been proven effective in LSTM and CNN (Dauphin et al., 2016). With the help of cluster centers, we would further explore related features with clusters in this layer. We employ a convolutional filter $W_k \in R^{D \times n}$ for mapping *n* words into a phrase-level feature, where *D* and *n* refer to the dimention of $h_{k,t}$ and the filter window size respectively. As shifting the filter across the *k*-th cluster-dependent text representation X_k, as formula (5), we can obtain a sequence of new features $C_k = [c_{k,1}, c_{k,2}, \dots, c_{k,L}]$. Here we use no-padding mode, i.e., *L=T-n+1*.

$$c_{k,i} = relu(h_{k,i:i+n} * W_k + b_k) \quad (5)$$

where b_k is the term bias.

Based on gated linear units (GLU) (Dauphin et al., 2016), we use word representations and cluster center to together decide the information passed on, as formulas (6) and (7).

$$g_{k,i} = \sigma(h_{k,i:i+n} * U_k + V_k \mu_k + d_k) \quad (6)$$

$$s_{k,i} = c_{k,i} \otimes g_{k,i} \quad (7)$$

where $U_k \in R^{D \times n}$, $V_k \in R^D$, $d_k \in R$ are learned parameters. σ is the sigmoid function, and $\otimes$ is the element-wise product between vectors. $g_{k,i}$ refers to the cluster-gated value, which is used to control the convolutional feature $c_{k,i}$. And $s_{k,i}$ is the final gated convolutional feature at position *t* for *k*-th cluster-dependent text representation.

Pooling Layer. In this layer, we apply a max-over-time pooling operation over each cluster-gated convolutional features to capture the maximum value as the feature for the corresponding cluster-dependent text representation, as formula (8). And then we concatenate all of them for the next classification layer, as formula (9).

$$s_k = \max\{s_{k,i}, i \in [1,T]\}, k \in [1,K] \quad (8)$$

$$s = s_1 \oplus s_2 \oplus \dots \oplus s_K \quad (9)$$

Classifier Layer. For each short text instance, we generate the high-level representations of the combination of multiple clusters' related information. To make full use of them, we use a fully connection with softmax function for prediction. The probability assigning a category label to this instance, can be calculated as formula (10).

$$p(\hat{y} = j) = soft\max(Ws + b) \quad (10)$$

where j is the category label. To avoid over-fitting, we can also employ dropout in this layer.

3.2 Training

The entire CGCNN model integrates a clustering method into the gated-CNN for classification, which can be updated simultaneously in one framework. Hence, we combine their loss effects into one objective function as formula (11).

$$L = L_{CLF} + \lambda L_{CLU} \quad (11)$$

where L_{CLF} is the cross-entropy loss of the classifier, and L_{CLU} is the clustering loss with Kullback-Leibler divergence (KL divergence) minimization. $\lambda > 0$ is a tradeoff parameter controlling the degree of clustering loss. The classifier loss can be defined as formula (12).

$$L_{CLF} = -\sum_i \sum_j 1\{y_i = j\} \log P(\hat{y}_i = j) \quad (12)$$

where i is the i-th sample instance, y_i is the ground truth label, and $1\{*\}$ is the indicator function.

For the clustering loss, we use KL divergence between the distribution of soft labels $q_{t,k}$ and the auxiliary distribution $p_{t,k}$ as (Maaten and Hinton, 2008; Xie et al., 2016), as formula (13).

$$L_{CLU} = \sum_i \sum_t \sum_k p_{t,k} \log \frac{p_{t,k}}{q_{t,k}} \quad (13)$$

where $p_{t,k}$ is the target distribution, as formula (14).

$$p_{t,k} = \frac{{q_{t,k}}^2 / \sum_{t'} q_{t',k}}{\sum_{k'} ({q_{t,k'}}^2 / \sum_{t'} q_{t',k'})} \quad (14)$$

As (Xie et al., 2016), this target distribution is computed by first raising the second power of $q_{t,k}$ to its corresponding soft cluster frequencies $\sum_{t'} q_{t',k}$ and then performing normalization to prevent large clusters from distorting the hidden feature space. It can not only improve cluster purity, but also emphasize the data points assigned to clusters with high confidence.

4 Experiments

4.1 Datasets and Preprocessing

To illustrate the effectiveness of our model, we conduct experiments on five public datasets: AG News, Sogou News, Amazon Reviews, Yahoo! Answers, and Search Snippets. The first three datasets are adopted from (Zhang et al., 2015b). The last two datasets are from the Yahoo! Webscope program and (Phan et al., 2008) respectively. For each dataset, we use 80% of the data for training, 10% for validation, and the remaining 10% for test. To construct short texts, we only use titles or some partial information of the datasets.

AG News and Sogou News. These two original datasets include 127,600 samples from 4 categories and 510,000 samples from 5 categories respectively. Sogou News is a dataset in Chinese, and Zhang et al. (2015b) combined pypinyin package and a Chinese segmentation tool to produce Pinyin – Roman spelling in Chinese. For both of them, each sample contains both title and content of news. To test for short texts, we remove contents and only use the titles in our experiment.

Amazon Reviews. The full dataset contains 3.65 million samples from one-to-five rating labels. In order to test for short texts, we remove the review contents and only use the review titles in our experiment.

Yahoo! Answers. This corpus includes 4,483,032 question titles, question contexts and their answers. We use 10 largest classes to construct a topic classification task. We randomly choose 50,000 samples for each class. Here we only use the question titles for classification.

Search Snippets. This dataset, released by Google search engine, includes 12,340 samples with predefined 8 categories by (Phan et al., 2008).

Note that we filter out punctuation and use Natural Language Toolkit (NLTK) for stemming. We do not remove stopwords since some of them may carry classification information, especially for users' reviews. The details of each dataset are listed in Table 1.

Datasets	Size	Classes	Avg. Len
AG News	127,600	4	7.0
Sogou News	510,000	5	15.4
Amazon Review	3,650,000	5	4.6
Yahoo! Answers	500,000	10	11.2
Search Snippets	12,340	8	17.9

Table 1: A summary of datasets.

4.2 Implementation Detail

The model hyper-parameters are tuned based on the AG News dataset. We also conduct experiments with the model directly using word embeddings instead of BiLSTM, representing as CGCNN*. We firstly set the dimension of word embeddings to 300, and pre-train word embeddings on each dataset with word2vec. The dimensions of all hidden vectors are set to 200. For the clustering method, we set the number of clusters to the number of ground-truth categories, and randomly initialize cluster center vectors. We set λ=0.5 and λ=0.6 for CGCNN* and CGCNN respectively to control the effects of clustering method. To avoid model over-fitting, we use dropout with rate of 0.2. We train the parameters by using Adam method with a learning rate of 0.001, and set the batch size to 64. The filter sizes of all convolution layers are set to 3 in these two methods.

4.3 Baselines and Experimental Settings

In this paper, we choose the following baseline algorithms for comparison:

CNN (Kim, 2014). It builds a multi-channel convolutional architecture with varying filter window sizes, and concatenates the important features extracted by a max-over-time pooling operation.

CNNM. To further illustrate the effectiveness of our model, we develop the multi-channel convolutional architecture (Kim, 2014) with multiple fixed size filters. As our model hyperparameters, the number of filters is equal to the number of ground-truth categories, and all their sizes are set to 3.

RCNN (Lai et al., 2015). It develops a recurrent convolutional structure. It employs a bi-directional recurrent structure to capture word context embeddings and uses a max-pooling layer to select the important features.

CNN-LSTM (Zhou et al., 2015). This method uses a multi-channel convolutional layer to extract higher-level phrase features, and employs a BiLSTM to capture their sequences for classification.

AttBiLSTM (Lin et al., 2017). It uses a BiLSTM to explore the sequences of texts, and develops a self-attention mechanism to get sentence-level representations.

For the multiple-channel convolutional architecture of CNN and CNN-LSTM, the filter sizes are 3, 4 and 5, as Kim (2014)'s default settings. For the hidden vectors of BiLSTM in these methods, we also set their dimensions to 200.

4.4 Results

We use accuracy as the evaluation metric, and Table 2 reports the different algorithms' performance on the five real-world datasets. We highlight the highest value in each column. As we can see, either CGCNN or CGCNN* has the best performance on the datasets. The CNN-LSTM outperforms the other baseline methods on AG News, Amazon Review and Yahoo! Answers datasets, while CNN and CNNM have the best performance on Sogou News and Search Snippets respectively. As compared with CNN-LSTM, CGCNN has about 1.5% performance improvements on Amazon Review and Yahoo! Answers, and 0.49% on AG News dataset. CGCNN* can achieve 0.6%~0.8% performance improvements over the second best baseline method on Sogou News and Search Snippets datasets. The AttBiLSTM method has poor performance. We suspect that lack of enough context might cause the failure of the self-attention mechanism.

	AG News	Sogou News	Amazon Review	Yahoo! Answers	Search Snippets
CNN	87.62%	90.47%	46.71%	61.64%	93.60%
CNNM	87.89%	90.17%	46.65%	61.59%	93.84%
CNN-LSTM	88.12%	89.67%	47.80%	62.61%	93.11%
RCNN	87.69%	88.43%	46.95%	61.90%	93.68%
AttBiLSTM	87.63%	87.63%	46.96%	61.92%	91.09%
CGCNN*	88.24%	**91.02%**	47.17%	63.01%	**94.57%**
CGCNN	**88.55%**	90.95%	**48.65%**	**63.55%**	92.30%

Note: CGCNN* represents that our model directly inputs word embeddings into the clustering layer.

Table 2: Accuracy comparison on different datasets.

The CNNM method using category number of convolutional filters, has similar performance with the CNN method using three convolutional filters, which illustrates increasing number of convolutional filters might have no active impact on performance. Differently, our CGCNN* method using category number of clusters for gated CNN, achieves better accuracies than both of them. It shows that our proposed architecture, integrating a clustering-gated mechanism into CNN, can significantly improve the performance in short text classification.

The CNN-LSTM method uses CNN and BiLSTM to capture phrase features and their sequences, outperforms CNN and CNNM on AG News, Amazon Reviews and Yahoo! Answers datasets, while it has poorer performance on Sogou News and Search Snippets datasets. Such cases also exist in the comparison between CGCNN and CGCNN* methods. We analyze the datasets, and suspect that weak sequential relationship in texts may result in the decreasing performances on Sogou News and Search Snippets. The original Sogou News was transferred from Chinese characters to Pinyin format (Zhang et al., 2015b). It might cause a homophone problem. For example, word "与(and)" and word "雨(rain)" have the same pronunciation but different meanings in Chinese. It breaks sequential patterns in texts. For Search Snippets, each sample is consisted of multiple keywords, and there are no obvious sequences among them. For example, a sample likes "… calorie count calories item ...", containing weak sequential semantics.

4.5 Clustering Analysis

To further study the impact of clustering method, we conduct additional experiments on AG News dataset by varying the tradeoff parameter λ and the cluster number K, and assess the sensitivity of our model.

Figure 2 reports the change of performance with increasing values of tradeoff parameter λ from 0.1 to 0.9 while keeping the cluster number K constant (as the category number). We can observe that CGCNN* and CGCNN reach the best performances when $\lambda = 0.5$ and $\lambda = 0.6$ respectively. When tradeoff parameter λ varies from 0.1 to the values of their best performances, their performances generally show an increasing trend, which implies the clustering effect can benefit for understanding short texts. When tradeoff parameter λ increases from the optimal values to 0.9, the performances of these two methods generally have a slight decrease, which shows excessive clustering might have a bad influence on short text classification.

Figure 3 reports the results of adjusting the number of clusters (K) in CGCNN* and CGCNN when we set λ to the optimal values (i.e., $\lambda = 0.5$ and $\lambda = 0.6$ respectively). For CGCNN method, we can observe that it reaches the best performance when the cluster number equals to the category number (i.e., $K = 4$). No matter the cluster number increases or decreases, its performance would have a decrease tendency. While the CGCNN* method's performance generally show an increasing trend, which relatively stabilizes when K reaches category number (although its performance has a slight decrease at $K = 5$). That is the reason that we set the cluster number to the category number.

4.6 Case Study

In this section, we take several concrete samples from AG News dataset to illustrate how the

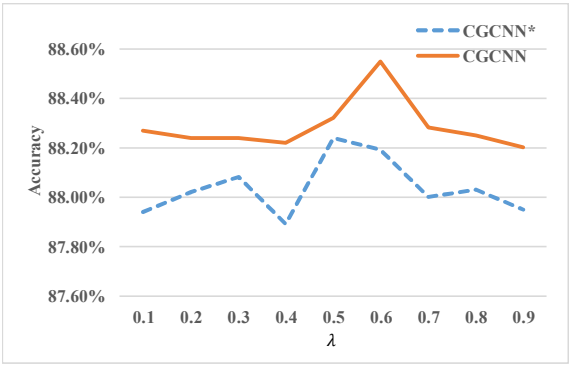

Figure 2: Performance with tradeoff parameter λ on AG News.

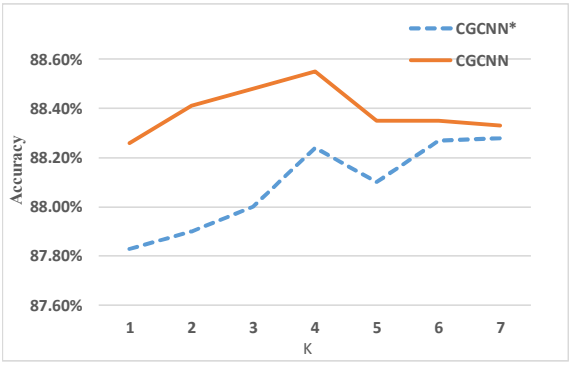

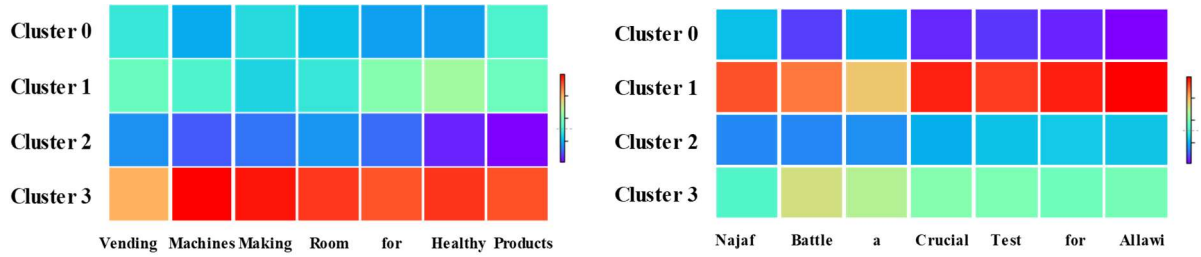

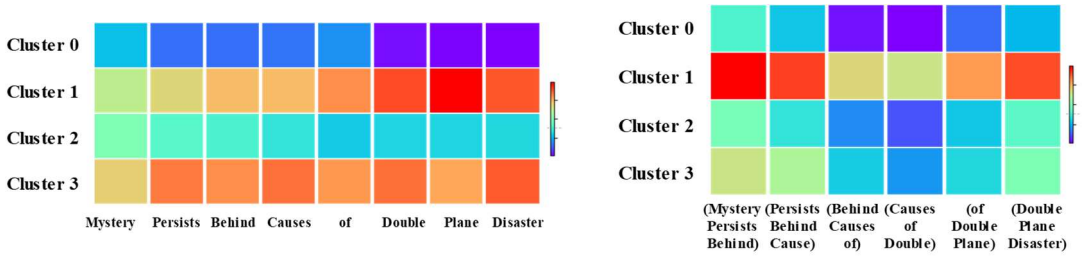

Figure 3: Performance with cluster number K on AG News.

(a) An instance with category "Sci/Tech" (b) An instance with category "World"

Figure 4: The similarities between words and clusters in a short text.

(a) The similarities between words and clusters in an instance with category "World"

(b) The outputs of the corresponding cluster-gated convolutional features

Figure 5: The role of the cluster-gated layer.

proposed method works. Here we use CGCNN method, because of strong sequential relationship in this dataset.

In the clustering layer, we leverage a soft clustering method to explore words' cluster centers, and build a linear function to project the representation of a short text to K cluster-dependent representations. Here we calculate the similarity between words and cluster centers, and normalize the values of each word belonging to clusters. Figure 4 (a) and (b) show two different instances from categories "Sci/Tech" and "World" respectively. We can observe the linear projection can strengthen the words' representations dependent on some cluster, and weaken them on others. These two figures have different distributions on the same word "for", which is due to different contexts explored by BiLSTM.

There might exist some instances closely related with two or more clusters, as figure 5 (a). To further control the information flows, we leverage cluster centers and phrase-level features for the gated mechanism. We use Xue and Li (2018)'s method to visualize the gated mechanism: summing the representation of each phrase-level feature and normalizing them according to clusters. Figure 5 (a) shows the similarities between words and clusters in an instance with category "World", while figure 5 (b) shows the corresponding cluster-gated convolutional features. We can observe that cluster-gated layer can further strengthen the corresponding cluster-dependent representation, and weaken others.

5 Conclusion

In this paper, we propose a joint model that couples clustering and classification methods. It employs a BiLSTM to learn word representations for local contexts in short texts. We take a soft clustering method to calculate the probability of each word assigning to each cluster, which can derive the semantic relation of word representations and the global corpus. We also perform a linear transformation to explore cluster-dependent text representations. Moreover, we develop a cluster-gated CNN by integrating cluster centers into GLU, which can select cluster-related features for classification. Experiments on five real-world datasets show that our model does better than the state-of-the-art methods for short text classification task.

In the future work, we will further analyze the mutual effects of document-level clustering and classification methods for long text, and attempt to develop more effective joint model for text classification. Moreover, we will study some other

mechanisms (e.g., highway units, attention mechanism) to further improve the performance.

Abstract

In hospitals, critical care patients are often susceptible to various complications that adversely affect their morbidity and mortality. Digitized patient data from Electronic Health Records (EHRs) can be utilized to facilitate risk stratification accurately and provide prioritized care. Existing clinical decision support systems are heavily reliant on the structured nature of the EHRs. However, the valuable patient-specific data contained in unstructured clinical notes are often manually transcribed into EHRs. The prolific use of extensive medical jargon, heterogeneity, sparsity, rawness, inconsistent abbreviations, and complex structure of the clinical notes poses significant challenges, and also results in a loss of information during the manual conversion process. In this work, we employ two coherence-based topic modeling approaches to model the free-text in the unstructured clinical nursing notes and capture its semantic textual features with the emphasis on human interpretability. Furthermore, we present *FarSight*, a long-term aggregation mechanism intended to detect the onset of disease with the earliest recorded symptoms and infections. We utilize the predictive capabilities of deep neural models for the clinical task of risk stratification through ICD-9 code group prediction. Our experimental validation on MIMIC-III (v1.4) database underlined the efficacy of *FarSight* with coherence-based topic modeling, in extracting discriminative clinical features from the unstructured nursing notes. The proposed approach achieved a superior predictive performance when benchmarked against the structured EHR data based state-of-the-art model, with an improvement of 11.50% in AUPRC and 1.16% in AUROC.

1 Introduction

Until recently, the healthcare industry had an inclination towards conservative approaches for the treatment and diagnosis of patients, resulting in less patient-centric and imprecise assessments (Mathew and Pillai, 2015). Intensive Care Units (ICUs) utilize the most advanced medical resources to treat and monitor critically ill patients. However, such advanced medical interventions in ICUs often make patients vulnerable to several complications (To and Napolitano, 2012). Various infections, including barotrauma, short- and long-term intubation, catheter-associated urinary tract infection, weaning errors, ventilator-associated pneumonia, gastrointestinal tract bleeding, and infections from unrecognized drug interactions, are associated with invasive ICU devices (Wollschlager and Conrad, 1988). The lack of accurate knowledge of the etiology of such complications leads to the inability to accurately stratify risk, due to which, in most cases, adequate care is provided to patients only after the development of a complication (Huddar et al., 2016). With the advent of digitization, advancement in technology, need for evidence-based medicine, increased population, and rising rates of chronic diseases, the utilization of ever-increasing heterogeneous medical data to improve the quality of life has become imperative. Specifically, ICUs are data-rich environments where several parameters of patients are monitored continuously. Such data can be vital to improve the existing Clinical Decision Support Systems (CDSSs), develop new treatments, and predict prominent clinical events and outcomes. Furthermore, such CDSSs could promote evidence-based and patient-centric treatments, resulting in reduced hospital mortality and morbidity rates, and improved risk assessment.

Pat is 83 yo F w/PMHx for CLL and hypotens, who was admited for an elective total hip arthroplasty for persistent hip pain. NGT to low cont suct. Family here to visit.

Pat initially sustained a right hip fracture after a fall in [**2137**], and had an ORIF performed at the time. Gave med for pain. Has had right hip pain ever since, and also has AVN of the right femoral head.

She came in today for elective tot hip repl. In the OR today, patient had an estimated 1600cc EBL, and received 6u pRBC. I/Os were 7200cc in (3.7L LR, 1.5L pRBCs).

Figure 1: Sample de-identified nursing note from critical care. Observe the absence of grammatical structure, informal word usage, and extensive medical jargon.

Structured medical data in the form of Electronic Health Records (EHRs) contain numerical assessments (e.g., lab results) and are amenable to standard statistical analysis (Huddar et al., 2016). However, unstructured clinical text and images also contain valuable information concerning the state of a patient. In particular, clinical nursing notes maintain objective and subjective assessments of a patient's condition. Such raw notes contain the intuitions and observations of nurses and caregivers who regularly monitor the patient. This valuable patient-specific information present in the clinical nursing notes has the potential to uncover hidden clues about the mental state (e.g., family support and mental fitness) and the health of a patient (Jo et al., 2015). Such information is not found in EHRs or elsewhere (Dubois et al., 2017). However, these notes are informally written, and modeling such notes is challenging due to their high-dimensionality, rawness, sparsity, complex linguistic and temporal nature, inconsistent abbreviations, and occurrence of rich medical jargon (a sample note is shown in Figure 1).

The voluminosity of nursing notes can be observed from the heavy-tailed distribution of the MIMIC-III nursing notes across various patients (see Figure 2), with an average of 176.49 nursing notes per patient. The presentation, analysis, and interpretation of the data present in such notes in a medically appropriate and usable format determine the competence of the underlying CDSS (Wang et al., 2018). Furthermore, there is often a need to assign multiple labels to a patient entry, owing to the diverse and manifold nature of the disease symptoms of the patients (Baumel et al., 2018). Risk stratification as ICD-9[1] code group prediction can help in predicting disease onset and its severity, thus facilitating preventive and prioritized care, and reduction of hospital mortality and morbidity rates.

With the availability of large de-identified healthcare databases such as MIMIC-III[2] (Johnson et al., 2016), modeling patient data using machine and deep learning to predict prominent clinical events and outcomes has sparked widespread interest. Early works (Tu and Guerriere, 1993; Doig et al., 1993; Grigsby et al., 1994; Clermont et al., 2001; Hanson and Marshall, 2001) have reported on the superior performance of machine learning models in forecasting the length-of-stay and mortality, for ICU patients. More recently, Pirracchio (2016) used an ensemble of several machine learning models that offered improved performance in ICU mortality prediction over various

[1]International Classification of Diseases, ninth revision.
[2]Medical Information Mart for Intensive Care.

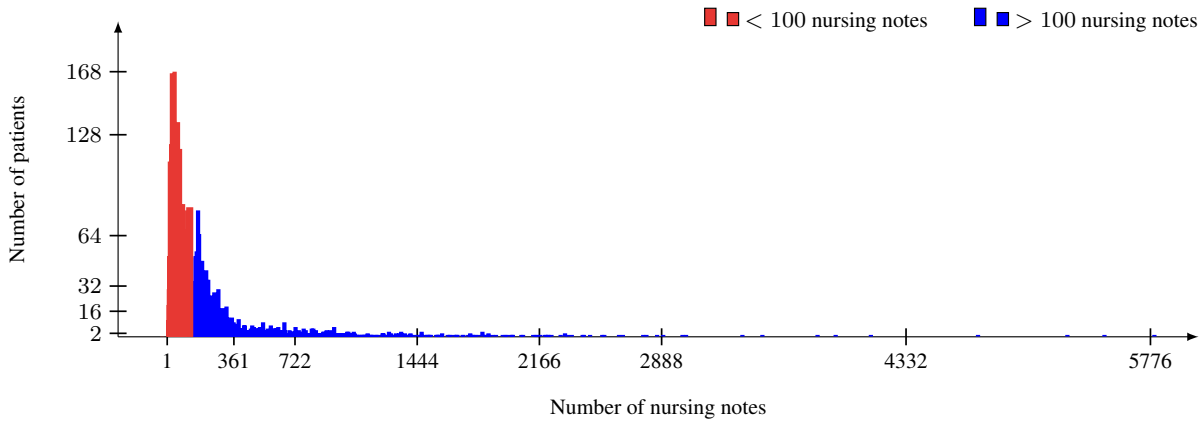

Figure 2: Distribution of the nursing notes across various MIMIC-III subjects.

severity scoring systems. Feldman et al. (2016) mined the clinical nursing, radiology, physician, and ECG narratives to study the linguistic, structural, and topical differences among them. The authors only provided a foundation for mining clinical notes effectively, and in our work, we extend their efforts by effectively modeling the underlying patient representations of the nursing text through effective topic modeling and deep neural learning. Johnson et al. (2017) extracted a set of features from the MIMIC-III database for ICU mortality prediction and compared several state-of-the-art models against gradient boosting and logistic regression. The authors stressed the need for improvement in the way of reporting performance to ensure a fairer comparison. Most of these models utilize machine learning models built on structured EHR data for the prediction of clinical tasks.

Recent works show promising results in modeling patient data using deep learning approaches. Harutyunyan et al. (2017) benchmarked their performance on four clinical prediction tasks on the MIMIC-III database using multitask recurrent neural networks. Zalewski et al. (2017) presented a viable framework to combine several modalities of a patient's health states for risk stratification. Their approach was built on the hierarchical Dirichlet method, aimed at tackling the sparsity and high-dimensionality of the nursing notes extracted from the MIMIC-II database. However, the authors used a logistic regression model to predict the mortality rate of the patients and did not evaluate their performance with the recent works and deep neural architectures. Purushotham et al. (2018) reported a suite of five clinical prediction tasks, including the length-of-stay, mortality, and ICD-9 code group prediction on the MIMIC-III database using deep learning models and benchmarked their performance against the existing state-of-the-art methods and severity scoring systems. However, mining and modeling the valuable patient-specific information in unstructured clinical nursing notes for the development of CDSSs remains mostly uncommon.

In this paper, we discuss an approach to model the rich patient-specific information in the unstructured clinical nursing notes, to aid in the risk stratification as an ICD-9 code group prediction task. ICD-9 codes are a taxonomy of diagnostic codes used for cost-effectiveness analysis, epidemiology studies, and designing healthcare policies. Accurate ICD-9 code group prediction not only promotes better ICD-9 code determination, but also facilitates more reliable risk stratification by reporting on the severity, symptoms, and the use of resources across code groups, thus aiding disease-specific staging systems. In our work, two coherence-based topic modeling approaches, Coherence-based Latent Dirichlet Allocation (C-LDA) and Coherence-based Nonnegative Matrix Factorization (C-NMF) are employed to capture the semantic relationships between the textual features of the clinical notes and derive optimal data representations with a higher guarantee on human interpretability. We employ *FarSight* to aggregate the documented patient data in a way intended to detect the onset of the disease with the earliest recorded symptoms. Furthermore, we benchmark the performance of our proposed topic models using two neural architectures, including Multi-Layer Perceptron (MLP) and Attention-based Long Short Term Memory (A-LSTM). Additionally, we perform a sensitivity analysis to assess the statistical significance of the obtained results.

The remainder of this paper is structured as follows: Section 2 describes the MIMIC-III database, the preprocessing steps, and the topic modeling approaches employed to obtain the optimal data representations from the raw clinical nursing notes. The deep neural architectures employed in the clinical task of ICD-9 code group prediction along with the discussion of the experimental results of our benchmarking are presented in Section 3. Finally, Section 4 summarizes this paper with highlights on future research possibilities.

2 Materials and Methods

In this section, we discuss in detail, the Natural Language Processing (NLP) pipeline designed to facilitate multi-label ICD-9 code group prediction, and the same is depicted in Figure 3.

2.1 Dataset and Cohort Selection

MIMIC-III (v1.4) is a publicly available large healthcare database with comprehensive medical data of over $40,000$ ICU patients. The healthcare database contains $223,556$ nursing notes extracted from $2,083,180$ note events (*noteevents* table), corresponding to $7,704$ distinct patients (*diagnoses_icd* table). Two selection criteria were employed in the cohort selection. Firstly, only

those records corresponding to the patients older than 15 (adults) were retained using the patient's age at the time of admission to the ICU (extracted from *admissions* and *patients* tables). Secondly, only the first admission of a patient to the hospital was considered. Both these steps were followed in accordance with the existing literature (Johnson et al., 2017; Purushotham et al., 2018). The resultant dataset comprises nursing notes of $7,638$ patients with a median age of 66 years (Quartile $Q_1 - Q_3$: $52 - 78$ years).

2.2 Data Cleaning

The data extracted from the MIMIC-III database contained erroneous patient entries due to several factors, including missing values, duplicate or incorrect records, outliers, and noise. The erroneous entries were filtered out using the *iserror* attribute of the *noteevents* table. Then, duplicate patient records were identified and deduplicated. The resultant dataset comprised of nursing notes corresponding to $6,532$ patients, and the data in these records were aggregated using the proposed *FarSight* technique.

2.3 FarSight: Long-Term Aggregation

It is crucial to detect the onset of the disease with the earliest detected symptoms, to provide preventive care and reduce the mortality and morbidity of complications. We propose *FarSight*, which is designed to aggregate the patient data using a future lookup on all the detected diseases in the later medical records concerning that patient. Let $\mathcal{P}$ be the set of all patients, and let a patient p have a sequence of N clinical notes, $\mathcal{S}^{(p)} = \{(\eta_i^{(p)}, \mathcal{I}_i^{(p)})\}_{i=1}^{N}$, with each clinical note $\eta_i^{(p)}$ mapped to an ICD-9 code $\mathcal{I}_i^{(p)}$ indexed in the order from the oldest to the most recent. Now, *FarSight* aggregates the ICD-9 codes across the nursing notes of a patient using a future lookup, resulting in $\mathcal{S}^{(p)} = \{(\eta_i^{(p)}, \mathcal{I}^{(p)})\}_{i=1}^{N}$, where $\mathcal{I}^{(p)} = \{\mathcal{I}_i^{(p)}\}_{i=1}^{N}$. Ultimately, we aim at learning a function $\mathcal{F}$ to estimate the probability of classifying a given nursing note $\eta_j^{(p)}$ into a set of diagnostic code groups: $\mathcal{F}(S^{(p)}) \approx Pr(\mathcal{I}^{(p)} \mid \eta_j^{p})$. Instead of aggregating several patient records, *FarSight* only aggregates the ICD-9 codes across a particular patient's nursing notes to facilitate risk stratification at the initial stages of the disease with the earliest recorded symptoms and infections.

2.4 Data Preprocessing

Data (text) normalization is performed to facilitate the transformation of inconsistent and informally written medical text into a consistent canonical form. Preprocessing includes tokenization, stopword removal, and stemming/lemmatization. Tokenization splits the nursing text into words (tokens). Using the NLTK English stopword corpus, we removed the stopwords from the generated set of tokens. Next, references to images (e.g., *PET_Scan.jpg*) were removed, and character case folding was performed. Word length based token removal was not performed to retain medical abbreviations such as *CT*, *MRI*, *DEXA*, and *PET*. Lastly, stemming was employed to facilitate suffix stripping, followed by lemmatization to convert the stripped tokens into their base forms. The tokens appearing in less than ten clinical notes were eliminated to mitigate overfitting and lower the computational complexity of training.

2.5 Topic Modeling of Clinical Notes

Let the set of all nursing notes be $\mathbb{S} = \{\mathcal{S}^{(p)}\}_{p=1}^{\mathcal{P}}$. Each nursing note η_j constitutes a variable length of words from a large vocabulary $\mathbb{V}$, making $\mathbb{S}$ very complex. Thus, a transformation (T) of the unstructured clinical text to a machine-processable form ($T : \mathbb{S} \rightarrow \mathbb{R}^k$ ($k \ll |\mathbb{V}|$)) is vital to the efficacy and performance of the underlying deep neural architectures.

Topic modeling aims at finding a set of topics

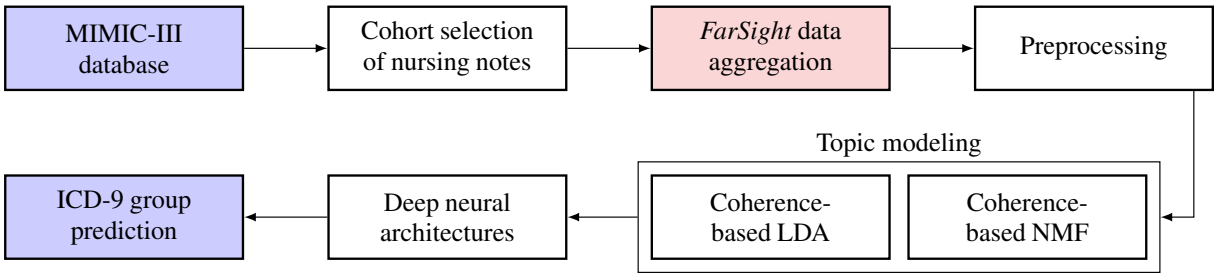

Figure 3: NLP pipeline used in the prediction of the ICD-9 code group.

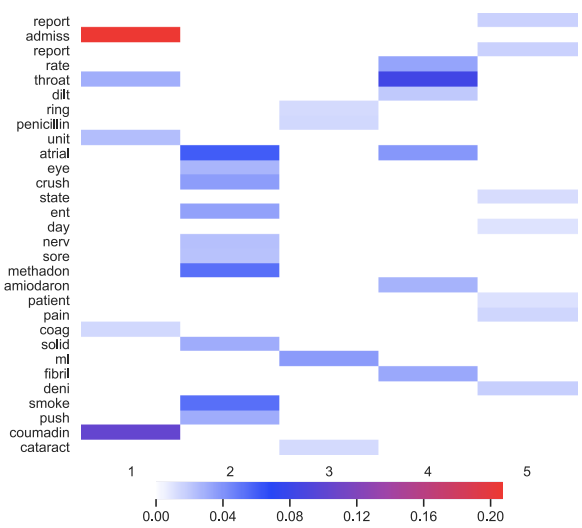
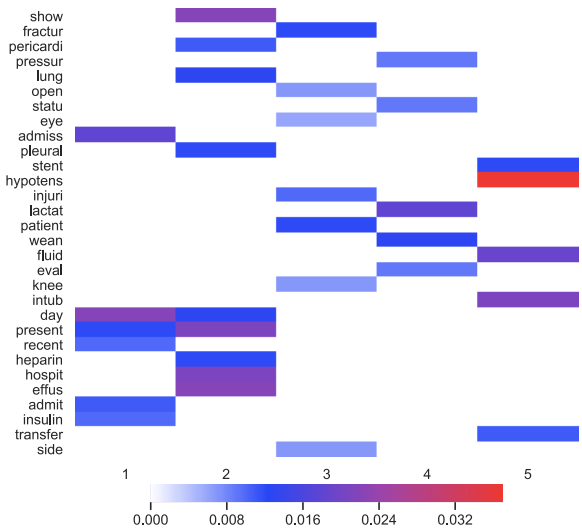
from a set of clinical notes that best represents the corpus. Latent Dirichlet Allocation (LDA) (Blei et al., 2003) is a cluster analysis approach based on the three-layer Bayesian framework including documents, topics, and tokens. LDA draws a mixture of topics from the Dirichlet distribution and facilitates a flat and soft probabilistic clustering of tokens into topics and documents into topics. LDA posits that each term and clinical note belong to a set of clinical topics with a certain probability. Nonnegative Matrix Factorization (NMF) (Lee and Seung, 2000) is a matrix factorization approach that decomposes multivariate data into topics. In NMF, each topic is a nonnegative linear combination of the tokens in the vocabulary. NMF iteratively decomposes the data matrix ($N \times |\mathbb{V}|$) into two lower rank matrices with $\mathcal{T}$ topics ($N \times \mathcal{T}$ and $\mathcal{T} \times |\mathbb{V}|$). These topic models capture the context of occurrence and co-occurrence, which is essential for accurate predictability of the underlying deep neural models.



Determining the optimal number of LDA or NMF clusters is a challenging task. To address this issue, we utilize the Topic Coherence (TC) or semantic coherence (Röder et al., 2015) between the topics to derive the optimal number of clusters. Furthermore, when topics are learned from a multinomial distribution over words from noisy and sparse text data, they are less coherent and hard to interpret. TC evaluates topic models with a greater guarantee of human interpretability. This study adopts LDA and NMF with TC (C-LDA and C-NMF) as TC accounts for the semantic similarity between the higher scoring tokens and facilitates the generation of human-understandable topics. We employ the C_v variant of coherence measurement with a Normalized Pointwise Mutual Information (NPMI) score (Bouma, 2009) as the confirmation measure, due to its high correlation with the available human-judged data (Röder et al., 2015). Let $\mathcal{T} = \{t_1, t_2, \ldots, t_k\}$ be a topic generated from a topic model which is represented using its top-k most probable tokens (t_is). Note that higher values of the average pairwise similarity among the tokens in $\mathcal{T}$ imply greater coherence of the topic. For a predetermined similarity measure $S(t_i, t_j)$ (here NPMI), the coherence score is computed as:

$$\text{Coherence}_S(\mathcal{T}) = \frac{\sum_{1 \le i \le k-1} \sum_{i+1 \le j \le k} S(t_i, t_j)}{\binom{k}{2}} \quad (1)$$



where $t_i, t_j \in \mathcal{T}$. The coherence score comes from external data, i.e., the data not used during training (we employed the full set of English Wikipedia articles), and is intended to regularize the topic models. The NPMI similarity score is an extension of the pointwise mutual information score, and is used in finding associations and collocations between the words (Aletras and Stevenson, 2013). The NPMI score is computed as:

$$\text{NPMI}(t_i, t_j) = \frac{\text{PMI}(t_i, t_j)}{-\log_2(\Pr(t_i, t_j))} \quad (2)$$

$$\text{PMI}(t_i, t_j) = \log_2 \left(\frac{\Pr(t_i, t_j)}{\Pr(t_i)\Pr(t_j)} \right) \quad (3)$$

(a) Coherence-based LDA.

(b) Coherence-based NMF.

Figure 4: Correlations between top terms' membership in top five topic modeling clusters.

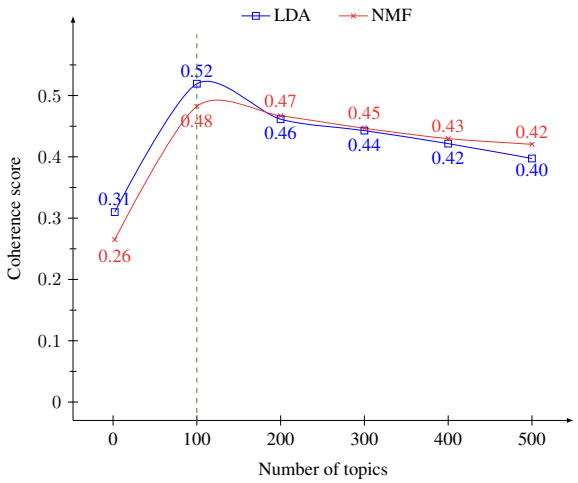


Figure 5: Coherence score comparison to determine the optimal number of topics.

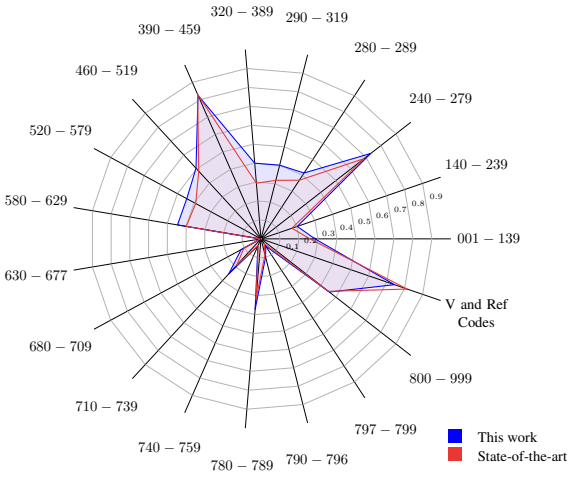

Figure 6: Comparison of ICD-9 code group statistics with the state-of-the-art model (Purushotham et al., 2018).

The individual confirmation measures obtained for all topics ($\mathcal{T}_i$s) are averaged to obtain the final coherence score.

The number of topics for both LDA and NMF models was determined to be 100, by computing the coherence score of several topic models obtained by varying the number of topics. The LDA and NMF matrices were built on a bag-of-words representation of the clinical notes. For the ease of interpretation, a heat map presenting the correlations between top terms' membership in top five C-LDA clusters is presented in Figure 4a, and top five C-NMF clusters is depicted in Figure 4b. From Figure 4, it can be observed that both the C-LDA and C-NMF models effectively capture specific clinical terms, including *penicillin*, *cataract*, *coumadin*, *insulin*, *heparin*, and *pleural* from the raw nursing text. Figure 5 shows the coherence score comparison of LDA and NMF models with the number of topics varying from 2 to 500.

3 ICD-9 Code Group Prediction

ICD-9 codes are a taxonomy of diagnostic codes typically used by healthcare professionals and insurers when discussing medical conditions. This study only focuses on category-level (group) predictions, owing to the high granularity of the diagnostic codes. Each code group comprises a set of similar diseases, and most of the health conditions can be categorized into a unique group. This study focuses on the risk stratification as a multi-label problem, where each nursing note is mapped to multiple ICD-9 code groups. The ICD-9 codes for a given admission are mapped into 19 distinct code groups[3]. Note that the ICD-9 code range of 760 – 779 was left out since it corresponds to the *conditions originating in the perinatal period*, which is usually assigned to newborns, who are excluded from this study as per the defined cohort selection criteria (see Section 2.1). Additionally, to lower the computational cost of training, we merged all the reference and supplemental V-codes into a single code group. Figure 6 presents a spider plot depicting the statistics of the ratio of the number of patients in a particular code group to the total number of patients in the cohort. Although our work and the state-of-the-art (Purushotham et al., 2018) differ in data and cohort selection, it can be observed from Figure 6 that both the works share similar statistics concerning the ICD-9 code groups, thus facilitating a fair comparison of performance.

3.1 Deep Neural Architectures

We used two deep neural architectures, Multilayer Perceptron (MLP) and Attention-based LSTM (A-LSTM), for the multi-label ICD-9 code group prediction task. The deep models were trained to minimize a binary cross-entropy loss function using an Adam optimizer, with a batch size of 128, for eight epochs.

3.1.1 Multi-Layer Perceptron

The MLP is a feed-forward artificial neural network consisting of multiple layers of neurons (nodes) interacting using weighted connections.

[3] http://tdrdata.com/ipd/ipd_SearchForICD9CodesAndDescriptions.aspx.

MLP offers several advantages including adaptive learning, fault tolerance, parallelism, and generalizability. The output of a neuron in every layer serves as an input to the subsequent layer. A neuron in the current layer (l) with the input $I^{(l)}$ is activated in the following layer ($l+1$) as $g^{(l)}(W^{(l)} \cdot I^{(l)} + b^{(l)})$, where $g^{(l)}$ is a non-linear activation such as Rectified Linear Unit (ReLU), tanh, or logistic sigmoid, and $b^{(l)}$ and $W^{(l)}$ are the bias and weight matrix at layer l. MLP uses backpropagation to determine the gradient of the loss function needed to learn an optimal set of weights and biases needed to minimize a loss function. This study employs an MLP network with one hidden layer of 75 nodes, activated using a ReLU function, and one output layer of 19 nodes, activated using a sigmoid function.

3.1.2 Attention-based LSTM

The LSTM effectively captures the long-term dependencies and overcomes the gradient vanishing problem which is crucial in the accurate risk stratification using unstructured nursing notes. LSTMs introduce an adaptive gating mechanism to determine the extent to which the LSTM memory units must retain the previous state (c_{t-1}) and memorize the features in the current state (c_t). Typically, four gates composite an LSTM network including the input gate i, the forget gate f, the output gate o, and the candidate value g for the cell state. The precise form of an LSTM update at a layer l and time step t is computed as:

$$\begin{pmatrix} i \\ f \\ o \\ g \end{pmatrix} = \begin{pmatrix} \text{sigm} \\ \text{sigm} \\ \text{sigm} \\ \tanh \end{pmatrix} W^{(l)} \begin{pmatrix} h_{t-1}^{(l)} \\ h_t^{(l-1)} \end{pmatrix} \quad (4)$$

$$c_t^{(l)} = f \odot c_{t-1}^{(l)} + i \odot g \quad (5)$$

$$h_t^{(l)} = o \odot \tanh(c_t^{(l)}) \quad (6)$$

where $\odot$ denotes element-wise multiplication, h_t is the output at a time step t, and $W^{(l)}$ is a $[4n \times 2n]$ weight matrix at layer l.

Attentive neural models have been successfully applied to several NLP tasks including sentence summarization, text entailment, and reading comprehension (Bahdanau et al., 2014). This study utilizes the attention mechanism for the clinical task of risk stratification as ICD-9 code group prediction. Let H be the matrix of output vectors $[h_1, h_2, \ldots, h_T]$ produced from LSTM. The representation r_j of a nursing note η_j after T time steps is computed as $H \cdot (\text{softmax}(v^T \cdot \tanh(H)))^T$, where v is a trainable parameter. This study utilizes an attention-based LSTM with dimension size of 289 for the embedding (17 time steps) and 300 for the LSTM hidden state. The multi-label classification is facilitated using a sigmoid activation of the final A-LSTM output.

3.2 Experimental Results and Discussion

To experimentally validate the proposed approach, we performed an exhaustive benchmarking on the clinical nursing notes obtained from the MIMIC-III database. The experiments were performed using a server running Ubuntu OS with 56 cores of Intel Xeon processors, 128 GB RAM, 3 TB hard drive, and two NVIDIA Tesla M40 GPUs. A significant challenge arose due to the manifold nature of diseases, as each patient record was assigned a set of ICD-9 code groups. This study employs a pair-wise comparison of the actual and predicted code group sets. Five standard evaluation metrics including Accuracy (ACC), F1 score, MCC score, Area Under the Precision-Recall Curve (AUPRC), and Area Under the ROC Curve (AUROC) were employed to evaluate the performance of the proposed coherence-based modeling approaches, classified using MLP and A-LSTM. Ten-fold cross-validation was performed to assess the predictability of the proposed models. Table 1 tabulates the performance of the proposed modeling approaches using the proposed *FarSight* approach for data aggregation along with two standard baselines. We observe that the proposed C-LDA model outperforms the C-NMF model in accurately classifying the diagnostic ICD-9 code groups. Additionally, from Table 1, we observe that the proposed C-LDA model outperforms the other standard baselines including LDA and NMF without coherence scores.

AUPRC varies with the change in the ratio of the target classes in the data and hence is more informative than AUROC while evaluating imbalanced data (Saito and Rehmsmeier, 2015). F1 score captures both precision and recall of the prediction, and MCC score takes into account, the true positives, false positives, and false negatives, thus serving as a balanced measure even with class imbalance. Due to the significant class imbalance in the underlying corpus (see Figure 6), AUROC and MCC scores serve as accurate evaluation metrics. The existing works, including the state-of-

the-art model (Purushotham et al., 2018), are built on the structured nature of the EHRs, modeled using numerical feature sets (e.g., lab results) to aid in the prediction of clinical events. From Figure 7, we remark that the proposed approach built on the unstructured medical text and preprocessed using the *FarSight* approach outperformed the state-of-the-art model by 11.50% in AUPRC and 1.16% in AUROC. Furthermore, the existing works do not benchmark their performance on metrics other than AUPRC and AUROC. We urge that the other metrics presented in this study aid in the accurate assessment of the proposed models, essential in determining the reliability of the underlying CDSS. It can also be noted that the *FarSight* approach effectively models the unstructured data to facilitate the detection of the onset of the disease with the earliest recorded symptoms, and such modeling results in an improvement in the clinical decision-making process. We observe that utilizing the proposed approach leads to accurate health risk appraisal well in advance, with an overall accuracy of 80%. Thus, CDSSs built on the predictive capabilities of *FarSight*-aggregated and C-LDA classified modeling could demonstrate effective patient-centric and evidence-based risk assessment, thus ensuring proper channeling of preventive and prioritized care.

3.3 Sensitivity Analysis

The experimental results in Table 1 highlight the efficacy of the proposed models over the state-of-the-art model (see Figure 7) and standard baselines, including LDA and NMF without coherence scores, in modeling the raw patient-specific clinical nursing notes. To analyze the significance of the observed performance further, we performed a statistical sensitivity analysis. Sensitivity analysis

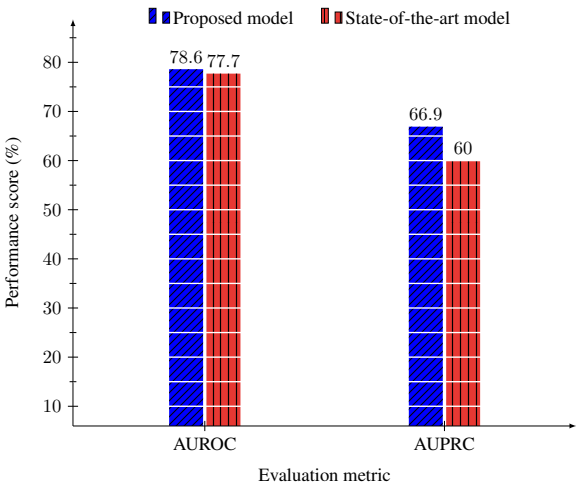

Figure 7: Comparison of the proposed approach with the state-of-the-art model (Purushotham et al., 2018).

(Simar and Wilson, 1998) is a potential approach that facilitates decision-making by measuring the extent to which the optimal solution is sensitive to the change in the input of one or more parameters.

To understand the distribution of the underlying data, we employed the Kolmogorov-Smirnov test for normality (J and Jr, 1951), which revealed that the data was not normally distributed. The performance of an algorithm measured as a result of ten-fold cross-validation forms the treatment population of that approach. Additionally, note that each sample (performance score) in the corresponding treatments of the algorithms under comparison utilize the same k^{th} fold data, and thus the samples are generated as a function of the same input population. Therefore, to perform the sensitivity analysis, we employed a nonparametric paired samples Wilcoxon signed-rank test (Wilcoxon, 1992) at a significance level (α) of 5%. The null hypothesis in Wilcoxon signed-rank test is that the two treatments are drawn from the same distribution,

Data Model	Classifier	Performance score

Table 2: A paired samples Wilcoxon signed-rank test (two-tailed, $p < 0.05$) for the proposed model with the best performance against other modeling strategies.

which is rejected in favor of the alternate hypothesis when the significance level (p-value) resulting from the test is higher than the preset α. Table 2 presents the results of our sensitivity analysis for the proposed model with the best performance against other modeling strategies. From Table 2, it can be observed that the value of p is always lower than the preset α of 0.05. Thus, we conclude that the proposed model with the best performance is statistically significant than the other approaches and baseline methods with respect to all the employed performance evaluation metrics.

4 Concluding Remarks

In this paper, we presented *FarSight*, a technique for detecting the onset of the disease with the earliest recorded symptoms and infections, to provide preventive and prioritized care, in turn aiding in the reduction of the morbidity rate. Two coherence-based topic modeling approaches were employed to capture the semantic information in the nursing notes and derive the optimal data representations with emphasis on the human interpretability of the derived clinical concepts. The obtained data representations were effectively leveraged for diagnostic ICD-9 code group prediction using deep neural architectures. Unlike in the previous works, we benchmarked the performance of our proposed models using several evaluation metrics which are essential in the accurate assessment of the reliability of the models. The proposed model captured the valuable patient-specific information present in the informally written nursing notes and outperformed the structured EHR data based state-of-the-art model with an improvement of 11.50% in terms of AUPRC and 1.16% in terms of AUROC. Furthermore, we also observed that the proposed *FarSight*-aggregated and C-LDA classified model captured the discriminative features of the nursing notes and consistently outperformed several other standard models, including C-NMF, LDA, and NMF. Moreover, our model eliminates the dependency on structured EHRs for the development of CDSSs and is extremely vital in countries with low EHR adoption rates.

Although the proposed approach effectively stratifies the patients' risk and the associated complications, it can be enhanced further, which calls for further research on this topic. First, the proposed approach only models the unstructured nursing text and neglects the structured EHR information (e.g., lab results), which can potentially be utilized to facilitate robust patient profiling. Second, the modeling presented in this study does not account for real-time clinical data. In the future, we intend on exploring the techniques for modeling structured EHR data along with the data modeled from the unstructured clinical nursing notes. We also aim at validating our model on real-time clinical data to enhance its predictability and adaptability, thus focusing on the need for time-aware, dependable architectures in real-world hospital scenarios.

Abstract

We investigate the political roles of "Internet trolls" in social media. Political trolls, such as the ones linked to the Russian Internet Research Agency (IRA), have recently gained enormous attention for their ability to sway public opinion and even influence elections. Analysis of the online traces of trolls has shown different behavioral patterns, which target different slices of the population. However, this analysis is manual and labor-intensive, thus making it impractical as a first-response tool for newly-discovered troll farms. In this paper, we show how to automate this analysis by using machine learning in a realistic setting. In particular, we show how to classify trolls according to their political role —left, news feed, right— by using features extracted from social media, i.e., Twitter, in two scenarios: (*i*) in a traditional supervised learning scenario, where labels for trolls are available, and (*ii*) in a distant supervision scenario, where labels for trolls are not available, and we rely on more-commonly-available labels for news outlets mentioned by the trolls. Technically, we leverage the community structure and the text of the messages in the online social network of trolls represented as a graph, from which we extract several types of learned representations, i.e., embeddings, for the trolls. Experiments on the "IRA Russian Troll" dataset show that our methodology improves over the state-of-the-art in the first scenario, while providing a compelling case for the second scenario, which has not been explored in the literature thus far.

1 Introduction

Internet "trolls" are users of an online community who quarrel and upset people, seeking to sow discord by posting inflammatory content. More recently, organized "troll farms" of political opinion manipulation trolls have also emerged. Such farms usually consist of state-sponsored agents who control a set of pseudonymous user accounts and personas, the so-called "sockpuppets", which disseminate misinformation and propaganda in order to sway opinions, destabilize the society, and even influence elections (Linvill and Warren, 2018).

The behavior of political trolls has been analyzed in different recent circumstances, such as the 2016 US Presidential Elections and the Brexit referendum in UK (Linvill and Warren, 2018; Llewellyn et al., 2018). However, this kind of analysis requires painstaking and time-consuming manual labor to sift through the data and to categorize the trolls according to their actions. Our goal in the current paper is to automate this process with the help of machine learning (ML). In particular, we focus on the case of the 2016 US Presidential Elections, for which a public dataset from Twitter is available. For this case, we consider only accounts that post content in English, and we wish to divide the trolls into some of the functional categories identified by Linvill and Warren (2018): *left troll*, *right troll*, and *news feed*.

We consider two possible scenarios. The first, prototypical ML scenario is supervised learning, where we want to learn a function from users to categories {*left*, *right*, *news feed*}, and the ground truth labels for the troll users are available. This scenario has been considered previously in the literature by Kim et al. (2019). Unfortunately, a solution for such a scenario is not directly applicable to a real-world use case. Suppose a new troll farm trying to sway the upcoming European or US elections has just been discovered. While the identities of the accounts might be available, the labels to learn from would not be present. Thus, any supervised machine learning approach would fall short of being a fully automated solution to our initial problem.

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 1023–1034
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

A more realistic scenario assumes that labels for troll accounts are *not available*. In this case, we need to use some external information in order to learn a labeling function. Indeed, we leverage more persistent entities and their labels: news media. We assume a learning scenario with distant supervision where labels for news media are available. By combining these labels with a citation graph from the troll accounts to news media, we can infer the final labeling on the accounts themselves without any need for manual labeling.

One advantage of using distant supervision is that we can get insights about the behavior of a newly-discovered troll farm quickly and effortlessly. Differently from troll accounts in social media, which usually have a high churn rate, news media accounts in social media are quite stable. Therefore, the latter can be used as an anchor point to understand the behavior of trolls, for which data may not be available.

We rely on embeddings extracted from social media. In particular, we use a combination of embeddings built on the user-to-user mention graph, the user-to-hashtag mention graph, and the text of the tweets of the troll accounts. We further explore several possible approaches using label propagation for the distant supervision scenario.

As a result of our approach, we improve the classification accuracy by more than 5 percentage points for the supervised learning scenario. The distant supervision scenario has not previously been considered in the literature, and is one of the main contributions of the paper. We show that even by hiding the labels from the ML algorithm, we can recover 78.5% of the correct labels.

The contributions of this paper can be summarized as follows:

- We predict the political role of Internet trolls (*left*, *news feed*, *right*) in a realistic, unsupervised scenario, where labels for the trolls are not available, and which has not been explored in the literature before.
- We propose a novel distant supervision approach for this scenario, based on graph embeddings, BERT, and label propagation, which projects the more-commonly-available labels for news media onto the trolls who cited these media.
- We improve over the state of the art in the traditional, fully supervised setting, where training labels are available.

2 Related Work

2.1 Trolls and Opinion Manipulation

The promise of social media to democratize content creation (Kaplan and Haenlein, 2010) has been accompanied by many malicious attempts to spread misleading information over this new medium, which quickly got populated by *sockpuppets* (Kumar et al., 2017), *Internet water army* (Chen et al., 2013), *astroturfers* (Ratkiewicz et al., 2011), and *seminar users* (Darwish et al., 2017). Several studies have shown that trust is an important factor in online relationships (Ho et al., 2012; Ku, 2012; Hsu et al., 2014; Elbeltagi and Agag, 2016; Ha et al., 2016), but building trust is a long-term process and our understanding of it is still in its infancy (Salo and Karjaluoto, 2007). This makes it easy for politicians and companies to manipulate user opinions in community forums (Dellarocas, 2006; Li et al., 2016; Zhuang et al., 2018).

Trolls. Social media have seen the proliferation of fake news and clickbait (Hardalov et al., 2016; Karadzhov et al., 2017a), aggressiveness (Moore et al., 2012), and trolling (Cole, 2015). The latter often is understood to concern malicious online behavior that is intended to disrupt interactions, to aggravate interacting partners, and to lure them into fruitless argumentation in order to disrupt online interactions and communication (Chen et al., 2013). Here we are interested in studying not just any trolls, but those that engage in opinion manipulation (Mihaylov et al., 2015a,b, 2018). This latter definition of *troll* has also become prominent in the general public discourse recently. Del Vicario et al. (2016) have also suggested that the spreading of misinformation online is fostered by the presence of polarization and echo chambers in social media (Garimella et al., 2016, 2017, 2018).

Trolling behavior is present and has been studied in all kinds of online media: online magazines (Binns, 2012), social networking sites (Cole, 2015), online computer games (Thacker and Griffiths, 2012), online encyclopedia (Shachaf and Hara, 2010), and online newspapers (Ruiz et al., 2011), among others.

Troll detection has been addressed by using domain-adapted sentiment analysis (Seah et al., 2015), various lexico-syntactic features about user writing style and structure (Chen et al., 2012; Mihaylov and Nakov, 2016), and graph-based approaches over signed social networks (Kumar et al., 2014).

Sockpuppet is a related notion, and refers to a person who assumes a false identity in an Internet community and then speaks to or about themselves while pretending to be another person. The term has also been used to refer to opinion manipulation, e.g., in Wikipedia (Solorio et al., 2014). Sockpuppets have been identified by using authorship-identification techniques and link analysis (Bu et al., 2013). It has been also shown that sockpuppets differ from ordinary users in their posting behavior, linguistic traits, and social network structure (Kumar et al., 2017).

Internet Water Army is a literal translation of the Chinese term *wangluo shuijun*, which is a metaphor for a large number of people who are well organized to flood the Internet with purposeful comments and articles. Internet water army has been allegedly used in China by the government (also known as *50 Cent Party*) as well as by a number of private organizations.

Astroturfing is an effort to simulate a political grass-roots movement. It has attracted strong interest from political science, and research on it has focused on massive streams of microblogging data (Ratkiewicz et al., 2011).

Identification of malicious accounts in social media includes detecting spam accounts (Almaatouq et al., 2016; McCord and Chuah, 2011), fake accounts (Fire et al., 2014; Cresci et al., 2015), compromised and phishing accounts (Adewole et al., 2017). Fake profile detection has also been studied in the context of cyber-bullying (Galán-García et al., 2016). A related problem is that of *Web spam detection*, which has been addressed as a text classification problem (Sebastiani, 2002), e.g., using spam keyword spotting (Dave et al., 2003), lexical affinity of arbitrary words to spam content (Hu and Liu, 2004), frequency of punctuation and word co-occurrence (Li et al., 2006).

Trustworthiness and veracity analytics of online statements is an emerging research direction, especially given the recent interest in fake news (Lazer et al., 2018). It is related to trolls, as they often engage in opinion manipulation and rumor spreading (Vosoughi et al., 2018). Research topics include predicting the credibility of information in social media (Ma et al., 2016; Mitra et al., 2017; Karadzhov et al., 2017b; Popat et al., 2017) and political debates (Hassan et al., 2015; Gencheva et al., 2017; Jaradat et al., 2018), as well as stance classification (Mohtarami et al., 2018). For example, Castillo et al. (2011) leverage user reputation, author writing style, and various time-based features, Canini et al. (2011) analyze the interaction of content and social network structure, and Morris et al. (2012) studied how Twitter users judge truthfulness. Zubiaga et al. (2016) study how people handle rumors in social media, and found that users with higher reputation are more trusted, and thus can spread rumors easily. Lukasik et al. (2015) use temporal patterns to detect rumors and to predict their frequency, and Zubiaga et al. (2016) focus on conversational threads. More recent work has focused on the credibility and the factuality in community forums (Nakov et al., 2017; Mihaylova et al., 2018, 2019; Mihaylov et al., 2018).

2.2 Understanding the Role of Political Trolls

None of the above work has focused on understanding the role of political trolls. The only closely relevant work is that of Kim et al. (2019), who predict the roles of the Russian trolls on Twitter by leveraging social theory and Actor-Network Theory approaches. They characterize trolls using the digital traces they leave behind, which is modeled using a time-sensitive semantic edit distance. For this purpose, they use the "IRA Russian Troll" dataset (Linvill and Warren, 2018), which we also use in our experiments. However, we have a very different approach based on graph embeddings, which we show to be superior to their method in the supervised setup. We further experiment with a new, and arguably more realistic, setup based on distant supervision, where labels are not available. To the best of our knowledge, this setup has not been explored in previous work.

2.3 Graph Embeddings

Graph embeddings are machine learning techniques to model and capture key features from a graph automatically. They can be trained either in a supervised or in an unsupervised manner (Cai et al., 2018). The produced embeddings are latent vector representations that map each vertex V in a graph G to a d-dimensional vector. The vectors capture the underlying structure of the graph by putting "similar" vertices close together in the vector space. By expressing our data as a graph structure, we can leverage and extract critical insights about the topology and the contextual relationships between the vertices in the graph.

In mathematical terms, graph embeddings can be expressed as a function $f : V \rightarrow R^d$ from the set of vertices V to a set of embeddings, where d is the dimensionality of the embeddings. The function f can be represented as a matrix of dimensions $|V| \times d$. In our experiments, we train Graph Embeddings in an unsupervised manner by using node2vec (Grover and Leskovec, 2016), which is based on random walks over the graph. Essentially, this is an application of the well-known skip-gram model (Mikolov et al., 2013) from word2vec to random walks on graphs.

Besides *node2vec*, there have been a number of competing proposals for building graph embeddings; see (Cai et al., 2018) for an extensive overview of the topic. For example, *SNE* (Liao et al., 2018) model both the graph structure and some node attributes. Similarly, *Line* (Tang et al., 2015) represent each node as the concatenation of two embedded vectors that model first- and second-order proximity. *TriDNR* (Pan et al., 2016) represents nodes by coupling several neural network models. For our experiments, we use node2vec, as we do not have access to user attributes: the users have been banned from Twitter, their accounts were suspended, and we only have access to their tweets thanks to the "IRA Russian Trolls" dataset.

3 Method

Given a set of known political troll users (each user being represented as a collection of their tweets), we aim to detect their role: *left*, *right*, or *news feed*. Linvill and Warren (2018) describe these roles as follows:

Right Trolls spread nativist and right-leaning populist messages. Such trolls support the candidacy and Presidency of Donald Trump and denigrate the Democratic Party; moreover, they often send divisive messages about mainstream and moderate Republicans.

Left Trolls send socially liberal messages and discuss gender, sexual, religious, and -especially- racial identity. Many tweets are seemed intentionally divisive, attacking mainstream Democratic politicians, particularly Hillary Clinton, while supporting Bernie Sanders prior to the elections.

News Feed Trolls overwhelmingly present themselves as US local news aggregators, linking to legitimate regional news sources and tweeting about issues of local interest.

Technically, we leverage the community structure and the text of the messages in the social network of political trolls represented as a graph, from which we learn and extract several types of vector representations, i.e., troll user embeddings. Then, armed with these representations, we tackle the following tasks:

T1 A fully supervised learning task, where we have labeled training data with example troll and their roles;

T2 A distant supervision learning task, in which labels for the troll roles are *not* available at training time, and thus we use labels for news media as a proxy, from which we infer labels for the troll users.

3.1 Embeddings

We use two graph-based (user-to-hashtag and user-to-mentioned-user) and one text-based (BERT) embedding representations.

3.1.1 U2H

We build a bipartite, undirected User-to-Hashtag (U2H) graph, where nodes are users and hashtags, and there is an edge (u, h) between a user node u and a hashtag node h if user u uses hashtag h in their tweets. This graph is bipartite as there are no edges connecting two user nodes or two hashtag nodes. We run node2vec (Grover and Leskovec, 2016) on this graph, and we extract the embeddings for the users (we ignore the hashtag embeddings). We use 128 dimensions for the output embeddings. These embeddings capture how similar troll users are based on their usage of hashtags.

3.1.2 U2M

We build an undirected User-to-Mentioned-User (U2M) graph, where the nodes are users, and there is an edge (u, v) between two nodes if user u mentions user v in their tweets (i.e., u has authored a tweet that contains "@v"). We run node2vec on this graph and we extract the embeddings for the users. As we are interested only in the troll users, we ignore the embeddings of users who are only mentioned by other trolls. We use 128 dimensions for the output embeddings. The embeddings extracted from this graph capture how similar troll users are according to the targets of their discussions on the social network.

3.1.3 BERT

BERT offers state-of-the-art text embeddings based on the Transformer architecture (Devlin et al., 2019). We use the pre-trained BERT-large, uncased model, which has 24-layers, 1024-hidden, 16-heads, and 340M parameters, which yields output embeddings with 768 dimensions. Given a tweet, we generate an embedding for it by averaging the representations of the BERT tokens from the penultimate layer of the neural network. To obtain a representation for a user, we average the embeddings of all their tweets. The embeddings extracted from the text capture how similar users are according to their use of language.

3.2 Fully Supervised Learning (T1)

Given a set of troll users for which we have labels, we use the above embeddings as a representation to train a classifier. We use an L2-regularized logistic regression (LR) classifier. Each troll user is an example, and the label for the user is available for training thanks to manual labeling. We can therefore use cross-validation to evaluate the predictive performance of the model, and thus the predictive power of the features.

We experiment with two ways of combining features: *embedding concatenation* and *model ensembling*. Embedding concatenation concatenates the feature vectors from different embeddings into a longer feature vector, which we then use to train the LR model. Model ensembling instead trains a separate model with each kind of embedding, and then merges the prediction of the different models by averaging the posterior probabilities for the different classes. Henceforth, we denote embedding concatenation with the symbol $\|$ and model ensembling with $\oplus$. For example, U2H $\|$ U2M is a model trained on the concatenation of U2H and U2M embeddings, while U2H $\oplus$ BERT represents the average predictions of two models, one trained on U2H embeddings and one on BERT.

3.3 Distant Supervision (T2)

In the distant supervision scenario, we assume not to have access to user labels. Given a set of troll users without labels, we use the embeddings described in Section 3.1 together with mentions of *news media* by the troll users to create proxy models. We assume that labels for news media are readily available, as they are stable sources of information that have a low churn rate.

We propagate labels from the given media to the troll user that mentions them according to the following media-to-user mapping:

$$\begin{aligned} \textit{LEFT} &\rightarrow \textit{left} \\ \textit{RIGHT} &\rightarrow \textit{right} \\ \textit{CENTER} &\rightarrow \textit{news feed} \end{aligned} \tag{1}$$

This propagation can be done in different ways: (a) by training a proxy model for media and then applying it to users, (b) by additionally using label propagation (LP) for semi-supervised learning.

Let us describe the proxy model propagation for (a) first. Let M be the set of media, and U be the set of users. We say a user $u \in U$ mentions a medium $m \in M$ if u posts a tweet that contains a link to the website of m. We denote the set of users that mention the medium m as $C_m \subseteq U$.

We can therefore create a representation for a medium by aggregating the embeddings of the users that mention the target medium. Such a representation is convenient as it lies in the same space as the user representation. In particular, given a medium $m \in M$, we compute its representation $R(m)$ as

$$R(m) = \frac{1}{|C_m|} \sum_{u \in C_m} R(u), \tag{2}$$

where $R(u)$ is the representation of user u, i.e., one (or a concatenation) of the embeddings described in Section 3.1.

Finally, we can train a LR model that uses $R(m)$ as features and the label for the medium $l(m)$. This model can be applied to predict the label of a user u by using the same type of representation $R(u)$, and the label mapping in Equation 1.

Label Propagation (b) is a transductive, graph-based, semi-supervised machine learning algorithm that, given a small set of labeled examples, assigns labels to previously unlabeled examples. The labels of each example change in relationship to the labels of *neighboring* ones in a properly-defined graph.

More formally, given a partially-labeled dataset of examples $X = X_u \cup X_l$, of which X_l are labeled examples with labels Y_l, and X_u are unlabeled examples, and a similarity graph $G(X, E)$, the label propagation algorithm finds the set of unknown labels Y_u such that the number of discordant pairs $(u, v) \in E : y_u \neq y_v$ is minimized, where y_z is the label assigned to example z.

Role	Users	Tweets	User Example	Tweet Example
Left	233	427 141	@samirgooden	@MichaelSkolnik @KatrinaPierson @samesfandiari Trump folks need to stop going on CNN.
Right	630	711 668	@chirrmorre	BREAKING: Trump ERASES Obama's Islamic Refugee Policy! https://t.co/uPTneTMNM5
News Feed	54	598 226	@dailysandiego	Exit poll: Wisconsin GOP voters excited, scared about Trump #politics

Table 1: Statistics and examples from the IRA Russian Trolls Tweets dataset.

The algorithm works as follows: At every iteration of propagation, each unlabeled node updates its label to the most frequent one among its neighbors. LP reaches convergence when each node has the same label as the majority of its neighbors. We define two different versions of LP by creating two different versions of the similarity graph G.

LP1 *Label Propagation using direct mention.*
In the first case, the set of edges among users U in the similarity graph G consists of the logical OR between the 2-hop closure of the U2H and the U2M graph. That is, for each two users $u, v \in U$, there is an edge in the similarity graph $(u, v) \in E$ if u and v share a common hashtag or a common user mention

$$(u, h) \in \text{U2H} \wedge (v, h) \in \text{U2H} \vee (u, w) \in \text{U2M} \wedge (v, w) \in \text{U2M}$$

The graph therefore uses the same information that is available to the embeddings.

To this graph, which currently encompasses only the set of users U, we add connections to the set of media M. We add an edge between each pair (u, m) if $u \in C_m$. Then, we run the label propagation algorithm, which propagates the labels from the labeled nodes M to the unlabeled nodes U, thanks to the mapping from Equation 1.

LP2 *Label Propagation based on a similarity graph.*
In this case, we use the same representation for the media as in the proxy model case above, as described by Equation 2. Then, we build a similarity graph among media and users based on their embeddings. For each pair $x, y \in U \cup M$ there is an edge in the similarity graph $(x, y) \in E$ iff

$$\text{sim}(R(x), R(y)) > \tau,$$

where sim is a similarity function between vectors, e.g., cosine similarity, and τ is a user-specified parameter that regulates the sparseness of the similarity graph.

Finally, we perform label propagation on the similarity graph defined by the embedding similarity, with the set of nodes corresponding to M starting with labels, and with the set of nodes corresponding to U starting without labels.

4 Data

4.1 IRA Russian Troll Tweets

Our main dataset contains 2 973 371 tweets by 2848 Twitter users, which the US House Intelligence Committee has linked to the Russian Internet Research Agency (IRA). The data was collected and published by Linvill and Warren (2018), and then made available online.[1] The time span covers the period from February 2012 to May 2018.

The trolls belong to the following manually assigned roles: Left Troll, Right Troll, News Feed, Commercial, Fearmonger, Hashtag Gamer, Non English, Unknown. Kim et al. (2019) have argued that the first three categories are not only the most frequent, but also the most interesting ones. Moreover, focusing on these troll types allows us to establish a connection between troll types and the political bias of the news media they mention. Table 1 shows a summary of the troll role distribution, the total number of tweets per role, as well as examples of troll usernames and tweets.

4.2 Media Bias/Fact Check

We use data from Media Bias/Fact Check (MBFC)[2] to label news media sites. MBFC divides news media into the following bias categories: Extreme-Left, Left, Center-Left, Center, Center-Right, Right, and Extreme-Right. We reduce the granularity to three categories by grouping Extreme-Left and Left as LEFT, Extreme-Right and Right as RIGHT, and Center-Left, Center-Right, and Center as CENTER.

Bias	Count	Example
LEFT	341	www.cnn.com
RIGHT	619	www.foxnews.com
CENTER	372	www.apnews.com

Table 2: Summary statistics about the Media Bias/Fact Check (MBFC) dataset.

Table 2 shows some basic statistics about the resulting media dataset. Similarly to the IRA dataset, the distribution is right-heavy.

5 Experiments and Evaluation

5.1 Experimental Setup

For each user in the IRA dataset, we extracted all the links in their tweets, we expanded them recursively if they were shortened, we extracted the domain of the link, and we checked whether it could be found in the MBFC dataset. By grouping these relationships by media, we constructed the sets of users C_m that mention a given medium $m \in M$.

The U2H graph consists of 108 410 nodes and 443 121 edges, while the U2M graph has 591 793 nodes and 832 844 edges. We ran node2vec on each graph to extract 128-dimensional vectors for each node. We used these vectors as features for the fully supervised and for the distant-supervision scenarios. For Label Propagation, we used an empirical threshold for edge materialization $\tau = 0.55$, to obtain a reasonably sparse similarity graph.

We used two evaluation measures: accuracy, and macro-averaged F1 (the harmonic average of precision and recall). In the supervised scenario, we performed 5-fold cross-validation. In the distant-supervision scenario, we propagated labels from the media to the users. Therefore, in the latter case the user labels were only used for evaluation.

5.2 Evaluation Results

Table 3 shows the evaluation results. Each line of the table represents a different combination of features, models, or techniques. As mentioned in Section 3, the symbol '$\|$' denotes a single model trained on the concatenation of the features, while the symbol '$\oplus$' denotes an averaging of individual models trained on each feature separately. The tags 'LP1' and 'LP2' denote the two label propagation versions, by mention and by similarity, respectively.

We can see that accuracy and macro-averaged F1 are strongly correlated and yield very consistent rankings for the different models. Thus, henceforth we will focus our discussion on accuracy.

We can see in Table 3 that it is possible to predict the roles of the troll users by using distant supervision with relatively high accuracy. Indeed, the results for T2 are lower compared to their T1 counterparts by only 10 and 20 points absolute in terms of accuracy and F1, respectively. This is impressive considering that the models for T2 have no access to labels for troll users.

Looking at individual features, for both T1 and T2, the embeddings from U2M outperform those from U2H and from BERT. One possible reason is that the U2M graph is larger, and thus contains more information. It is also possible that the social circle of a troll user is more indicative than the hashtags they used. Finally, the textual content on Twitter is quite noisy, and thus the BERT embeddings perform slightly worse when used alone.

All our models with a single type of embedding easily outperform the model of Kim et al. (2019). The difference is even larger when combining the embeddings, be it by concatenating the embedding vectors or by training separate models and then combining the posteriors of their predictions.

By concatenating the U2M and the U2H embeddings (U2H $\|$ U2M), we fully leverage the hashtags and the mention representations in the latent space, thus achieving accuracy of 88.7 for T1 and 78.0 for T2, which is slightly better than when training separate models and then averaging their posteriors (U2H $\oplus$ U2M): 88.3 for T1 and 77.9 for T2. Adding BERT embeddings to the combination yields further improvements, and follows a similar trend, where feature concatenation works better, yielding 89.2 accuracy for T1 and 78.2 for T2 (compared to 89.0 accuracy for T1 and 78.0 for T2 for U2H $\oplus$ U2M $\oplus$ BERT).

Adding label propagation yields further improvements, both for LP1 and for LP2, with the latter being slightly superior: 89.6 vs. 89.3 accuracy for T1, and 78.5 vs. 78.3 for T2.

Overall, our methodology achieves sizable improvements over previous work, reaching an accuracy of 89.6 vs. 84.0 of Kim et al. (2019) in the fully supervised case. Moreover, it achieves 78.5 accuracy in the distant supervised case, which is only 11 points behind the result for T1, and is about 10 points above the majority class baseline.

Method	Full Supervision (T1)		Distant Supervision (T2)	
	Accuracy	Macro F1	Accuracy	Macro F1
Baseline (majority class)	68.7	27.1	68.7	27.1
Kim et al. (2019)	84.0	75.0	N/A	N/A
BERT	86.9	83.1	75.1	60.5
U2H	87.1	83.2	76.3	60.9
U2M	88.1	83.9	77.3	62.4
U2H $\oplus$ U2M	88.3	84.1	77.9	64.1
U2H $\|$ U2M	88.7	84.4	78.0	64.6
U2H $\oplus$ U2M $\oplus$ BERT	89.0	84.4	78.0	65.0
U2H $\|$ U2M $\|$ BERT	89.2	84.7	78.2	65.1
U2H $\|$ U2M $\|$ BERT + LP1	89.3	84.7	78.3	65.1
U2H $\|$ U2M $\|$ BERT + LP2	89.6	84.9	78.5	65.7

Table 3: Predicting the role of the troll users using full vs. distant supervision.

6 Discussion

6.1 Ablation Study

We performed different experiments with the hyper-parameters of the graph embeddings. With smaller dimensionality (i.e., using 16 dimensions instead of 128), we noticed 2–3 points of absolute decrease in accuracy across the board.

Moreover, we found that using all of the data for learning the embeddings was better than focusing only on users that we target in this study, namely *left*, *right*, and *news feed*, i.e., using the rest of the data adds additional context to the embedding space, and makes the target labels more contextually distinguishable. Similarly, we observe 5–6 points of absolute drop in accuracy when training our embeddings on tweets by trolls labeled as *left*, *right*, and *news feed*.

6.2 Comparison to Full Supervision

Next, we compared to the work of Kim et al. (2019), who had a fully supervised learning scenario, based on Tarde's Actor-Network Theory. They paid more attention to the content of the tweet by applying a text-distance metric in order to capture the semantic distance between two sequences. In contrast, we focus on critical elements of information that are salient in Twitter: *hashtags* and *user mentions*. By building a connection between users, hashtags, and user mentions, we effectively filtered out the noise and we focused only on the most sensitive type of context, thus automatically capturing features from this network via graph embeddings.

Method	Accuracy	Macro F1
Baseline (majority)	46.5	21.1
BERT	61.8	60.4
U2H	61.6	60.0
U2M	62.7	61.4
U2H $\oplus$ U2M	63.5	61.8
U2H $\|$ U2M	63.8	61.9
U2H $\oplus$ U2M $\oplus$ BERT	63.7	61.8
U2H $\|$ U2M $\|$ BERT	64.0	62.2

Table 4: Leveraging user embeddings to predict the bias of the media cited by troll users.

6.3 Reverse Classification: Media from Trolls

Table 4 shows an experiment in distant supervision for reverse classification, where we trained a model on the IRA dataset with the troll labels, and then we applied that model to the representation of the media in the MBFC dataset, where each medium is represented as the average of the embeddings of the users who cited that medium. We can see that we could improve over the baseline by 20 points absolute in terms of accuracy and by 41 in terms absolute in terms of macro-averaged F1.

We can see in Table 4 that the relative ordering in terms or performance for the different models is consistent with that for the experiments in the previous section. This suggests that the relationship between trolls and media goes both ways, and thus we can use labels for media as a way to label users, and we can also use labels for troll users as a way to label media.

7 Conclusion and Future Work

We have proposed a novel approach to analyze the behavior patterns of political trolls according to their political leaning (*left* vs. *news feed* vs. *right*) using features from social media, i.e., from Twitter. We experimented with two scenarios: (*i*) supervised learning, where labels for trolls are provided, and (*ii*) distant supervision, where such labels are not available, and we rely on more common labels for news outlets cited by the trolls. Technically, we leveraged the community structure and the text of the messages in the online social network of trolls represented as a graph, from which we extracted several types of representations, i.e., embeddings, for the trolls. Our experiments on the "IRA Russian Troll" dataset have shown improvements over the state-of-the-art in the supervised scenario, while providing a compelling case for the distant-supervision scenario, which has not been explored before.[3]

In future work, we plan to apply our methodology to other political events such as *Brexit* as well as to other election campaigns around the world, in connection to which large-scale troll campaigns have been revealed. We further plan experiments with other graph embedding methods, and with other social media. Finally, the relationship between media bias and troll's political role that we have highlighted in this paper is extremely interesting. We have shown how to use it to go from the media-space to the user-space and vice-versa, but so far we have just scratched the surface in terms of understanding of the process that generated these data and its possible applications.

Acknowledgments

This research is part of the Tanbih project,[4] which aims to limit the effect of "fake news", propaganda and media bias by making users aware of what they are reading. The project is developed in collaboration between the Qatar Computing Research Institute, HBKU and the MIT Computer Science and Artificial Intelligence Laboratory.

Towards a Unified End-to-End Approach for Fully Unsupervised Cross-lingual Sentiment Analysis

Abstract

Sentiment analysis in low-resource languages suffers from the lack of training data. Cross-lingual sentiment analysis (CLSA) aims to improve the performance on these languages by leveraging annotated data from other languages. Recent studies have shown that CLSA can be performed in a fully unsupervised manner, without exploiting either target language supervision or cross-lingual supervision. However, these methods rely heavily on unsupervised cross-lingual word embeddings (CLWE), which has been shown to have serious drawbacks on distant language pairs (e.g. English - Japanese). In this paper, we propose an end-to-end CLSA model by leveraging unlabeled data in multiple languages and multiple domains and eliminate the need for unsupervised CLWE. Our model applies to two CLSA settings: the traditional cross-lingual in-domain setting and the more challenging cross-lingual cross-domain setting. We empirically evaluate our approach on the multilingual multi-domain Amazon review dataset. Experimental results show that our model outperforms the baselines by a large margin despite its minimal resource requirement. [1]

1 Introduction

While English sentiment analysis has achieved great success with the help of large-scale annotated corpus, this is not the case for most of languages where only limited data is available. Cross-lingual sentiment analysis (CLSA) tackles this problem by adapting the sentiment resource in a source language to a poor-resource language (the target language).

Current state-of-the-art CLSA methods rely heavily on cross-lingual word embeddings (CLWE) to transfer sentiment information from the source language to the target language. CLWE encodes words from multiple languages in a common space, thus making it possible to share a classifier across languages. Recent studies have shown that CLWE can be obtained in an unsupervised way, i.e., without any cross-lingual resources (Zhang et al., 2017; Conneau et al., 2017; Artetxe et al., 2018). This motivates fully unsupervised CLSA approaches (Chen et al., 2018a) that do not rely on either target language supervision or cross-lingual supervision. These methods generally involve the following steps:

1. Train monolingual embeddings separately on multiple languages using monolingual unlabeled data.

2. Map the monolingual embeddings to a shared space using unsupervised CLWE methods, either adversarial training methods (Conneau et al., 2017) or non-adversarial methods (Artetxe et al., 2018; Xu et al., 2018).

3. Train a sentiment classifier using the annotated corpus in the source language.

However, it has been shown that the quality of unsupervised CLWE is highly sensitive to the choice of language pairs and the comparability of the monolingual data (Søgaard et al., 2018). Therefore, these methods fail when the source language and the target language have very different linguistic structures (e.g. English and Japanese) and require additional cross-lingual supervision (e.g. a small seed dictionary or shared identical strings) in such cases (Chen et al., 2018a).

In this paper, we propose a unified end-to-end framework to perform unsupervised CLSA, bypassing the complex multi-step process and the drawbacks of unsupervised CLWE methods. Instead of mapping monolingual embeddings to a

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 1035–1044
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

shared continuous space, we propose to bridge the language gap by multilingual multi-domain language modeling (i.e., we model the probabilities of sentences from multiple language-domain pairs). The language modeling objective is jointly trained with a classification objective in an end-to-end fashion using the unlabeled data in multiple language-domain pairs and labeled data in a source language-domain pair. Our model applies to two CLSA settings: the traditional cross-lingual in-domain setting and the more challenging cross-lingual cross-domain setting.

The rationale for using unlabeled data in multiple domains is that there may not be a domain shared by all languages in low-resource scenarios. If we want to perform CLSA on two languages that only have resources in two different domains, it is natural to bridge the language gap with another language that have resources on both domains. Even in the case where resources in a specific domain are available for all languages, which is a common assumption made by most CLSA approaches, we show that exploiting unlabeled data in other domains significantly improves performance.

Our contributions are as follows:

1. We propose a unified end-to-end framework to perform CLSA. Our approach is fully unsupervised and does not rely on any form of cross-lingual supervision (even shared identical strings) or target language supervision.

2. We show that cross-lingual language modeling based methods are able to outperform CLWE based methods in the unsupervised setting.

3. Our model can be easily generalized to different CLSA settings. Experiments on the multilingual multi-domain Amazon review dataset show that our method achieves state of the art in both the cross-lingual in-domain setting and the cross-lingual cross-domain setting despite its minimal resource requirement.

2 Related Work

Cross-lingual Sentiment Analysis The most related topic to our work is cross-lingual sentiment analysis. Some CLSA methods rely on machine translation systems (Wan, 2009; Demirtas and Pechenizkiy, 2013; Xiao and Guo, 2012; Zhou et al., 2016a) to provide cross-lingual supervision, making themselves implicitly dependant on large-scale parallel corpus which may not be available for low-resource languages. Wan (2009) apply the co-training algorithm to translated data while other researchers have proposed multi-view learning (Xiao and Guo, 2012).

Another line of CLSA research bridges the language gap using CLWE, which saves the efforts of training a machine translation system thus requires less cross-lingual resources. Some work has proposed to map pretrained monolingual embeddings to a shared space (Barnes et al., 2018) to obtain CLWE while others proposed jointly learning CLWE and a sentiment classifier, allowing the embeddings to encode sentiment information (Zhou et al., 2016b; Xu and Wan, 2017).

Very recently, unsupervised CLSA methods that do not require either cross-lingual supervision or target language supervision have been proposed (Chen et al., 2018b,a). Chen et al. (2018a) transfer sentiment information from multiple source languages by jointly learning language invariant and language specific features. Yet, these unsupervised CLSA methods rely on unsupervised CLWE which builds on the assumption that pretrained monolingual embeddings can be properly aligned. This assumption, however, is not true in low-resource scenarios (Søgaard et al., 2018).

It is worth pointing out that the language-adversarial training model of (Chen et al., 2018b) is able to perform unsupervised CLSA without CLWE. The proposed model consists of a feature extractor, a sentiment classifier and a language discriminator. The feature extractor is trained to fool the discriminator so that the extracted features are language invariant. However, its performance is significantly lower than the variant that uses pretrained CLWE.

While traditional CLSA methods assume that data in both languages is within the same domain (e.g. English hotel reviews for training and Chinese hotel review for testing, we refer to this setting as "cross-lingual in-domain sentiment analysis"), the more challenging cross-lingual cross-domain setting has also been explored. Ziser and Reichart (2018) extend pivot-based monolingual domain adaption methods to the cross-lingual setting. However, their method is not unsupervised and requires expensive cross-lingual resources.

Cross-lingual Language Modeling Our work is also related to cross-lingual language modeling, which is a topic that has been explored by researchers very recently. Lample and Conneau (2019), pretrain a language model with a joint vocabulary on the concatenation of multiple large-scale monolingual corpora and finetune it on labeled data. However, this approach exploits cross-lingual supervision provided by shared sub-word units, which has been shown to improve performance (Lample et al., 2018), and it remains a challenge to efficiently perform cross-lingual transfer without exploiting shared identical strings. In this work, we treat identical words from different languages as different words and thus eliminate any form of cross-lingual supervision.

Wada and Iwata (2018) proposed a similar cross-lingual language modeling architecture for unsupervised word translation. They show that it outperforms mapping based approaches (Artetxe et al., 2018; Lample et al., 2017), but only when a small amount of monolingual data is used. The difference between their model and ours is that we adopt different parameter sharing strategies and consider the correlation between multiple domains.

3 Cross-lingual In-Domain Sentiment Analysis

3.1 Overview

In this section we describe our cross-lingual in-domain sentiment analysis model (CLIDSA). It assumes the training data and test data come from different languages but are within the same domain (e.g. English hotel reviews as training data and Chinese hotel reviews as test data), which is the most common setting of previous CLSA approaches.

Although we use the same set of labeled data as previous CLSA approaches, we adopt a different strategy for utilizing the unlabeled data. Suppose there is a set of languages $\mathcal{L}$ and a set of domains $\mathcal{D}$. Let $\mathcal{P} \subseteq \mathcal{L} \times \mathcal{D}$ denote a set of language-domain pairs. For each language-domain pair $(l, d) \in \mathcal{P}$, we have a set of unlabeled reviews $\mathcal{C}^{l,d}_{mono}$. We also have a annotated sentiment corpus $\mathcal{C}^{l_s,d_s}_{senti}$ in a source language-domain pair (l_s, d_s). Our goal is to predict the sentiment polarity of the examples in a target language-domain pair (l_t, d_t) (note that $d_s = d_t$ in the cross-lingual in-domain setting).

In Section 5 we compare two CLIDSA variants. CLIDSA$_{full}$ exploits unlabeled data from all possible language-domain pairs, i.e., we set $\mathcal{P} = \mathcal{L} \times \mathcal{D}$. However, since most previous CLSA methods do not use multi-domain or multilingual unlabeled data, we create a variant CLIDSA$_{min}$ that requires minimal resources by setting $\mathcal{P} = \{(l_s, d_s), (l_t, d_t)\}$.

A natural way to utilize unlabeled data is to perform the language modeling task. Our CLIDSA model consists of multiple language models for mutiple language-domain pairs, with some of their parameters shared across languages or across domains. It also includes a classifier component which takes the hidden states (produced by the LSTM language model) as input features and predicts the sentiment polarity. We also adopt a language discriminator to force the features to be language invariant. The overall architecture of our model is illustrated in Figure 1. We detail each component of our CLIDSA model in the following subsections.

3.2 Multilingual Multi-Domain Language Modeling

Language modeling is the most critical part in our model since it acts as a language invariant feature extractor. Intuitively, if we share the LSTM layers of language models across languages, these layers are likely to process sentences from different languages in the same space, thus inducing language invariant features. In this subsection we detail our parameter sharing strategies for modeling sentences from multiple language-domain pairs.

Following previous work, we compute the probability of a sentence x by modeling the probability of a word w_k given the previous words:

$$p(x) = \prod_{k=1}^{|x|} p(w_k \mid w_1, \ldots, w_k - 1) \qquad (1)$$

For sentences in a certain language-domain pair (l, d), the probabilities are computed using a two-layer LSTM language model, which includes an embedding layer, two LSTM layers and a linear decoding layer. We first pass the input words through the embedding layer of language l which is parameterized by θ^l_{emb}. Then we forward the word embeddings to a LSTM layer parameterized by θ_{lstm1}, which is shared across all languages and all domains, generating a sequence of intermediate

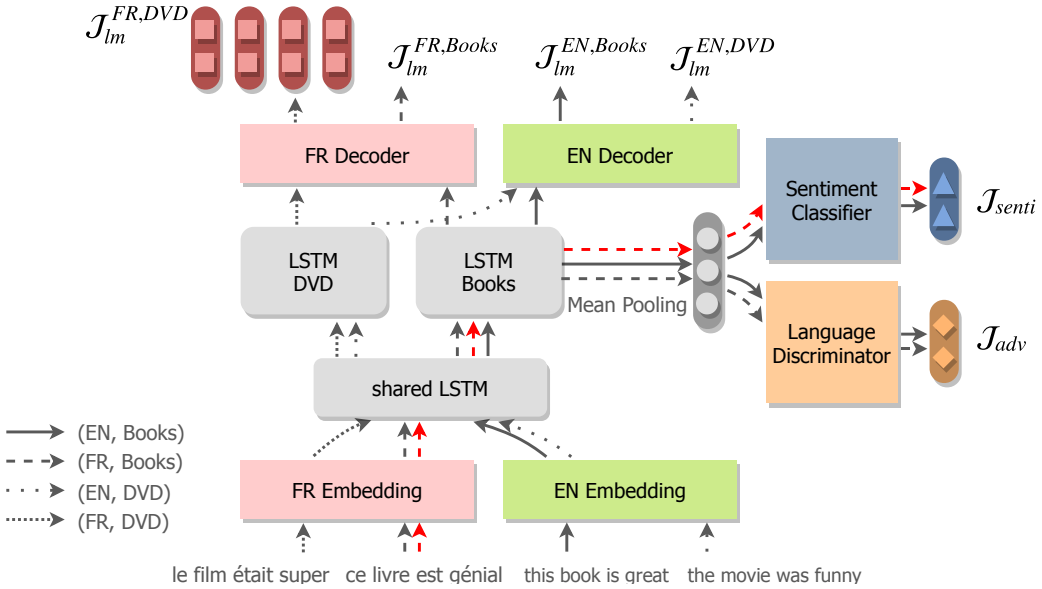

Figure 1: Illustration of the CLIDSA model. In this example, $\mathcal{L} = \{\text{EN}, \text{FR}\}$, $\mathcal{D} = \{\text{Books}, \text{DVD}\}$, $\mathcal{P} = \mathcal{L} \times \mathcal{D}$, $l_s = \text{EN}$, $l_t = \text{FR}$ and $d_s = d_t = \text{Books}$. We visualize the forward pass of input sentences from different language-domain pairs. The path shown in red only occurs at test time.

hidden states:

$$h_k = \text{LSTM}(h_{k-1}, \vec{w}_k; \theta_{lstm1}) \tag{2}$$

where $\vec{w}_k$ denotes the embedding of word w_k. These hidden states are then passed through the second LSTM layer which is domain specific but language invariant, generating a sequence of final hidden states:

$$z_k = \text{LSTM}(z_{k-1}, h_k; \theta^d_{lstm2}) \tag{3}$$

where the second LSTM layer of domain d is parameterized by θ^d_{lstm2}. The final hidden states $(z_1, z_2, \ldots, z_{|x|})$ thus can be considered as language invariant features for cross-lingual classification.

For the purpose of language modeling, we adopt a language-specific linear decoding layer to transform the final hidden states into probability distributions for next word prediction. The decoding layer of language l is parameterized by θ^l_{dec} and is shared across domains.

The intuition of adopting a domain-specific LSTM layer is that the distribution of sentences varies across domains. For example, given the first three words "I love this", the next word is most likely to be "book" in a book review dataset or "movie" in a movie review dataset. While it is possible to address this issue by using domain-specific linear decoding layers, we find that sharing the decoders across domains substantially reduces the total number of parameters thus provides regularization when only limited resources are available (see Section 5.5 for the ablation study). Sharing the decoders further enables the weight tying technique (Inan et al., 2016) to tie the decoder weight with the embedding layer.

For language-domain pair (l, d), the language modeling objective is written as follows:

$$\mathcal{J}^{l,d}_{lm}(\theta^l_{emb}, \theta_{lstm1}, \theta^d_{lstm2}, \theta^l_{dec}) = \mathbb{E}_{x \sim \mathcal{C}^{l,d}_{mono}} \left[-\frac{1}{|x|} \sum_{k=1}^{|x|} \log p(w_k \mid w_1, \ldots, w_{k-1}) \right] \tag{4}$$

where the sentence likelihood is normalized by the sentence length and $x \sim \mathcal{C}^{l,d}_{mono}$ indicates that x is sampled from the unlabeled text in $\mathcal{C}^{l,d}_{mono}$.

3.3 Sentiment Classifier

We adopt a simple linear classifier that takes the averaged final hidden states $\frac{1}{|x|}\sum_{k=1}^{|x|} z_k$ as input features and outputs the probabilities of different labels. The classification objective can be written as:

$$\mathcal{J}_{senti}(\theta^{l_s}_{emb}, \theta_{lstm1}, \theta^{d_s}_{lstm2}, \theta_{clf}) = \mathbb{E}_{(x,y) \sim \mathcal{C}^{l_s,d_s}_{senti}} \big[-\log p(y \mid x) \big] \tag{5}$$

where $(x, y) \sim \mathcal{C}^{l_s,d_s}_{senti}$ indicates that the sentence x and its label y are sampled from the source sen-

timent corpus and θ_{clf} denotes the parameters of the linear classifier.

The classification objective is jointly minimized with the language modeling objective, allowing sentiment-specific supervision signals to back-propagate through the model so that it can learn to extract useful features for sentiment prediction.

3.4 Language Adversarial Training

To further force the features used for sentiment classification to be language invariant, we adopt the language adversarial training technique (Chen et al., 2018b). A language discriminator is trained to predict the language ID given the features by minimizing the cross entropy loss, while the LSTM network is trained to fool the discriminator by maximizing the loss:

$$\mathcal{J}_{adv}(\theta_{emb}, \theta_{lstm1}, \theta^{d_s}_{lstm2}, \theta_{dis}) = \mathbb{E}_{(x,l)}[-\log p(l \mid x)] \quad (6)$$

where $\theta_{emb} = \theta^1_{emb} \oplus \cdots \oplus \theta^{|\mathcal{L}|}_{emb}$ denotes the parameters of all the embedding layers and θ_{dis} denotes the parameters of the language discriminator. The sentence x and the language id l are sampled from all the unlabeled data in domain $d_s = d_t$. We do not employ language adversarial training on the features of other domain since we only perform classification in a single domain.

3.5 The Full Objective Function

Putting all the components together, the final objective function is thus:

$$\mathcal{J}_{full}(\theta_{emb}, \theta_{lstm}, \theta_{dec}, \theta_{clf}, \theta_{dis}) = \sum_{(l,d)\in\mathcal{P}} \mathcal{J}^{l,d}_{lm} + \alpha\mathcal{J}_{senti} - \beta\mathcal{J}_{adv} \quad (7)$$

where $\theta_{lstm} = \theta_{lstm1} \oplus \theta^1_{lstm2} \oplus \cdots \oplus \theta^{|\mathcal{D}|}_{lstm2}$ denotes the parameters of all the LSTM layers, $\theta_{dec} = \theta^1_{dec} \oplus \cdots \oplus \theta^{|\mathcal{L}|}_{dec}$ denotes the parameters of all the decoding layers, α and β are the hyper-parameters controlling the importance of the classification objective and the language adversarial training objective. Parameters θ_{dis} are trained to maximize this objective function while the others are trained to minimize it:

$$\hat{\theta}_{dis} = \arg\max_{\theta_{dis}} \mathcal{J}_{full} \quad (8)$$

$$(\hat{\theta}_{emb}, \hat{\theta}_{lstm}, \hat{\theta}_{dec}, \hat{\theta}_{clf}) = \arg\min_{\theta_{emb},\theta_{lstm},\theta_{dec},\theta_{clf}} \mathcal{J}_{full} \quad (9)$$

4 Cross-lingual Cross-Domain Sentiment Analysis

In this section we focus on a more challenging CLSA setting, where the training data and test data are from different languages and different domain (e.g. English hotel reviews as training data, Chinese book reviews as test data). We show that the CLIDSA model can be applied to this setting with only slight modification.

Following previous notations, we denote the source language-domain pair as (l_s, d_s) and the target language pair as (l_t, d_t) with $l_s \neq l_t$ and $d_s \neq d_t$. Ziser and Reichart (2018) rely on expensive resources to perform cross-lingual cross-domain transfer, including unlabeled data from (l_s, d_s) and (l_t, d_t), CLWE and machine translation. In this work, we also use the unlabeled data from (l_s, d_s) and (l_t, d_t). However, instead of relying on CLWE and machine translation, we propose to leverage the unlabeled data in a "pivot" pair (l_s, d_t) to bridge the language-domain gap. This is reasonable since source languages are those with rich resources and we do not use additional annotation. Formally, we have a set of unlabeled reviews for each language-domain pair in $\mathcal{P} = \{(l_s, d_s), (l_s, d_t), (l_t, d_t)\}$ and a set of labeled reviews from (l_s, d_s).

In the CLIDSA model, inputs from (l_t, d_t) do not go through the source-domain LSTM layer (parameterized by $\theta^{l_s}_{lstm2}$), thus can not be forwarded to the sentiment classifier for sentiment prediction. Nevertheless, we now show that we can directly apply the CLIDSA model to this setting by slightly altering the forward pass of (l_t, d_t). Figure 2 illustrates our CLCDSA model for cross-lingual cross-domain sentiment analysis. The architecture of CLCDSA is identical to CLIDSA (i.e. parameterized by the same set of parameters), but the data forwarding process is slightly different. The key idea is simple: instead of viewing the sentiment classifier as a linear classifier that takes the domain-specific final hidden states $z_1, z_2, \ldots, z_{|x|}$ as input features, we consider the source-domain LSTM layer and the linear classifier together as a "LSTM+Linear" classifier (parameterized by $\theta^{d_s}_{lstm2} \oplus \theta_{clf}$) that takes the domain invariant and language invariant hidden states $h_1, h_2, \ldots, h_{|x|}$ as input features. From

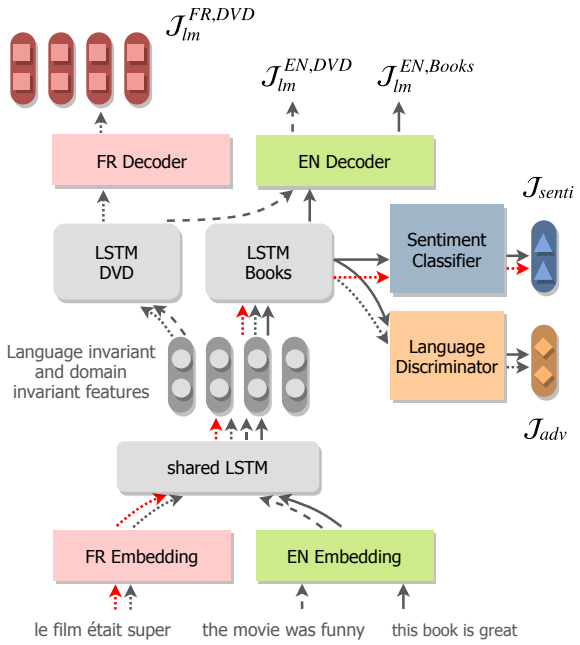

Figure 2: Illustration of the CLCDSA model. In this example, $(l_s, d_s) = (\text{EN}, \text{Books})$ and $(l_t, d_t) = (\text{FR}, \text{DVD})$. The architecture of CLCDSA is identical to CLIDSA, but the data forwarding process is different. We visualize the forward pass of input sentences from different language-domain pairs. The path shown in red only occurs at test time.

this point of view, we can pass the first-layer hidden states to the source-domain LSTM layer and the sentiment classifier to obtain the sentiment prediction at test time.

At training time, the first-layer hidden states generated from a target sentence are forwarded to the source-domain LSTM layer ($\theta_{lstm2}^{d_s}$) and the language discriminator (θ_{dis}) to compute the adversarial loss. The LSTM layers are trained to fool the language discriminator so that it cannot distinguish the examples in (l_s, d_s) from those in (l_t, d_t). We jointly optimize three language modeling objectives for each language-domain pair, the adversarial objective, and a sentiment classification objective for (l_s, d_s).

5 Experiments

5.1 Datasets

We evaluate our model on the multilingual multi-domain Amazon review dataset (Prettenhofer and Stein, 2010) which contains product reviews in four languages (English, French, German, Japanese) and three domains (Books, DVD, Music). For each language-domain pair, there are 2000 examples for training and 2000 examples for testing. The statistics of unlabeled data is summarized in Table 1. For cross-lingual in-domain sentiment analysis, we use English as the source language and the others as target languages, resulting in nine tasks in total. For cross-lingual cross-domain sentiment analysis, we follow the setting in (Ziser and Reichart, 2018) and use English as the source language, French and German as target languages, and consider all the domain combinations, resulting in twelve tasks in total. Note that we would also want to evaluate our model on some low resource languages. However, since there isn't an public benchmark for such languages, we leave it to future work.

5.2 Implementation Details

Most of the hyperparamters are set empirically without tuning. For language modeling, we adopt the AWD-LSTM language model (Merity et al., 2017) with 1150 hidden units and a weight dropout rate of 0.5. We refer readers to (Merity et al., 2017) for a more detailed description. The sentiment classifier is a linear classifier with a dropout rate of 0.6. The language discriminator is a three-layer MLP with 400 hidden units.

As the only exceptions, hyperparameters α and β are tuned on the target development set following standard CLSA practice. We set (α, β) to $(0.01, 0.1)$ for CLIDSA$_{full}$ and CLCDSA, $(0.01, 0.03)$ for CLIDSA$_{min}$ in all tasks and do not perform any task-specific tuning.

The Adam optimizer (Kingma and Ba, 2014) with a base learning rate of 0.003 and $\beta_1 = 0.7$ is used for training. In each iteration, we sample a batch from every language-domain pairs in $\mathcal{P}$ to compute the language modeling loss and discriminator loss. Then we sample a batch from the source annotated corpus to compute the sentiment classification loss. All the parameters are jointly updated using the Gradient Reversal Layer (Ganin et al., 2016) and standard backpropagation. We

run 50000 iterations for CLIDSA and 30000 iterations for CLCDSA without early stopping.

5.3 Baselines

We compare our model to the following CLSA baselines, including methods that require cross-lingual resources (either in the form of machine translation or parallel data), methods that rely on unsupervised CLWE, and a few variants of our proposed model. **PBLM-BE** is a cross-lingual cross-domain model, **MWE** applies to both settings, while others are cross-lingual in-domain methods.

CL-SCL Prettenhofer and Stein (2010) map the bag-of-word representations to a cross-lingual space via structural correspondence learning.

BiDRL Zhou et al. (2016b) learn bilingual document representation for CLSA. The authors translate each document into both languages and enforce a bilingual constraint between the original document and the translated version.

UMM Xu and Wan (2017) jointly learn multilingual word embeddings and a sentiment classifier using parallel corpora of multiple language pairs. Languages that do not have direct parallel corpus are bridged via a third pivot language.

CLDFA Xu and Yang (2017) propose cross-lingual distillation using translated reviews.

MAN-MoE Chen et al. (2018a) propose the state-of-the-art unsupervised CLSA model that learns language invariant features and language specific features. It relies on unsupervised CLWE for cross-lingual transfer. Unlike other CLSA approaches, it transfers the sentiment information from multiple source languages.

MWE This is a variant of our proposed model that relies on unsupervised CLWE instead of language modeling. We map all target language embeddings to the English space using the MUSE library (Conneau et al., 2017) and use them to initialize the embedding layers. We train the sentiment classifier using the labeled data in the source language-domain pair and directly apply it to the test data. The same architecture is used but we only optimize the classification objective.

PBLM-BE Ziser and Reichart (2018) extend existing pivot-based domain adaption approaches to the cross-lingual settings using CLWE and machine translation.

5.4 Results and Analysis

Cross-lingual In-Domain Results Table 2 presents the performance of different CLSA methods on various cross-lingual in-domain tasks. Our proposed model achieves new state of the art on all nine tasks. Even in the restricted setting where only minimal resources are used (no cross-lingual resources, no pretrained embeddings, no multilingual multi-domain unlabeled data), CLIDSA$_{min}$ outperforms the strongest baseline on four out of nine tasks, validating the efficacy of our proposed model. Exploiting multilingual multi-domain unlabeled data leads to an average improvement of $+4.27\%$ across all tasks. We

also find that it is most beneficial to sentiment analysis on distant language pairs, with an average improvement of $+8.85\%$ on EN-JA.

Among methods that do not require cross-lingual resources, CLWE based methods are lower than the proposed cross-lingual language modeling based methods. This is interesting because it has been shown in previous work (Wada and Iwata, 2018) that cross-lingual language modeling does not perform well on the word translation task when sufficient monolingual data is available. Nevertheless, we demonstrate that this is not the case for cross-lingual sentiment analysis.

Cross-lingual Cross-Domain Results Table 3 shows the results of various cross-lingual cross-domain tasks. MWE suffers greatly from domain discrepancy compared to the in-domain results. Nevertheless, our model outperforms all baselines on all tasks, with an average improvement of $+5\%$ across all tasks.

5.5 Ablation Study

We perform an ablation study to investigate the contribution of individual components. The results are summarized in Table 4. We first create a variant that does not share the decoding layers across domain, and another one that does not share the first LSTM layer across domain. Disabling parameter sharing hurts the performance most on EN-JA (-1.75%). We also observed that the performance gap is much more significant when less training data is used (not shown here).

Surprisingly, removing the language discriminator does not lead to significant performance drop, which indicates that the language modeling alone is able to produce language invariant features. Intuitively, parameter sharing would force the LSTM layers to process sentences from different languages in the same space, thus inducing cross-lingual feature representation. Note that we also try removing the language modeling objective and rely on language adversarial training to provide cross-lingual features, but find that the resulting performance is rather poor.

Finally, we explore a different training strategy where the sentiment classifier is not jointly trained with the other components. Instead, we use the labeled data to train the classifier only after we have trained the other components on the unlabeled data. We observe that the resulting performance drop is due to underfitting, i.e., the extracted features do not encode enough information for sentiment prediction. This highlights the importance of end-to-end training.

6 Conclusion and Future Work

In this work we present an end-to-end approach for cross-lingual sentiment analysis. Our method is fully unsupervised thus does not rely on any cross-lingual supervision and target language supervision. We rely on language modeling to provide language invariant feature representations. We propose two model variants, one for cross-lingual in-domain transfer and the other for cross-lingual cross-domain transfer. Both models achieve state of the art on the Amazon review dataset. Experimental results also show that exploiting multilingual multi-domain unlabeled data greatly benefits CLSA on distant language pairs.

There are several straight-forward extensions

of our model: cross-lingual in-domain sentiment analysis with multiple source languages, cross-lingual cross-domain sentiment analysis with multiple target languages, etc. We leave the exploration of these extensions to future work.

Acknowledgment

This work was supported by National Natural Science Foundation of China (61772036) and Key Laboratory of Science, Technology and Standard in Press Industry (Key Laboratory of Intelligent Press Media Technology). We appreciate the anonymous reviewers for their helpful comments. Xiaojun Wan is the corresponding author.
