Introduction

The 2019 Conference on Computational Natural Language Learning (CoNLL) is the 23rd in the series of annual meetings organized by SIGNLL, the ACL special interest group on natural language learning. CoNLL 2019 will be held on November 3–4, 2019, and is co-located with the 2019 Conference on Empirical Methods in Natural Language Processing (EMNLP) in Hong Kong.

CoNLL 2019 followed the tradition of previous CoNLL conferences in inviting only long papers, in order to accommodate papers with experimental material and detailed analysis. The final, camera-ready submissions were allowed a maximum of nine content pages plus unlimited pages of references and supplementary material.

CoNLL 2019 received a record number of 485 submissions in total, out of which 97 papers were chosen to appear in the conference program (after desk-rejections and a few papers withdrawn by the authors during the review period), with an overall acceptance rate of 22%. 27 were selected for oral presentation, and the remaining 70 for poster presentation. All 97 papers appear as long papers here in the conference proceedings.

CoNLL 2019 features two invited speakers, Christopher Manning (Stanford University) and Gabriella Vigliocco (University College London). As in recent years, it also features one shared task: Cross-Framework Meaning Representation Parsing. Papers accepted for the shared tasks are published in companion volumes of the CoNLL 2019 proceedings.

We would like to thank all the authors who submitted their work to CoNLL 2019, and the program committee for helping us select the best papers out of many high-quality submissions. We are grateful to the many program committee members who did a thorough job reviewing our submissions. Due to the growing size of of the conference, we also had area chairs, for the second time, supporting the CoNLL organization. We were fortunate to have 24 excellent areas chairs who assisted us greatly in selecting the best program:

Jason Baldridge, Google AI Language, USA;
Laurent Besacier, Université Grenoble Alpes, France;
Chris Biemann, Universität Hamburg, Germany;
Asli Celikyilmaz, Microsoft Research, USA;
Snigdha Chaturvedi, UCSC, USA;
Grzegorz Chrupala, Tilburg University, The Netherlands;
Mathieu Constant, Université de Lorraine, France;
Ryan Cotterell, University of Cambridge, UK;
Dipanjan Das, Google AI Language, USA;
Greg Durrett, UT Austin, USA;
Manaal Faruqui, Google Assistant, USA;
Michel Galley, Microsoft Research, USA;
Manuel Montes y Gómez, INAOE, Mexico;
Dilek Hakkani-Tur, Amazon Alexa AI, USA;
Mohit Iyyer, UMass Amherst, USA;
Yangfeng Ji, University of Virginia, USA;
Preethi Jyothi, IIT Bombay, India;
Douwe Kiela, Facebook Research, USA;
Graham Neubig, CMU, USA;
Horacio Saggion, Universitat Pompeu Fabra, Spain;
Avirup Sil, IBM Research AI, USA;
Amanda Stent, Bloomberg Research, USA;

Mark Stevenson, University of Sheffield, UK;
Andreas Vlachos, University of Cambridge, UK.

We are immensely thankful to Julia Hockenmaier and to the members of the SIGNLL board for their valuable advice and assistance in putting together this year's program. We also thank Pieter Fivez and Marcely Zanon Boito for maintaining the CoNLL 2019 website, and Sebastian Ruder and Miikka Silfverberg for preparing the proceedings for the main conference. We would like to thank our hard working assistants Darryl Hannan, Ramakanth Pasunuru and Reyhaneh Hashempour for their support with data checking and publicity. Our heartfelt gratitude also goes to Rodrigo Wilkens for system administration and general START management.

Our thanks to the program co-chairs of CoNLL 2018, Anna Korhonen and Ivan Titov, who provided us with excellent advice and help; to Vera Demberg, Naoaki Okazaki, Priscilla Rasmussen and the EMNLP 2019 Organization Committee for their helpful advice on issues involving the conference venue and local organization.

We would also like to thank the following reviewers who were nominated for commendation: Peter Anderson; Awais Athar; Niranjan Balasubramanian; Joost Bastings; Lisa Beinborn; Robert Berwick; Xavier Carreras; Elizabeth Clark; Pablo Duboue; Asif Ekbal; Zhe Gan; Dan Garrette; Sebastian Gehrmann; Kevin Gimpel; Carlos Gomez-Rodriguez; William L. Hamilton; David Harwath; Jack Hessel; Jonathan K. Kummerfeld; Miryam de Lhoneux; Nelson F. Liu; Ryan McDonald; Einat Minkov; Preslav Nakov; Jason Naradowsky; Khanh Nguyen; Vlad Niculae; Brendan O'Connor; Niki Parmar; Rebecca J. Passonneau; Iria del Rio Gayo; Kenji Sagae; Marten van Schijndel; Kevin Small; Kristina Striegnitz; James Thorne; Diyi Yang.

Finally, our gratitude goes to our sponsors, Facebook and Google, for supporting the conference financially.

We hope you enjoy the conference!

Aline Villavicencio and Mohit Bansal
CoNLL 2019 conference co-chairs

Conference Chairs:

Mohit Bansal, University of North Carolina at Chapel Hill, USA
Aline Villavicencio, University of Sheffield, UK and Federal University of Rio Grande do Sul, Brazil

Invited speakers:

Christopher Manning, Stanford University, USA
Gabriella Vigliocco, University College London, UK

Area Chairs:

Jason Baldridge, Google AI Language, USA
Laurent Besacier, Université Grenoble Alpes, France
Chris Biemann, Universität Hamburg, Germany
Asli Celikyilmaz, Microsoft Research, USA
Snigdha Chaturvedi, UCSC, USA
Grzegorz Chrupala, Tilburg University, The Netherlands
Mathieu Constant, Université de Lorraine, France
Ryan Cotterell, University of Cambridge, UK
Dipanjan Das, Google AI Language, USA
Greg Durrett, UT Austin, USA
Manaal Faruqui, Google Assistant, USA
Michel Galley, Microsoft Research, USA
Manuel Montes y Gómez, INAOE, Mexico
Dilek Hakkani-Tur, Amazon Alexa AI, USA
Mohit Iyyer, UMass Amherst, USA
Yangfeng Ji, University of Virginia, USA
Preethi Jyothi, IIT Bombay, India
Douwe Kiela, Facebook Research, USA
Graham Neubig, CMU, USA
Horacio Saggion, Universitat Pompeu Fabra, Spain
Avirup Sil, IBM Research AI, USA
Amanda Stent, Bloomberg Research, USA
Mark Stevenson, University of Sheffield, UK
Andreas Vlachos, University of Cambridge, UK

Publication Chairs:

Sebastian Ruder, National University of Ireland and Aylien Ltd. Dublin, Ireland
Miikka Silfverberg, University of Helsinki, Finland

Administration Chair:

Rodrigo Wilkens, University of Strasbourg, France

Supervision Chairs:

Darryl Hannan, University of North Carolina at Chapel Hill, USA
Reyhaneh Hashempour, University of Essex, UK

Publicity/Sponsorship Chair:

Ramakanth Pasunuru, University of North Carolina at Chapel Hill, USA

Website Chairs:

Marcely Zanon Boito, Université Grenoble Alpes, France
Pieter Fivez, University of Antwerp, Belgium

Program Committee:

Omri Abend, Ahmed AbuRa'ed, Pablo Accuosto, Heike Adel, Rodrigo Agerri, Eljko Agi, Aishwarya Agrawal, Roee Aharoni, Alan Akbik, Nader Akoury, Chris Alberti, Amal Alharbi, Afra Alishahi, Peter Anderson, Gabor Angeli, Saba Anwar, Marianna Apidianaki, Yuki Arase, Awais Athar, Fan Bai, Simon Baker, Niranjan Balasubramanian, Timothy Baldwin, Miguel Ballesteros, Colin Bannard, Francesco Barbieri, Leslie Barrett, Alberto Barrn-Cedeo, Fabian Barteld, Roberto Basili, Joost Bastings, David Batista, Timo Baumann, Barend Beekhuizen, Lisa Beinborn, Nria Bel, Jonathan Berant, Robert Berwick, Archna Bhatia, Pushpak Bhattacharyya, Lidong Bing, Philippe Blache, Eduardo Blanco, Bernd Bohnet, Danushka Bollegala, Kalina Bontcheva, Stefan Bott, Samuel R. Bowman, Faeze Brahman, Antnio Branco, Chlo Braud, lex Bravo, Chris Brockett, Elia Bruni, Harry Bunt, Davide Buscaldi, Jan Buys, Jose Camacho-Collados, Ricardo Campos, Cristian Cardellino, Xavier Carreras, Helena Caseli, Giovanni Cassani, Thiago Castro Ferreira, Asli Celikyilmaz, Daniel Cer, Muthu Kumar Chandrasekaran, Ming-Wei Chang, Yun-Nung Chen, Boxing Chen, Xinchi Chen, Hanjie Chen, Emmanuele Chersoni, Niyati Chhaya, Monojit Choudhury, George Chrysostomou, Volkan Cirik, Alexander Clark, Stephen Clark, Elizabeth Clark, Trevor Cohn, Guillem Collell, Danish Contractor, Paul Cook, Caio Corro, Marta R. Costajuss, Francisco M Couto, Raj Dabre, Walter Daelemans, Forrest Davis, Miryam de Lhoneux, Iria del Ro Gayo, Vera Demberg, Thomas Demeester, Nina Dethlefs, Daniel Deutsch, Jacob Devlin, Maria Pia di Buono, Shuoyang Ding, Simon Dobnik, Jesse Dodge, Lucia Donatelli, Li Dong, Zi-Yi Dou, Gabriel Doyle, Maximillian Droog-Hayes, Xinya Du, Pablo Duboue, Kevin Duh, Jonathan Dunn, Nadir Durrani, Richard Eckart de Castilho, Thomas Efer, Yo Ehara, Asif Ekbal, Ahmed El Kholy, Desmond Elliott, Micha Elsner, Chris Emmery, Erkut Erdem, Aykut Erdem, Akiko Eriguchi, Hugo Jair Escalante, Luis Espinosa Anke, Richard Evans, Benjamin Fagard, Stefano Faralli, Maryam Fazel-Zarandi, Christian Federmann, Yansong Feng, Raquel Fernndez, Orhan Firat, Andrea K. Passonneau, Ramakanth Pasunuru, Panupong Pasupat, Roma Patel, Amandalynne Paullada, Lisa Pearl, Anselmo Peas, Hao Peng, Nanyun Peng, Ethan Perez, Sandro Pezzelle, Janet Pierrehumbert, Mohammad Taher Pilehvar, Yuval Pinter, Lidia Pivovarova, Thierry Poibeau, Maja Popovi, Matt Post, Christopher Potts, Bruno Pouliquen, Vahed Qazvinian, Paulo Quaresma, Ella Rabinovich, Daniele P. Radicioni, Preethi Raghavan, Afshin Rahimi, Taraka Rama, Rohan Ramanath, Carlos Ramisch, Sudha Rao, Ari Rappoport, Mohammad Sadegh Rasooli, Sagnik Ray Choudhury, Andreas Rckl, Marek Rei, Roi Reichart, Steffen Remus, Xiang Ren, Horacio Rodriguez, Laurent Romary, Francesco Ronzano, Aiala Ros, Paolo Rosso, Michael Roth, Salim Roukos, Tania Roy, Subhro Roy, Alla Rozovskaya, Mrinmaya Sachan, Devendra Sachan, Mehrnoosh Sadrzadeh, Kenji Sagae, Diarmuid Saghdha, Magnus Sahlgren, Hassan Sajjad, Keisuke Sakaguchi, Sakriani Sakti, Rajhans Samdani, Ivan Sanchez, Carolina Scarton, Natalie Schluter, Nathan Schneider, Steven Schockaert, Djam Seddah, Marco Silvio Giuseppe Senaldi, zge Sevgili, Amr Sharaf, Dinghan Shen, Wei Shi, Alexander Shvets, Carina Silberer, Miikka Silfverberg, Jonathan Simon, Kevin Small, Artem Sokolov, Lucia Specia, Vivek Srikumar, Shashank Srivastava, Efstathios Stamatatos, Milo Stanojevi, Gabriel Stanovsky, Egon Stemle, Suzanne Stevenson, Karl Stratos, Kristina Striegnitz, Pei-Hao Su, Shivashankar Subramanian, Alane Suhr, Anas Tack, Jiwei Tan, Christoph Teichmann, Ian Tenney, Jesse Thomason, James Thorne, Ran Tian, Amalia Todirascu, Gaurav Singh Tomar, Juan-Manuel Torres-Moreno, Harsh Trivedi, Gokhan Tur, Shyam Upadhyay, Tim Van de Cruys, Marten van Schijndel, Lucy Vanderwende, Shikhar Vashishth, Ramakrishna Vedantam, Yannick Versley, Supriya Vijay, David Vilar, Esau Villatoro-Tello, Marta Villegas, Tatiana Vodolazova, Tu Vu, Ivan Vuli, Xin Wang, Miaosen Wang, Leo Wanner, Taro Watanabe, Austin Waters, Noah Weber, Kellie Webster, Michael Wiegand, John Wieting, Gijs Wijnholds, Rodrigo Wilkens, Steven Wilson, Sam Wiseman, Vinicius Woloszyn, Dekai Wu, Kun Xu, Yang Xu, Yadollah Yaghoobzadeh, Mohamed Yahya, Rui Yan, Jie Yang, Diyi Yang, Weiwei Yang, Roman Yangarber, Ziyu Yao, Semih Yavuz, Seid Yimam, Wenpeng Yin, Zhou Yu, Licheng Yu, Franois Yvon, Roberto Zamparelli, Marcos Zampieri, Neil Zeghidour, Luke Zettlemoyer, Feifei Zhai, Yuan Zhang, Xingxing Zhang, Zhisong Zhang, Yizhe Zhang, Yue Zhang, Wei Zhao, Tiancheng Zhao, Kai Zhao, Chao Zhao, Steven Zimmerman, Heike Zinsmeister, Michael Zock, Chengqing Zong, Shi Zong, and Willem Zuidema.

Table of Contents

Invited Talk I: Ecological Language: A Multimodal Approach to the Study of Human Language Learning and Processing
Gabriella Vigliocco xxvi

Invited Talk II: Multi-Step Reasoning for Answering Complex Questions
Christopher Manning xxvii

Analysing Neural Language Models: Contextual Decomposition Reveals Default Reasoning in Number and Gender Assignment
Jaap Jumelet, Willem Zuidema and Dieuwke Hupkes 1

Deconstructing Supertagging into Multi-Task Sequence Prediction
Zhenqi Zhu and Anoop Sarkar 12

Multilingual Model Using Cross-Task Embedding Projection
Jin Sakuma and Naoki Yoshinaga 22

Investigating Cross-Lingual Alignment Methods for Contextualized Embeddings with Token-Level Evaluation
Qianchu Liu, Diana McCarthy, Ivan Vulić and Anna Korhonen 33

Large-Scale, Diverse, Paraphrastic Bitexts via Sampling and Clustering
J. Edward Hu, Abhinav Singh, Nils Holzenberger, Matt Post and Benjamin Van Durme 44

Large-Scale Representation Learning from Visually Grounded Untranscribed Speech
Gabriel Ilharco, Yuan Zhang and Jason Baldridge 55

Using Priming to Uncover the Organization of Syntactic Representations in Neural Language Models
Grusha Prasad, Marten van Schijndel and Tal Linzen 66

Say Anything: Automatic Semantic Infelicity Detection in L2 English Indefinite Pronouns
Ella Rabinovich, Julia Watson, Barend Beekhuizen and Suzanne Stevenson 77

Compositional Generalization in Image Captioning
Mitja Nikolaus, Mostafa Abdou, Matthew Lamm, Rahul Aralikatte and Desmond Elliott 87

Representing Movie Characters in Dialogues
Mahmoud Azab, Noriyuki Kojima, Jia Deng and Rada Mihalcea 99

Cross-Lingual Word Embeddings and the Structure of the Human Bilingual Lexicon
Paola Merlo and Maria Andueza Rodriguez 110

Federated Learning of N-Gram Language Models
Mingqing Chen, Ananda Theertha Suresh, Rajiv Mathews, Adeline Wong, Cyril Allauzen, Françoise Beaufays and Michael Riley 121

Learning Conceptual Spaces with Disentangled Facets
Rana Alshaikh, Zied Bouraoui and Steven Schockaert 131

Weird Inflects but OK: Making Sense of Morphological Generation Errors
Kyle Gorman, Arya D. McCarthy, Ryan Cotterell, Ekaterina Vylomova, Miikka Silfverberg and Magdalena Markowska 140

Learning to Represent Bilingual Dictionaries
Muhao Chen, Yingtao Tian, Haochen Chen, Kai-Wei Chang, Steven Skiena and Carlo Zaniolo 152

Improving Natural Language Understanding by Reverse Mapping Bytepair Encoding
Chaodong Tong, Huailiang Peng, Qiong Dai, Lei Jiang and Jianghua Huang 163

Made for Each Other: Broad-Coverage Semantic Structures Meet Preposition Supersenses
Jakob Prange, Nathan Schneider and Omri Abend 174

Generating Timelines by Modeling Semantic Change
Guy D. Rosin and Kira Radinsky 186

Diversify Your Datasets: Analyzing Generalization via Controlled Variance in Adversarial Datasets
Ohad Rozen, Vered Shwartz, Roee Aharoni and Ido Dagan 196

Fully Unsupervised Crosslingual Semantic Textual Similarity Metric Based on BERT for Identifying Parallel Data
Chi-kiu Lo and Michel Simard 206

On the Importance of Subword Information for Morphological Tasks in Truly Low-Resource Languages
Yi Zhu, Benjamin Heinzerling, Ivan Vulić, Michael Strube, Roi Reichart and Anna Korhonen . 216

Comparing Top-Down and Bottom-Up Neural Generative Dependency Models
Austin Matthews, Graham Neubig and Chris Dyer 227

Representation Learning and Dynamic Programming for Arc-Hybrid Parsing
Joseph Le Roux, Antoine Rozenknop and Mathieu Lacroix 238

Policy Preference Detection in Parliamentary Debate Motions
Gavin Abercrombie, Federico Nanni, Riza Batista-Navarro and Simone Paolo Ponzetto 249

Improving Neural Machine Translation by Achieving Knowledge Transfer with Sentence Alignment Learning
Xuewen Shi, Heyan Huang, Wenguan Wang, Ping Jian and Yi-Kun Tang 260

Code-Switched Language Models Using Neural Based Synthetic Data from Parallel Sentences
Genta Indra Winata, Andrea Madotto, Chien-Sheng Wu and Pascale Fung 271

Unsupervised Neural Machine Translation with Future Rewarding
Xiangpeng Wei, Yue Hu, Luxi Xing and Li Gao 281

Automatically Extracting Challenge Sets for Non-Local Phenomena in Neural Machine Translation
Leshem Choshen and Omri Abend 291

Low-Resource Parsing with Crosslingual Contextualized Representations
Phoebe Mulcaire, Jungo Kasai and Noah A. Smith 304

Improving Pre-Trained Multilingual Model with Vocabulary Expansion
Hai Wang, Dian Yu, Kai Sun, Jianshu Chen and Dong Yu 316

On the Relation between Position Information and Sentence Length in Neural Machine Translation
Masato Neishi and Naoki Yoshinaga 328

Word Recognition, Competition, and Activation in a Model of Visually Grounded Speech
William N. Havard, Jean-Pierre Chevrot and Laurent Besacier 339

EQUATE: A Benchmark Evaluation Framework for Quantitative Reasoning in Natural Language Inference
Abhilasha Ravichander, Aakanksha Naik, Carolyn Rose and Eduard Hovy 349

Linguistic Analysis Improves Neural Metaphor Detection
Kevin Stowe, Sarah Moeller, Laura Michaelis and Martha Palmer 362

Cross-Lingual Dependency Parsing with Unlabeled Auxiliary Languages
Wasi Uddin Ahmad, Zhisong Zhang, Xuezhe Ma, Kai-Wei Chang and Nanyun Peng 372

A Dual-Attention Hierarchical Recurrent Neural Network for Dialogue Act Classification
Ruizhe Li, Chenghua Lin, Matthew Collinson, Xiao Li and Guanyi Chen 383

Mimic and Rephrase: Reflective Listening in Open-Ended Dialogue
Justin Dieter, Tian Wang, Arun Tejasvi Chaganty, Gabor Angeli and Angel X. Chang 393

Automated Pyramid Summarization Evaluation
Yanjun Gao, Chen Sun and Rebecca J. Passonneau 404

A Case Study on Combining ASR and Visual Features for Generating Instructional Video Captions
Jack Hessel, Bo Pang, Zhenhai Zhu and Radu Soricut 419

Leveraging Past References for Robust Language Grounding
Subhro Roy, Michael Noseworthy, Rohan Paul, Daehyung Park and Nicholas Roy 430

Procedural Reasoning Networks for Understanding Multimodal Procedures
Mustafa Sercan Amac, Semih Yagcioglu, Aykut Erdem and Erkut Erdem 441

On the Limits of Learning to Actively Learn Semantic Representations
Omri Koshorek, Gabriel Stanovsky, Yichu Zhou, Vivek Srikumar and Jonathan Berant 452

How Does Grammatical Gender Affect Noun Representations in Gender-Marking Languages?
Hila Gonen, Yova Kementchedjhieva and Yoav Goldberg 463

Active Learning via Membership Query Synthesis for Semi-Supervised Sentence Classification
Raphael Schumann and Ines Rehbein 472

A General-Purpose Algorithm for Constrained Sequential Inference
Daniel Deutsch, Shyam Upadhyay and Dan Roth 482

A Richly Annotated Corpus for Different Tasks in Automated Fact-Checking
Andreas Hanselowski, Christian Stab, Claudia Schulz, Zile Li and Iryna Gurevych 493

Detecting Frames in News Headlines and Its Application to Analyzing News Framing Trends Surrounding U.S. Gun Violence
Siyi Liu, Lei Guo, Kate Mays, Margrit Betke and Derry Tanti Wijaya 504

Learning a Unified Named Entity Tagger from Multiple Partially Annotated Corpora for Efficient Adaptation
Xiao Huang, Li Dong, Elizabeth Boschee and Nanyun Peng 515

Learning Dense Representations for Entity Retrieval
Daniel Gillick, Sayali Kulkarni, Larry Lansing, Alessandro Presta, Jason Baldridge, Eugene Ie and Diego Garcia-Olano 528

CogniVal: A Framework for Cognitive Word Embedding Evaluation
Nora Hollenstein, Antonio de la Torre, Nicolas Langer and Ce Zhang 538

KnowSemLM: A Knowledge Infused Semantic Language Model
Haoruo Peng, Qiang Ning and Dan Roth 550

Neural Attentive Bag-of-Entities Model for Text Classification
Ikuya Yamada and Hiroyuki Shindo 563

Roll Call Vote Prediction with Knowledge Augmented Models
Pallavi Patil, Kriti Myer, Ronak Zala, Arpit Singh, Sheshera Mysore, Andrew McCallum, Adrian Benton and Amanda Stent 574

BeamSeg: A Joint Model for Multi-Document Segmentation and Topic Identification
Pedro Mota, Maxine Eskenazi and Luísa Coheur 582

MrMep: Joint Extraction of Multiple Relations and Multiple Entity Pairs Based on Triplet Attention
Jiayu Chen, Caixia Yuan, Xiaojie Wang and Ziwei Bai 593

Effective Attention Modeling for Neural Relation Extraction
Tapas Nayak and Hwee Tou Ng 603

Exploiting the Entity Type Sequence to Benefit Event Detection
Yuze Ji, Youfang Lin, Jianwei Gao and Huaiyu Wan 613

Named Entity Recognition - Is There a Glass Ceiling?
Tomasz Stanislawek, Anna Wróblewska, Alicja Wójcicka, Daniel Ziembicki and Przemyslaw Biecek 624

Low-Rank Approximations of Second-Order Document Representations
Jarkko Lagus, Janne Sinkkonen and Arto Klami 634

Named Entity Recognition with Partially Annotated Training Data
Stephen Mayhew, Snigdha Chaturvedi, Chen-Tse Tsai and Dan Roth 645

Contextualized Cross-Lingual Event Trigger Extraction with Minimal Resources
Meryem M'hamdi, Marjorie Freedman and Jonathan May 656

Deep Structured Neural Network for Event Temporal Relation Extraction
Rujun Han, I-Hung Hsu, Mu Yang, Aram Galstyan, Ralph Weischedel and Nanyun Peng 666

Investigating Entity Knowledge in BERT with Simple Neural End-To-End Entity Linking
Samuel Broscheit 677

Unsupervised Adversarial Domain Adaptation for Implicit Discourse Relation Classification
Hsin-Ping Huang and Junyi Jessy Li 686

Evidence Sentence Extraction for Machine Reading Comprehension
Hai Wang, Dian Yu, Kai Sun, Jianshu Chen, Dong Yu, David McAllester and Dan Roth 696

SimVecs: Similarity-Based Vectors for Utterance Representation in Conversational AI Systems
Ashraf Mahgoub, Youssef Shahin, Riham Mansour and Saurabh Bagchi 708

Incorporating Interlocutor-Aware Context into Response Generation on Multi-Party Chatbots
Cao Liu, Kang Liu, Shizhu He, Zaiqing Nie and Jun Zhao 718

Memory Graph Networks for Explainable Memory-grounded Question Answering
Seungwhan Moon, Pararth Shah, Anuj Kumar and Rajen Subba 728

TripleNet: Triple Attention Network for Multi-Turn Response Selection in Retrieval-Based Chatbots
Wentao Ma, Yiming Cui, Nan Shao, Su He, Wei-Nan Zhang, Ting Liu, Shijin Wang and Guoping Hu 737

Relation Module for Non-Answerable Predictions on Reading Comprehension
Kevin Huang, Yun Tang, Jing Huang, Xiaodong He and Bowen Zhou 747

Slot Tagging for Task Oriented Spoken Language Understanding in Human-to-Human Conversation Scenarios
Kunho Kim, Rahul Jha, Kyle Williams, Alex Marin and Imed Zitouni 757

Window-Based Neural Tagging for Shallow Discourse Argument Labeling
René Knaebel, Manfred Stede and Sebastian Stober 768

TILM: Neural Language Models with Evolving Topical Influence
Shubhra Kanti Karmaker Santu, Kalyan Veeramachaneni and Chengxiang Zhai 778

Pretraining-Based Natural Language Generation for Text Summarization
Haoyu Zhang, Jingjing Cai, Jianjun Xu and Ji Wang 789

Goal-Embedded Dual Hierarchical Model for Task-Oriented Dialogue Generation
Yi-An Lai, Arshit Gupta and Yi Zhang 798

Putting the Horse before the Cart: A Generator-Evaluator Framework for Question Generation from Text
Vishwajeet Kumar, Ganesh Ramakrishnan and Yuan-Fang Li 812

In Conclusion Not Repetition: Comprehensive Abstractive Summarization with Diversified Attention Based on Determinantal Point Processes
Lei Li, Wei Liu, Marina Litvak, Natalia Vanetik and Zuying Huang 822

Generating Formality-Tuned Summaries Using Input-Dependent Rewards
Kushal Chawla, Balaji Vasan Srinivasan and Niyati Chhaya 833

Do Massively Pretrained Language Models Make Better Storytellers?
Abigail See, Aneesh Pappu, Rohun Saxena, Akhila Yerukola and Christopher D. Manning 843

Self-Adaptive Scaling for Learnable Residual Structure
Fenglin Liu, Meng Gao, Yuanxin Liu and Kai Lei 862

BIOfid Dataset: Publishing a German Gold Standard for Named Entity Recognition in Historical Biodiversity Literature
Sajawel Ahmed, Manuel Stoeckel, Christine Driller, Adrian Pachzelt and Alexander Mehler . . 871

Slang Detection and Identification
Zhengqi Pei, Zhewei Sun and Yang Xu 881

Alleviating Sequence Information Loss with Data Overlapping and Prime Batch Sizes
Noémien Kocher, Christian Scuito, Lorenzo Tarantino, Alexandros Lazaridis, Andreas Fischer and Claudiu Musat 890

Global Autoregressive Models for Data-Efficient Sequence Learning
Tetiana Parshakova, Jean-Marc Andreoli and Marc Dymetman 900

Learning Analogy-Preserving Sentence Embeddings for Answer Selection
Aïssatou Diallo, Markus Zopf and Johannes Fürnkranz 910

A Simple and Effective Method for Injecting Word-Level Information into Character-Aware Neural Language Models
Yukun Feng, Hidetaka Kamigaito, Hiroya Takamura and Manabu Okumura 920

On Model Stability as a Function of Random Seed
Pranava Madhyastha and Rishabh Jain 929

Studying Generalisability across Abusive Language Detection Datasets
Steve Durairaj Swamy, Anupam Jamatia and Björn Gambäck 940

Reduce & Attribute: Two-Step Authorship Attribution for Large-Scale Problems
Michael Tschuggnall, Benjamin Murauer and Günther Specht 951

Variational Semi-Supervised Aspect-Term Sentiment Analysis via Transformer
Xingyi Cheng, Weidi Xu, Taifeng Wang, Wei Chu, Weipeng Huang, Kunlong Chen and Junfeng Hu 961

Learning to Detect Opinion Snippet for Aspect-Based Sentiment Analysis
Mengting Hu, Shiwan Zhao, Honglei Guo, Renhong Cheng and Zhong Su 970

Multi-Level Sentiment Analysis of PolEmo 2.0: Extended Corpus of Multi-Domain Consumer Reviews
Jan Kocoń, Piotr Miłkowski and Monika Zaśko-Zielińska 980

A Personalized Sentiment Model with Textual and Contextual Information
Siwen Guo, Sviatlana Höhn and Christoph Schommer 992

Cluster-Gated Convolutional Neural Network for Short Text Classification
Haidong Zhang, Wancheng Ni, Meijing Zhao and Ziqi Lin 1002

Coherence-Based Modeling of Clinical Concepts Inferred from Heterogeneous Clinical Notes for ICU Patient Risk Stratification
Tushaar Gangavarapu, Gokul S Krishnan and Sowmya Kamath 1012

Predicting the Role of Political Trolls in Social Media
Atanas Atanasov, Gianmarco De Francisci Morales and Preslav Nakov 1023

Towards a Unified End-to-End Approach for Fully Unsupervised Cross-Lingual Sentiment Analysis
Yanlin Feng and Xiaojun Wan 1035

Conference Program

Sunday, November 3, 2019

8:45–9:00 *Opening session*
Aline Villavicencio and Mohit Bansal

9:00–10:30 Session 1

9:00–9:15 *Analysing Neural Language Models: Contextual Decomposition Reveals Default Reasoning in Number and Gender Assignment*
Jaap Jumelet, Willem Zuidema and Dieuwke Hupkes

9:15–9:30 *Deconstructing Supertagging into Multi-Task Sequence Prediction*
Zhenqi Zhu and Anoop Sarkar

9:30–9:45 *Multilingual Model Using Cross-Task Embedding Projection*
Jin Sakuma and Naoki Yoshinaga

9:45–10:00 *Investigating Cross-Lingual Alignment Methods for Contextualized Embeddings with Token-Level Evaluation*
Qianchu Liu, Diana McCarthy, Ivan Vulić and Anna Korhonen

10:00–10:15 *Large-Scale, Diverse, Paraphrastic Bitexts via Sampling and Clustering*
J. Edward Hu, Abhinav Singh, Nils Holzenberger, Matt Post and Benjamin Van Durme

10:15–10:30 *Large-Scale Representation Learning from Visually Grounded Untranscribed Speech*
Gabriel Ilharco, Yuan Zhang and Jason Baldridge

Sunday, November 3, 2019 (continued)

10:30–11:00 Coffee Break

11:00–12:00 Invited Speaker

11:00–12:00 *Invited Talk: Ecological Language: a multimodal approach to the study of human language learning and processing*
Gabriella Vigliocco

12:00–12:30 Session 2

12:00–12:15 *Using Priming to Uncover the Organization of Syntactic Representations in Neural Language Models*
Grusha Prasad, Marten van Schijndel and Tal Linzen

12:15–12:30 *Say Anything: Automatic Semantic Infelicity Detection in L2 English Indefinite Pronouns*
Ella Rabinovich, Julia Watson, Barend Beekhuizen and Suzanne Stevenson

12:30–14:00 Lunch

14:00–15:30 CoNLL 2019 Shared Task: Cross-Framework Meaning Representation Parsing (MRP 2019)

15:30–16:00 Coffee Break

Sunday, November 3, 2019 (continued)

16:00–16:30 Session 3

16:00–16:15 *Compositional Generalization in Image Captioning*
Mitja Nikolaus, Mostafa Abdou, Matthew Lamm, Rahul Aralikatte and Desmond Elliott

16:15–16:30 *Representing Movie Characters in Dialogues*
Mahmoud Azab, Noriyuki Kojima, Jia Deng and Rada Mihalcea

16:30–18:00 Poster Session 1

16:30–18:00 *Cross-Lingual Word Embeddings and the Structure of the Human Bilingual Lexicon*
Paola Merlo and Maria Andueza Rodriguez

16:30–18:00 *Federated Learning of N-Gram Language Models*
Mingqing Chen, Ananda Theertha Suresh, Rajiv Mathews, Adeline Wong, Cyril Allauzen, Françoise Beaufays and Michael Riley

16:30–18:00 *Learning Conceptual Spaces with Disentangled Facets*
Rana Alshaikh, Zied Bouraoui and Steven Schockaert

16:30–18:00 *Weird Inflects but OK: Making Sense of Morphological Generation Errors*
Kyle Gorman, Arya D. McCarthy, Ryan Cotterell, Ekaterina Vylomova, Miikka Silfverberg and Magdalena Markowska

16:30–18:00 *Learning to Represent Bilingual Dictionaries*
Muhao Chen, Yingtao Tian, Haochen Chen, Kai-Wei Chang, Steven Skiena and Carlo Zaniolo

16:30–18:00 *Improving Natural Language Understanding by Reverse Mapping Bytepair Encoding*
Chaodong Tong, Huailiang Peng, Qiong Dai, Lei Jiang and Jianghua Huang

16:30–18:00 *Made for Each Other: Broad-Coverage Semantic Structures Meet Preposition Supersenses*
Jakob Prange, Nathan Schneider and Omri Abend

16:30–18:00 *Generating Timelines by Modeling Semantic Change*
Guy D. Rosin and Kira Radinsky

Sunday, November 3, 2019 (continued)

16:30–18:00 *Diversify Your Datasets: Analyzing Generalization via Controlled Variance in Adversarial Datasets*
Ohad Rozen, Vered Shwartz, Roee Aharoni and Ido Dagan

16:30–18:00 *Fully Unsupervised Crosslingual Semantic Textual Similarity Metric Based on BERT for Identifying Parallel Data*
Chi-kiu Lo and Michel Simard

16:30–18:00 *On the Importance of Subword Information for Morphological Tasks in Truly Low-Resource Languages*
Yi Zhu, Benjamin Heinzerling, Ivan Vulić, Michael Strube, Roi Reichart and Anna Korhonen

16:30–18:00 *Comparing Top-Down and Bottom-Up Neural Generative Dependency Models*
Austin Matthews, Graham Neubig and Chris Dyer

16:30–18:00 *Representation Learning and Dynamic Programming for Arc-Hybrid Parsing*
Joseph Le Roux, Antoine Rozenknop and Mathieu Lacroix

16:30–18:00 *Policy Preference Detection in Parliamentary Debate Motions*
Gavin Abercrombie, Federico Nanni, Riza Batista-Navarro and Simone Paolo Ponzetto

16:30–18:00 *Improving Neural Machine Translation by Achieving Knowledge Transfer with Sentence Alignment Learning*
Xuewen Shi, Heyan Huang, Wenguan Wang, Ping Jian and Yi-Kun Tang

16:30–18:00 *Code-Switched Language Models Using Neural Based Synthetic Data from Parallel Sentences*
Genta Indra Winata, Andrea Madotto, Chien-Sheng Wu and Pascale Fung

16:30–18:00 *Unsupervised Neural Machine Translation with Future Rewarding*
Xiangpeng Wei, Yue Hu, Luxi Xing and Li Gao

16:30–18:00 *Automatically Extracting Challenge Sets for Non-Local Phenomena in Neural Machine Translation*
Leshem Choshen and Omri Abend

16:30–18:00 *Low-Resource Parsing with Crosslingual Contextualized Representations*
Phoebe Mulcaire, Jungo Kasai and Noah A. Smith

16:30–18:00 *Improving Pre-Trained Multilingual Model with Vocabulary Expansion*
Hai Wang, Dian Yu, Kai Sun, Jianshu Chen and Dong Yu

Sunday, November 3, 2019 (continued)

16:30–18:00 *On the Relation between Position Information and Sentence Length in Neural Machine Translation*
Masato Neishi and Naoki Yoshinaga

16:30–18:00 *Word Recognition, Competition, and Activation in a Model of Visually Grounded Speech*
William N. Havard, Jean-Pierre Chevrot and Laurent Besacier

16:30–18:00 *EQUATE: A Benchmark Evaluation Framework for Quantitative Reasoning in Natural Language Inference*
Abhilasha Ravichander, Aakanksha Naik, Carolyn Rose and Eduard Hovy

16:30–18:00 *Linguistic Analysis Improves Neural Metaphor Detection*
Kevin Stowe, Sarah Moeller, Laura Michaelis and Martha Palmer

18:00–18:30 Reception

Monday, November 4, 2019

8:45–10:30 Session 4

8:45–9:00 *Cross-Lingual Dependency Parsing with Unlabeled Auxiliary Languages*
Wasi Uddin Ahmad, Zhisong Zhang, Xuezhe Ma, Kai-Wei Chang and Nanyun Peng

9:00–9:15 *A Dual-Attention Hierarchical Recurrent Neural Network for Dialogue Act Classification*
Ruizhe Li, Chenghua Lin, Matthew Collinson, Xiao Li and Guanyi Chen

9:15–9:30 *Mimic and Rephrase: Reflective Listening in Open-Ended Dialogue*
Justin Dieter, Tian Wang, Arun Tejasvi Chaganty, Gabor Angeli and Angel X. Chang

9:30–9:45 *Automated Pyramid Summarization Evaluation*
Yanjun Gao, Chen Sun and Rebecca J. Passonneau

9:45–10:00 *A Case Study on Combining ASR and Visual Features for Generating Instructional Video Captions*
Jack Hessel, Bo Pang, Zhenhai Zhu and Radu Soricut

10:00–10:15 *Leveraging Past References for Robust Language Grounding*
Subhro Roy, Michael Noseworthy, Rohan Paul, Daehyung Park and Nicholas Roy

Monday, November 4, 2019 (continued)

10:15–10:30 *Procedural Reasoning Networks for Understanding Multimodal Procedures*
Mustafa Sercan Amac, Semih Yagcioglu, Aykut Erdem and Erkut Erdem

10:30–11:00 Coffee Break

11:00–12:00 Invited Speaker

11:00–12:00 *Invited Talk: Multi-step reasoning for answering complex questions*
Chris Manning

12:00–12:30 Session 5

12:00–12:15 *On the Limits of Learning to Actively Learn Semantic Representations*
Omri Koshorek, Gabriel Stanovsky, Yichu Zhou, Vivek Srikumar and Jonathan Berant

12:15–12:30 *How Does Grammatical Gender Affect Noun Representations in Gender-Marking Languages?*
Hila Gonen, Yova Kementchedjhieva and Yoav Goldberg

12:30–14:00 Best Paper Awards and Community Business Meeting

14:00–15:30 Session 6

14:00–14:15 *Active Learning via Membership Query Synthesis for Semi-Supervised Sentence Classification*
Raphael Schumann and Ines Rehbein

14:15–14:30 *A General-Purpose Algorithm for Constrained Sequential Inference*
Daniel Deutsch, Shyam Upadhyay and Dan Roth

14:30–14:45 *A Richly Annotated Corpus for Different Tasks in Automated Fact-Checking*
Andreas Hanselowski, Christian Stab, Claudia Schulz, Zile Li and Iryna Gurevych

14:45–15:00 *Detecting Frames in News Headlines and Its Application to Analyzing News Framing Trends Surrounding U.S. Gun Violence*
Siyi Liu, Lei Guo, Kate Mays, Margrit Betke and Derry Tanti Wijaya

Monday, November 4, 2019 (continued)

15:00–15:15 *Learning a Unified Named Entity Tagger from Multiple Partially Annotated Corpora for Efficient Adaptation*
Xiao Huang, Li Dong, Elizabeth Boschee and Nanyun Peng

15:15–15:30 *Learning Dense Representations for Entity Retrieval*
Daniel Gillick, Sayali Kulkarni, Larry Lansing, Alessandro Presta, Jason Baldridge, Eugene Ie and Diego Garcia-Olano

15:30–16:00 Coffee Break

16:00–16:30 Session 7

16:00–16:15 *CogniVal: A Framework for Cognitive Word Embedding Evaluation*
Nora Hollenstein, Antonio de la Torre, Nicolas Langer and Ce Zhang

16:15–16:30 *KnowSemLM: A Knowledge Infused Semantic Language Model*
Haoruo Peng, Qiang Ning and Dan Roth

16:30–18:00 Poster Session 2

16:30–18:00 *Neural Attentive Bag-of-Entities Model for Text Classification*
Ikuya Yamada and Hiroyuki Shindo

16:30–18:00 *Roll Call Vote Prediction with Knowledge Augmented Models*
Pallavi Patil, Kriti Myer, Ronak Zala, Arpit Singh, Sheshera Mysore, Andrew McCallum, Adrian Benton and Amanda Stent

16:30–18:00 *BeamSeg: A Joint Model for Multi-Document Segmentation and Topic Identification*
Pedro Mota, Maxine Eskenazi and Luísa Coheur

16:30–18:00 *MrMep: Joint Extraction of Multiple Relations and Multiple Entity Pairs Based on Triplet Attention*
Jiayu Chen, Caixia Yuan, Xiaojie Wang and Ziwei Bai

16:30–18:00 *Effective Attention Modeling for Neural Relation Extraction*
Tapas Nayak and Hwee Tou Ng

Monday, November 4, 2019 (continued)

16:30–18:00 *Exploiting the Entity Type Sequence to Benefit Event Detection*
Yuze Ji, Youfang Lin, Jianwei Gao and Huaiyu Wan

16:30–18:00 *Named Entity Recognition - Is There a Glass Ceiling?*
Tomasz Stanislawek, Anna Wróblewska, Alicja Wójcicka, Daniel Ziembicki and Przemyslaw Biecek

16:30–18:00 *Low-Rank Approximations of Second-Order Document Representations*
Jarkko Lagus, Janne Sinkkonen and Arto Klami

16:30–18:00 *Named Entity Recognition with Partially Annotated Training Data*
Stephen Mayhew, Snigdha Chaturvedi, Chen-Tse Tsai and Dan Roth

16:30–18:00 *Contextualized Cross-Lingual Event Trigger Extraction with Minimal Resources*
Meryem M'hamdi, Marjorie Freedman and Jonathan May

16:30–18:00 *Deep Structured Neural Network for Event Temporal Relation Extraction*
Rujun Han, I-Hung Hsu, Mu Yang, Aram Galstyan, Ralph Weischedel and Nanyun Peng

16:30–18:00 *Investigating Entity Knowledge in BERT with Simple Neural End-To-End Entity Linking*
Samuel Broscheit

16:30–18:00 *Unsupervised Adversarial Domain Adaptation for Implicit Discourse Relation Classification*
Hsin-Ping Huang and Junyi Jessy Li

16:30–18:00 *Evidence Sentence Extraction for Machine Reading Comprehension*
Hai Wang, Dian Yu, Kai Sun, Jianshu Chen, Dong Yu, David McAllester and Dan Roth

16:30–18:00 *SimVecs: Similarity-Based Vectors for Utterance Representation in Conversational AI Systems*
Ashraf Mahgoub, Youssef Shahin, Riham Mansour and Saurabh Bagchi

16:30–18:00 *Incorporating Interlocutor-Aware Context into Response Generation on Multi-Party Chatbots*
Cao Liu, Kang Liu, Shizhu He, Zaiqing Nie and Jun Zhao

16:30–18:00 *Memory Graph Networks for Explainable Memory-grounded Question Answering*
Seungwhan Moon, Pararth Shah, Anuj Kumar and Rajen Subba

Monday, November 4, 2019 (continued)

16:30–18:00 *TripleNet: Triple Attention Network for Multi-Turn Response Selection in Retrieval-Based Chatbots*
Wentao Ma, Yiming Cui, Nan Shao, Su He, Wei-Nan Zhang, Ting Liu, Shijin Wang and Guoping Hu

16:30–18:00 *Relation Module for Non-Answerable Predictions on Reading Comprehension*
Kevin Huang, Yun Tang, Jing Huang, Xiaodong He and Bowen Zhou

16:30–18:00 *Slot Tagging for Task Oriented Spoken Language Understanding in Human-to-Human Conversation Scenarios*
Kunho Kim, Rahul Jha, Kyle Williams, Alex Marin and Imed Zitouni

16:30–18:00 *Window-Based Neural Tagging for Shallow Discourse Argument Labeling*
René Knaebel, Manfred Stede and Sebastian Stober

16:30–18:00 *TILM: Neural Language Models with Evolving Topical Influence*
Shubhra Kanti Karmaker Santu, Kalyan Veeramachaneni and Chengxiang Zhai

16:30–18:00 *Pretraining-Based Natural Language Generation for Text Summarization*
Haoyu Zhang, Jingjing Cai, Jianjun Xu and Ji Wang

16:30–18:00 *Goal-Embedded Dual Hierarchical Model for Task-Oriented Dialogue Generation*
Yi-An Lai, Arshit Gupta and Yi Zhang

16:30–18:00 *Putting the Horse before the Cart: A Generator-Evaluator Framework for Question Generation from Text*
Vishwajeet Kumar, Ganesh Ramakrishnan and Yuan-Fang Li

16:30–18:00 *In Conclusion Not Repetition: Comprehensive Abstractive Summarization with Diversified Attention Based on Determinantal Point Processes*
Lei Li, Wei Liu, Marina Litvak, Natalia Vanetik and Zuying Huang

16:30–18:00 *Generating Formality-Tuned Summaries Using Input-Dependent Rewards*
Kushal Chawla, Balaji Vasan Srinivasan and Niyati Chhaya

16:30–18:00 *Do Massively Pretrained Language Models Make Better Storytellers?*
Abigail See, Aneesh Pappu, Rohun Saxena, Akhila Yerukola and Christopher D. Manning

16:30–18:00 *Self-Adaptive Scaling for Learnable Residual Structure*
Fenglin Liu, Meng Gao, Yuanxin Liu and Kai Lei

Monday, November 4, 2019 (continued)

16:30–18:00 *BIOfid Dataset: Publishing a German Gold Standard for Named Entity Recognition in Historical Biodiversity Literature*
Sajawel Ahmed, Manuel Stoeckel, Christine Driller, Adrian Pachzelt and Alexander Mehler

16:30–18:00 *Slang Detection and Identification*
Zhengqi Pei, Zhewei Sun and Yang Xu

16:30–18:00 *Alleviating Sequence Information Loss with Data Overlapping and Prime Batch Sizes*
Noémien Kocher, Christian Scuito, Lorenzo Tarantino, Alexandros Lazaridis, Andreas Fischer and Claudiu Musat

16:30–18:00 *Global Autoregressive Models for Data-Efficient Sequence Learning*
Tetiana Parshakova, Jean-Marc Andreoli and Marc Dymetman

16:30–18:00 *Learning Analogy-Preserving Sentence Embeddings for Answer Selection*
Aïssatou Diallo, Markus Zopf and Johannes Fürnkranz

16:30–18:00 *A Simple and Effective Method for Injecting Word-Level Information into Character-Aware Neural Language Models*
Yukun Feng, Hidetaka Kamigaito, Hiroya Takamura and Manabu Okumura

16:30–18:00 *On Model Stability as a Function of Random Seed*
Pranava Madhyastha and Rishabh Jain

16:30–18:00 *Studying Generalisability across Abusive Language Detection Datasets*
Steve Durairaj Swamy, Anupam Jamatia and Björn Gambäck

16:30–18:00 *Reduce & Attribute: Two-Step Authorship Attribution for Large-Scale Problems*
Michael Tschuggnall, Benjamin Murauer and Günther Specht

16:30–18:00 *Variational Semi-Supervised Aspect-Term Sentiment Analysis via Transformer*
Xingyi Cheng, Weidi Xu, Taifeng Wang, Wei Chu, Weipeng Huang, Kunlong Chen and Junfeng Hu

16:30–18:00 *Learning to Detect Opinion Snippet for Aspect-Based Sentiment Analysis*
Mengting Hu, Shiwan Zhao, Honglei Guo, Renhong Cheng and Zhong Su

16:30–18:00 *Multi-Level Sentiment Analysis of PolEmo 2.0: Extended Corpus of Multi-Domain Consumer Reviews*
Jan Kocoń, Piotr Miłkowski and Monika Zaśko-Zielińska

Monday, November 4, 2019 (continued)

16:30–18:00 *A Personalized Sentiment Model with Textual and Contextual Information*
Siwen Guo, Sviatlana Höhn and Christoph Schommer

16:30–18:00 *Cluster-Gated Convolutional Neural Network for Short Text Classification*
Haidong Zhang, Wancheng Ni, Meijing Zhao and Ziqi Lin

16:30–18:00 *Coherence-Based Modeling of Clinical Concepts Inferred from Heterogeneous Clinical Notes for ICU Patient Risk Stratification*
Tushaar Gangavarapu, Gokul S Krishnan and Sowmya Kamath

16:30–18:00 *Predicting the Role of Political Trolls in Social Media*
Atanas Atanasov, Gianmarco De Francisci Morales and Preslav Nakov

16:30–18:00 *Towards a Unified End-to-End Approach for Fully Unsupervised Cross-Lingual Sentiment Analysis*
Yanlin Feng and Xiaojun Wan

Invited Talk I

Ecological Language: A Multimodal Approach to the Study of Human Language Learning and Processing

Gabriella Vigliocco
Department of Experimental Psychology, University College London, UK

Abstract

The human brain has evolved the ability to support communication in complex and dynamic environments. In such environments, language is learned, and mostly used in face-to-face contexts in which processing and learning are based on multiple cues both linguistic and non-linguistic (such as gestures, eye gaze, mouth patterns and prosody). Yet, our understanding of how language is learnt and processed - as well as applications of this knowledge - comes mostly from reductionist approaches in which the multimodal signal is reduced to speech or text. I will introduce our current programme of research that investigates language in real-world settings in which the listener/learner has access to – and therefore can take advantage of – the multiple cues provided by the speaker. I will then describe studies that aim at characterising the distribution of the multimodal cues in the language used by caregivers when interacting with their children (mostly 2-4 years old) and provide data concerning how these cues are differentially distributed depending upon whether the child knows the objects being talked about (allowing us to more clearly isolate learning episodes), and whether objects being talked about are present. I will then move to a study using EEG addressing the question of how discourse but crucially also the non-linguistic cues modulate predictions about the next word in a sentence. Throughout the talk, I will highlight the ways in which this real world, more ecologically valid, approach to the study of language bear promise across disciplines.

Biography

Gabriella Vigliocco is Professor of the Psychology of Language in the Department of Experimental Psychology at University College London, Royal Society Wolfson Research Merit Fellow and Director of the Leverhulme Doctoral training Programme for the Ecological Study of the Brain. She received her PhD from University of Trieste in 1995, was a post-doc at University of Arizona, and after being at University of Wisconsin as Assistant Professor and the Max Planck Institute for Psycholinguistics as a visiting scientist, she moved to UCL. Vigliocco leads a multidisciplinary team composed of psychologists, linguists, computer scientists and cognitive neuroscientists sharing the vision that understanding language and cognition requires integration of multiple levels of analysis and methodological approaches. Her research focuses on the cognitive and neurobiological basis of human communication. More specifically she is interested in how we learn and process language in real-word settings, how our semantic knowledge interfaces with perception, action and emotion and how these systems are recruited during language learning. Through the years, her work has been supported by numerous prestigious awards, including Human Frontier Science Programme and currently European Research Council.

Invited Talk II

Multi-Step Reasoning for Answering Complex Questions

Christopher Manning
Department of Linguists and Computer Science, Stanford University, USA

Abstract

Current neural network systems have had enormous success on matching but still struggle in supporting multi-step inference. In this talk, I will examine two recent lines of work to address this gap, done with Drew Hudson and Peng Qi. In one line of work we have developed neural networks with explicit structure to support attention, composition, and reasoning, with an explicitly iterative inference architecture. Our Neural State Machine design also emphasizes the use of a more symbolic form of internal computation, represented as attention over symbols, which have distributed representations. Such designs encourage modularity and generalization from limited data. We show the model's effectiveness on visual question answering datasets. The second line of work makes progress in doing multi-step question answering over a large open-domain text collection. Most previous work on open-domain question answering employs a retrieve-and-read strategy, which fails when the question requires complex reasoning, because simply retrieving with the question seldom yields all necessary supporting facts. I present a model for explainable multi-hop reasoning in open-domain QA that iterates between finding supporting facts and reading the retrieved context. This GoldEn Retriever model is not only explainable but shows strong performance on the recent HotpotQA dataset for multi-step reasoning.

Biography

Christopher Manning is the inaugural Thomas M. Siebel Professor in Machine Learning in the Departments of Computer Science and Linguistics at Stanford University and Director of the Stanford Artificial Intelligence Laboratory (SAIL). His research goal is computers that can intelligently process, understand, and generate human language material. Manning is a leader in applying Deep Learning to Natural Language Processing, with well-known research on Tree Recursive Neural Networks, the GloVe model of word vectors, sentiment analysis, neural network dependency parsing, neural machine translation, question answering, and deep language understanding. He also focuses on computational linguistic approaches to parsing, robust textual inference and multilingual language processing, including being a principal developer of Stanford Dependencies and Universal Dependencies. He is an ACM Fellow, a AAAI Fellow, and an ACL Fellow, and a Past President of the ACL (2015). His research has won ACL, Coling, EMNLP, and CHI Best Paper Awards. He has a B.A. (Hons) from The Australian National University and a Ph.D. from Stanford in 1994, and he held faculty positions at Carnegie Mellon University and the University of Sydney before returning to Stanford. He is the founder of the Stanford NLP group (@stanfordnlp) and manages development of the Stanford CoreNLP software.

Analysing Neural Language Models: Contextual Decomposition Reveals Default Reasoning in Number and Gender Assignment

Jaap Jumelet

ILLC, University of Amsterdam

Dieuwke Hupkes
d.hupkes@uva.nl
ILLC, University of Amsterdam

Abstract

Extensive research has recently shown that recurrent neural language models are able to process a wide range of grammatical phenomena. *How* these models are able to perform these remarkable feats so well, however, is still an open question. To gain more insight into what information LSTMs base their decisions on, we propose a *generalisation* of *Contextual Decomposition* (GCD). In particular, this setup enables us to accurately distil which part of a prediction stems from semantic heuristics, which part truly emanates from syntactic cues and which part arise from the model biases themselves instead. We investigate this technique on tasks pertaining to syntactic agreement and co-reference resolution and discover that the model strongly relies on a *default reasoning* effect to perform these tasks.

1 Introduction

Modern language models that use deep learning architectures such as LSTMs, bi-LSTMs and Transformers, have shown enormous gains in performance in the last few years and are finding applications in novel domains, ranging from speech recognition and writing assistance to autonomous generation of fake news. Understanding how they reach their predictions has become a key question for NLP, not only for purely scientific, but also for practical and ethical reasons.

From a linguistic perspective, a natural approach is to test the extent to which these models have learned classical linguistic constructs, such as inflectional morphology, constituency structure, agreement between verb and subject, filler-gap dependencies, negative polarity or reflexive anaphora. An influential paper using this approach was presented by Linzen et al. (2016), who investigated the performance of an LSTM-based language model on number agreement. In many later papers (e.g. Gulordava et al., 2018; Wilcox et al., 2018; Jumelet and Hupkes, 2018; Marvin and Linzen, 2018; Giulianelli et al., 2018) a wide spectrum of grammatical phenomena has been investigated, assessing these grammatical abilities in a mainly "behavioural" fashion, by considering the model's output.

In this paper, we take it as established that neural language models have indeed learned a great number of non-trivial linguistic patterns and ask instead *how* language models come to show this behaviour, and, more specifically, what kind of information they use to come to their decisions. There exist already a number of approaches that look inside the high-dimensional vector representations and non-linear functions of these models, trying to track the flow of information. In the next section, we will review some of that work, distinguishing between hypothesis-driven and data-driven methods. We highlight in particular one method called Contextual Decomposition (CD, Murdoch et al., 2018), that combines the strengths of hypothesis- and data-driven analysis methods.

In the remainder of this paper, we then propose a generalisation of this method, which we call Generalised Contextual Decomposition ("GCD"). We derive equations for GCD for the case of a unidirectional (one or multi-layer) LSTM (Hochreiter and Schmidhuber, 1997), and use the method to analyse how a language model processes two different phenomena: number agreement and gendered pronoun resolution.

We demonstrate the power of GCD through the revelation of some important asymmetries in the way that both the singular-plural and the male-female distinction are handled. In particular, we find evidence for a *default reasoning* effect, which we believe could also be important for future work on detecting and removing bias: a default category (singular, masculine) appears to be hard-coded in

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 1–11
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

the weights of the language model, number and gender information in the word embeddings themselves mainly plays a role for phrases of the opposite category (plural, feminine). Furthermore, GCD enables us to investigate pronoun resolution in a way that has not been done before: by delving into the model reasoning we are able to accurately pinpoint where and how this resolution takes place.[1]

2 Network analysis methods

Recently, methods to open the blackbox of deep neural networks have become an important research area (see Poerner et al., 2018; Belinkov and Glass, 2019, for recent reviews of proposed methods in NLP). We distinguish between hypothesis-driven methods, and data-driven methods. Hypothesis-driven methods include probes or *diagnostic classifiers*, that test whether specific, a priori defined information can be decoded from the internal states of a neural model, many ablation studies, and types of correlation analysis, where correlations between the structure of internal representations of better and lesser understood models are studied). An example of this approach is Giulianelli et al. (2018), who trained linear diagnostic classifiers on all layers and gate activations of an LSTM to predict the number of the subject that the verb, occurring later in the sentence, needs to agree with (i.e. the number-agreement task). Their results show that the relevant information is encoded in a different way in different components of the model, and at different times while processing a sentence. This result is interesting, because it starts from a clearly interpretable hypothesis (number information must be maintained somewhere while the network traverses the sentence), but the work also demonstrates the limitations of the approach: It progresses one hypothesis about one linguistic pattern at a time and involves much training, work, and computation at each step.

Data-driven methods include gradient-based methods and contextual decomposition. An example of a gradient-based method is Arras et al. (2017), who adapt Layer-wise Relevance Propagation (LRP, Bach et al., 2015) to the case of LSTMs. The key idea is to run the LSTM on each input of interest (the forward pass), then define a relevance vector at the output layer and propagate that relevance backwards through the network. The relevance vector simply singles out the dimensions of the output of interest, and sets all other dimension to zero. The backward pass is almost standard backpropagation, except that relevance does not backpropagate into the gates.While Arras et al.'s results reveal interesting patterns in sentences used in a sentiment classification task, their work illustrates some limitations as well. In particular, the work deals with a classification task with few classes, aggregates relevance per word for each predicted class, but offers little insight in how word meanings interact to build up sentence meaning beyond 'pushing in the right direction' vs. 'pushing in the wrong direction'.

An alternative data driven method, and the one that we will expand on in this paper, is Contextual Decomposition for LSTMs (CD, Murdoch et al., 2018). The key idea behind this technique is to partition the hidden states into two components, that Murdoch et al. label 'relevant' and 'irrelevant'. For each word in a sentence, they do a forward pass that computes all cell and gate activations as in normal operation of the neural network, but also partition each activation value of each neuron in h or c in a part that is *caused* by some selected token or phrase in focus, and a part that is not. They achieve this by deriving a factorisation of the update formulas for h and c, that expresses them as a long sum of components and then selecting some of these components as being relevant, and others as irrelevant. Qualitative results on sentiment analysis suggest that CD can attribute roles to words in a sentence very well, better than alternatives the authors considered (which, unfortunately, did not include LRP).

CD thus requires no extra training and requires only the forward pass of the network. It can easily be extended to work efficiently with many classes, such as the language modelling task that we are interested in. In the next section, we will define CD more precisely, where we will use the terms *inside* and *outside* rather than relevant and irrelevant. We then propose a generalisation that allows us to experiment with different *hypotheses* on what goes into the *inside* and *outside* bins, enabling some of the advantages of hypothesis-driven analysis methods to be brought into this data-driven method.

[1] We have integrated all our code in `diagnnose` (Jumelet and Hupkes, 2019), a well-documented analysis library which facilitate the diagnosis of neural network activations: `github.com/i-machine-think/diagnnose`.

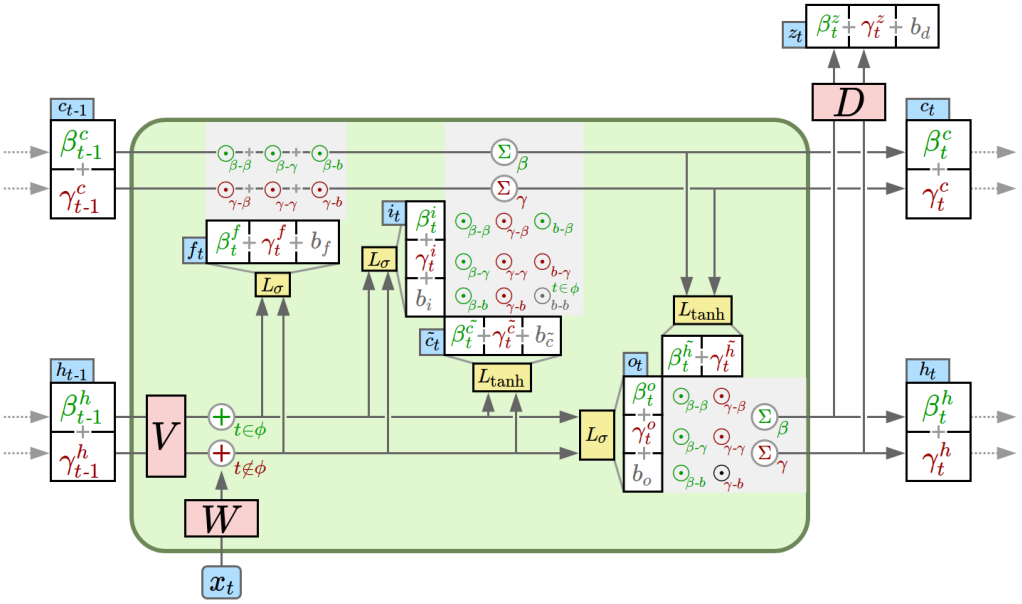

Figure 1: A graphical overview of GCD, based on the LSTM design of Olah (2015). ϕ denotes the phrase in focus, and $t \in \phi$ implies the action is only performed when step t is part of ϕ. $\odot$ denotes an individual interaction; green interactions are added the β part and red interactions to γ. V, W, and D represent the linear projections of the LSTM itself. The interaction set denoted here corresponds to the IN set of Equation 12.

3 Generalised Contextual Decomposition

In this particular study, we consider the LSTM language model that was made available by Gulordava et al. (2018). This language model (LM) is a 2-layer LSTM with 650 hidden units in both layers, trained on a corpus with Wikipedia data. Given the relevance of the specific LSTM-dynamics for the understanding of the main method of our paper, we repeat the equations that describe it below.

$$f_t = \sigma(W_f x_t + V_f h_{t-1} + b_f) \quad (1)$$
$$i_t = \sigma(W_i x_t + V_i h_{t-1} + b_i) \quad (2)$$
$$\tilde{c}_t = \tanh(W_{\tilde{c}} x_t + V_{\tilde{c}} h_{t-1} + b_{\tilde{c}}) \quad (3)$$
$$o_t = \sigma(W_o x_t + V_o h_{t-1} + b_o) \quad (4)$$
$$c_t = f_t \odot c_{t-1} + i_t \odot \tilde{c}_t \quad (5)$$
$$h_t = o_t \odot \tanh(c_t) \quad (6)$$
$$z_t = D h_t + b_d \quad (7)$$
$$p_t = \text{SoftMax}\,(z_t) \quad (8)$$

The final model output p_t represents a multinomial distribution over the model's vocabulary. Throughout the paper we refer to the bias terms b as the model *intercepts*, to avoid confusion with general biases that the model may have.

CD To compute the contributions of one or multiple input tokens (said to be *in focus*) to the output of an LSTM cell, Murdoch et al. (2018) divide each cell and hidden state into a sum of two parts: a β part, which contains the part of this particular state that stems from **inside** this phrase, and a γ part, which contains information coming from words **outside** this phrase. The output logit z_t can then be redefined as

$$\begin{aligned} z_t = D h_t + b_d &= D\beta_t^h + D\gamma_t^h + b_d \\ &= \beta_t^z + \gamma_t^z + b_d \end{aligned}$$

with β_t^z providing a quantitative score of the phrase's contribution to the logit. How a particular hidden state h_t is partitioned into β_t^h and γ_t^h is determined by two things: **i)** The decomposition of the *previous* states c_{t-1} (β_{t-1}^c and γ_{t-1}^c) and h_{t-1} (β_{t-1}^h and γ_{t-1}^h), and **ii)** Which *interactions* between the different β and γ terms, the intercepts b, and the input x_t are considered to be part of the inside contribution of the phrase. We provide a graphical overview of our setup in Figure 1.

Factorised activation functions The gate interactions cannot yet be expanded into a cross-term of their input parts, due to the non-linear activation that wraps them. Murdoch et al. define a method to factorise the sigmoid and tanh functions for each specific gate into a sum of contributions of the input terms, such that

$$\tanh(\sum_{i=1}^{N} y_i) = \sum_{i=1}^{N} L_{\tanh}(y_i)$$

$L_{\tanh}$ expresses the *contribution* of each input, which is computed by averaging over the differences of all possible permutations of the input

terms; a procedure that corresponds to the calculation of the Shapley values (Shapley, 1953).[2]

Before this factorisation is performed, an input token x_t is added to the inside part β if it is part of the phrase for which we decompose (i.e. the phrase *in focus*), otherwise it is added to γ. Equation 1, for example, can then be rewritten as:

$$\begin{aligned} f_t &= \sigma\left(V_f\beta^h_{t-1} + V_f\gamma^h_{t-1} + W_f x_t + b_f\right) \\ &= L_\sigma\left(V_f\beta^h_{t-1} + W_f x_t\right) + L_\sigma(\gamma^h_{t-1}) + L_\sigma(b_f) \end{aligned} \tag{9}$$

where x_t is considered to be inside the phrase in focus and therefore added to the β part (denoted in green for extra emphasis). A similar sum can be written down for the input gate i_t and the candidate cell state $\tilde{c}_t$. This allows the two products $f_t \odot c_t$ and $i_t \odot \tilde{c}_t$ of Equation 5 to be expanded into a sum of cross-terms between the decomposed gate and (candidate) cell values. Expanding the forget and input gate results in 15 cross-terms, that each express different interactions between the current input, previous β and γ terms, and the model intercepts.

Murdoch et al. state they observed improvements when the intercept term is fixed to the first position in each permutation. Consequently, however, these intercepts are assigned a relatively larger contribution, as their fixed position makes their contribution independent of the magnitudes of the other terms. We therefore pose that the full set of permutations should be considered, to assign unbiased contributions to each input term.[3]

Decomposing interactions Based on all the different interaction terms, the decomposition is determined by *which* of these interactions should be considered to belong to the inside part β of the next cell state and which to the outside part γ.

In the formulation of Murdoch et al., all interactions with outside parts γ_t are disregarded for the computation of β_{t+1}, and therefore only information directly stemming from the β_t terms with no interference from γ_t is taken into account. Of the 15 cross-product terms described above, this leaves 5 terms to be part of β^c_{t+1}:

$$\begin{aligned} \beta^c_{t+1} = {} & L_\sigma(V_f\beta^h_t + W_f x_t) \odot \beta^c_t && \beta\text{-}\beta \\ & + L_\sigma(b_f) \odot \beta^c_t && \beta\text{-}b \\ & + L_\sigma(V_i\beta^h_t + W_i x_t) \odot L_{\tanh}(V_{\tilde{c}}\beta^h_t + W_{\tilde{c}} x_t) && \beta\text{-}\beta \\ & + L_\sigma(V_i\beta^h_t + W_i x_t) \odot L_{\tanh}(b_{\tilde{c}}) && \beta\text{-}b \\ & + L_{\tanh}(V_{\tilde{c}}\beta^h_t + W_{\tilde{c}} x_t) \odot L_\sigma(b_i) && \beta\text{-}b \end{aligned} \tag{10}$$

The remaining 10 terms from the cross-product are put in γ^c_{t+1}. We use the notation $\{\beta\text{-}\beta,\ \beta\text{-}b\}$ to concisely describe this set of interactions. The decomposition of the hidden state is created by decomposing the output gate:

$$\begin{aligned} \beta^h_{t+1} = {} & L_\sigma(V_o\beta^h_t + W_o x_t) \odot \beta^c_{t+1} \\ & + L_\sigma(b_o) \odot \beta^c_{t+1} \end{aligned} \tag{11}$$

The decomposed contribution score β^z_T over the model vocabulary at step T of some phrase in focus is then calculated by passing the decomposed hidden state to the decoder, i.e. $D\beta^h_T$. This score can be expressed as a relative contribution by normalising it by the full model logit z (including b_d). In a multi-layer LSTM, β and γ parts are not only propagated *forward*, but also *upward*, where they are added to their respective parts in the layer above them. For initialisation β is set to a zero vector, and γ is set to the initial LSTM states.[4]

Generalising CD While Murdoch et al. (2018) consider only one way of partitioning interactions between inside and outside components, their setup can be quite easily generalised to also allow other interactions to be included in the inside terms β. To obtain a better insight into how different interactions contribute to the final prediction, we experiment with various ways of defining the set of relevant interactions.

A particular case concerns the interactions between β and γ. It wouldn't be correct to completely attribute the information flowing from these interactions to the phrase in focus, but disallowing any information stemming from interactions of a phrase with a subsequent token results in loss of relevant information. Consider, for instance, the verb prediction in a number agreement task. While the correct verb *form* depends only on the subject, the right *time* for this information to surface depends on the material in between, which in the setup described in Equation 10 would be discarded by assigning the β-γ interactions to γ.

[2] In the original formulation this procedure is called *linearizing*. We deemed this term to be slightly confusing, as the resulting functions L are still non-linear.

[3] We only discovered the impact of this decision after the paper had already been reviewed. While using the full set of permutations did, fortunately, not qualitatively change our conclusions, the exact numbers presented in this work thus differ from the earlier version of this paper. For completeness, we report the original results with the fixed intercept positions in the supplementary materials of this article.

[4] For the initial states we use the activations that follow from the short phrase ". <eos>". This phrase resets the model state to a clean slate, and leads to better results than using 0-valued activations.

Taking inspiration from Arras et al. (2017), and based on their motivation, we add the β_s-γ_g interaction to the relevant interaction set, while still disregarding a γ_s-β_g interaction. The g subscript denotes the part of the interaction that is coming from the gate, and s the source part. We denote this amended interaction as β-γ^*.

Furthermore, we follow the addition of Singh et al. (2019) of only adding the intercept interactions b-b to the inside part if the current time step is part of the phrase in focus, which we denote as $b\text{-}b \in x$. We add these β-γ^* and $b\text{-}b \in x$ interactions to Equation 10, resulting in the following decomposition that is presumed to come from **inside** the phrase in focus (denoted as IN):

$$\begin{aligned}\beta^c_{t+1} = \{&\beta\text{-}\beta, \beta\text{-}b\} \\ &+ L_\sigma(V_f\gamma^h_t) \odot \beta^c_t && \beta\text{-}\gamma^* \\ &+ L_\sigma(V_i\gamma^h_t) \odot L_{\tanh}(V_{\tilde{c}}\beta^h_t + W_{\tilde{c}}x_t) && \beta\text{-}\gamma^* \\ &+ L_\sigma(b_i) \odot L_{\tanh}(b_{\tilde{c}}) && b\text{-}b \in x \quad (12)\end{aligned}$$

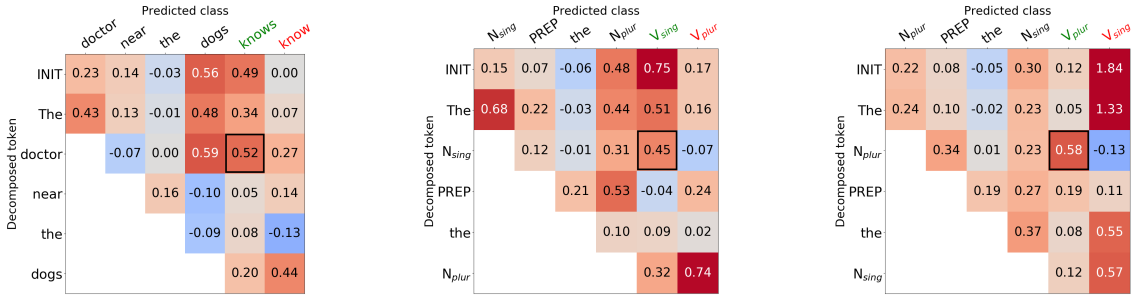
We also experimented with various other interaction sets. To determine the influence of the gate intercepts, we create an interaction set that does not take the input embeddings into account at all: $\{\beta\text{-}\beta, \beta\text{-}\gamma^*, \beta\text{-}b, b\text{-}b\}$, with x always added to γ, denoted as INTERCEPT*. We include β-γ^* to still account for the way the intercepts are gated by the input sentence. The initial hidden and cell state are added to β now as well, as we consider these states to be part of the model bias. Finally, to determine the dependence of the input on the gate intercepts we use an interaction set that never takes the interactions with any intercept into account: $\{\beta\text{-}\beta, \beta\text{-}\gamma^*\}$, denoted as $\neg$INTERCEPT.

4 Experimental setup

We use GCD to study how our LSTM model handles two different linguistic phenomena: subject-verb agreement and anaphora resolution in relation to *gender*. Next to the model of Gulordava et al. (for which we present our results), we also ran our experiments on the LM of Józefowicz et al. (2016), which arrives at similar results.

4.1 Subject-verb agreement

We consider a variant of the *number-agreement* (NA) task that was proposed by Linzen et al. (2016) to assess the syntax-sensitivity of language models. In this task, a model is evaluated based on its ability to track a long-distance subject-verb relation, which is assessed by the percentage of times that the verb-form it prefers matches the *number* of the syntactic subject. Commonly, the material in between subject and verb contains an *attractor* noun that competes with the syntactic subject, e.g. *The **keys** on the table **are***.



Here, we consider the NA corpora made available by Lakretz et al. (2019), which consists of a number of data sets containing a range of syntactic constructions in which number agreement plays a role. We report results for several of their data sets, but focus in particular on their *NounPP* subset, in which sentences contain an attractor embedded in a prepositional phrase. These sentences are formed following the template *The* `N Prep` *the* `N V` [..], e.g. *The boys near the car greet* [..]. The sentences in this data set are split based on the number of the subject and the attractor, resulting in four different conditions: SS, SP, PS, and PP.

4.2 Anaphora resolution and gender bias

Our second experiment concerns anaphora resolution and the possible gender biases that networks may use to perform this task. We focus on intra-sentential anaphora resolution, in which a pronoun in a subordinate clause refers to an entity in the main clause, based on *gender information*. For example: *The monk liked the **nun**, because **she** was always nice to him*.

Compared to number agreement it is more difficult to formulate a setup for anaphora resolution in which there is a right or wrong prediction that directly reflects how the model handles the phenomenon: when predicting ***she*** in the example, it could have been equally probable to predict ***he***. Rather, to establish if a model correctly resolves the referent of a pronoun, it should be checked what the model considered to be the source of this prediction, which cannot directly be inferred from the prediction itself. GCD gives us exactly this information and is therefore an excellent tool to study anaphora resolution in language modeling.

To create our corpus, we use the templates from the WinoBias corpus created by Zhao et al. (2018). This corpus contains sentences with job titles that are gender neutral, yet contain a stereotypical bias towards one gender (doctors and CEOs are *male*, nurses and housekeepers *female*). We construct two types of corpora, one containing the stereotypical job titles of Zhao et al. and one in which we replace these titles by entity descriptions that are unambiguously gendered (*king*, *bride*, *father*, etc.). Similar to the *NounPP* corpus for NA, we

(a) A single *NounPP* sentence: singular subject with plural attractor (SP).

(b) Average *NounPP* SP: singular subject with plural attractor.

(c) Average *NounPP* PS: plural subject with singular attractor.

Figure 2: Average contributions for the NounPP corpus of Lakretz et al. (2019), defined as β_t^z / z_t. INIT denotes the contribution of the initial states. The picture depicts an asymmetry in the way that the model encodes singularity and plurality: while plural verbs depend strongly on the subject, for singular sentences this is not the case.

create 4 different conditions, based on the gender of the subject and object (FF, FM, MF, and MM). An example of an MF sentence would be *The father likes the woman, because he/she*. We sample from the set of entity descriptions to create 500 sentences per condition, for both corpus types.

4.3 Experiment types

Phrase contributions In the first type of experiment, we consider the contributions of different words in the input to a later prediction of the model. This allows us to compare the contributions of different words in the sentence and track which words the model uses to come to its prediction. We compute a phrase's contribution to a prediction at step t as β_t^z / z_t.

Pruning information In the second type of experiment, we focus on the model's *predictions*. In particular, we study how the model's predictions change when it is forced to consider only specific parts of the input, by disregarding all information that does not belong to the inside information of that part of the input. This allows us to quantify the extent to which a correct prediction does in fact stem from that phrase. For this experiment, we consider several different interaction sets, that differ in what is considered to be inside the contribution of the phrase: IN describes the direct contribution of some phrase, INTERCEPT the contribution of the model intercepts, and ¬INTERCEPT the contribution of some phrase without its intercept interactions.

5 Subject-verb Agreement

We now study what information the LM uses to achieve the high prediction accuracies that were reported by Lakretz et al. (2019).

5.1 Phrase contributions

For every word in a sentence, we compute the GCD contribution for all words preceding this word. We plot these contributions in a *decomposition matrix* (akin to the attention plots often seen in machine translation papers). Every cell of this matrix represents the contribution of an input x_i (row i) to an output y_j (column j). The complete decomposition of an output word y_j can thus be found in column j. The reported scores are the decomposed scores normalised by the total model logit, resulting in the relative contribution.

In Figure 2, we plot the average decomposition matrices for the SP and PS splits of the NounPP data set. While many interesting observations can be made here, we would like to focus on the final 2 columns that represent the decompositions of the correct and wrong verb in the sentence, and on the contribution of the subject to this verb. In the singular case (2b), this contribution is, surprisingly, relatively low: The correct verb prediction does not seem to depend solely on the syntactic subject, but stems from elements that lie outside the subject as well. For the plural case, this picture is strikingly different: The highest contribution now stems from the subject of the sentence. When considering the decomposition of the wrong verb (the final column) it becomes even more clear that contributions to a plural verb predominantly stem from a plural noun, whereas singular verbs receive strong contributions from non-numbered tokens as well. This quite remarkable difference provides the first evidence for one of our conclusions: A singular prediction acts as the default number for the model, and predicting a plural verb requires

			GCD		
Task	**C**	FULL	IN	INTERCEPT*	¬INTERCEPT
Simple	S	100	73.3 (91.3)	97.3 (100)	69.7 (86.3)
Simple	P	100	100 (100)	32.7 (7.7)	100 (100)

nounPP	PS	92.0	100 (100)	0.0 (0.0)	100 (100)
nounPP	PP	99.0	100 (99.3)	7.0 (0.5)	99.8 (100)
namePP	SS	99.3	97.7 (91.3)	99.4 (100)	76.2 (90.9)
namePP	PS	68.9	98.3 (98.2)	1.3 (0.0)	99.9 (99.9)

Table 1: Accuracies on various subject-verb agreement tasks of Lakretz et al. (2019). FULL denotes the full model accuracies. IN is the decomposition of the subject, INTERCEPT* only decomposes the gate intercepts of the model. ¬INTERCEPT takes no interactions with the intercepts into account. Singular conditions are denoted in green. $(\cdot)$ denotes accuracies of scores without decoder bias, i.e. Dh_t vs $Dh_t + b_d$.

some explicit evidence coming from the subject.

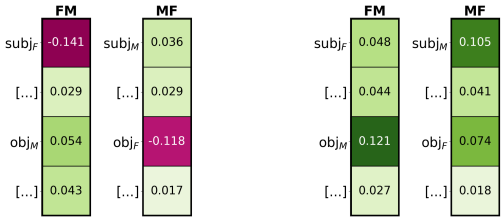
5.2 Pruning information

To quantify to which extent the model bases its prediction on the subject, we prune all information that is not directly related to the subject and repeat Lakretz et al.'s NA tasks. If the model prediction were based solely on the number of the subject, its accuracy should go up, as we filter out all potentially intervening or confusing information. If, on the other hand, the prediction of the verb is not causally linked to the subject, but the model is using heuristics that require the rest of the sentence, no increase in accuracy is to be expected. We show the results, along with the accuracy of the full model in Table 1.

These numbers show a strong causal relation between plural subjects and verbs: The number prediction accuracy for the IN decomposition goes up for all cases with a plural subject. This confirms our previous finding from the decomposition matrix, which showed a relatively high contribution of plural subjects to plural verbs, as well as the conclusion of Lakretz et al. (2019) that the model is in fact keeping track of syntactic structure.

When considering the singular subjects an interesting pattern emerges: The decomposition of sentences for which the intervening attractor has the same number leads to a *lower* accuracy. This confirms that the model is in fact basing its prediction for these conditions on information that lies outside the subject itself.

Intercepts When we only decompose with respect to the gate intercepts (INTERCEPT*, column 5) it turns out the model has an extreme preference for selecting singular verbs. Decomposing without the intercept interactions (NO INTERCEPT, column 6) leads (as expected) to opposite results: the decomposed model now has a strong preference towards plural verbs as the singular prediction no longer can depend on these intercepts. This further confirms that singular verbs are used as a default baseline, which is partly encoded in its intercepts. To predict plural verbs, on the other hand, some evidence is needed, which the model picks up correctly from the subject number.



Corpus frequency One would expect that due to the model's default number being singular, this class to be more encountered during training. This turns out not to be the case: in the model's training corpus the plural verbs of the NA tasks occurred over 5 times as often as their singular counterparts. This higher frequency is in fact represented in the decoder intercept, which is higher on average for plural verbs, but it is surprising that the LSTM weights encode a default for the minority class.

6 Anaphora-resolution and gender

For the NA-tasks, the full model accuracy provides evidence that the model can perform the task well; for anaphora resolution, it is not possible to create such accuracies based on the full model predictions alone. In this section, we therefore address two different questions: 1) *Does the model correctly resolve referents?* In other words: When the model generates a male or female pronoun, does it consistently do this based on male and female referents encountered earlier in the sentence, and 2) If the model correctly performs anaphora resolution, what types of interactions and information does it use to do so? In our analysis we furthermore consider the difference between sentences with unambiguously gendered referents with sentences in which the gender of the referents is ambiguous but contains a stereotypical male or female bias.

6.1 Phrase contributions

As the template that the sentences in our anaphora data set follow is not as rigid as those of the NA tasks, creating an averaged decomposition matrix for all words in the sentences does not result in a comprehensive picture. To evaluate whether the model links pronouns to referents of the correct gender, we subtract the referent contribution to *she* from that to *he*: $\beta^z_{he}/z_{he} - \beta^z_{she}/z_{she}$. A positive

(a) unambiguous (b) stereotypical

Figure 3: Average decomposed preference of *he* over *she*, calculated as the difference between the relative contributions: $\beta^z_{he}/z_{he} - \beta^z_{she}/z_{she}$. Positive values denote male preference, negative values female preference. Phrases occurring between subject and object, and object and pronoun are denoted with `[...]`.

difference then indicates this referent had a greater contribution towards predicting *he* than *she*, and a negative difference vice versa. Little difference indicates that the referent did not contribute much to the gender of the predicted pronoun.

Unambiguous referents In Figure 3a we plot this relative contribution difference for the two conditions in our data set that contain both an unambiguous female and male referent. It is evident that the model bases its prediction on a referent of the right gender: The female subjects and objects contribute more to the prediction of *she* (reflected by the negative purple cells) and the male subjects and objects more to the prediction of *he* (the positive green cells).

Interestingly, this effect is much stronger visible for the female connections. The reason for this can be found in the model intercepts; male preference is more strongly encoded in the intercepts of the decoder: *he* has an intercept of 7.75, *she* only 6.09. This enables the model to use this male prediction as a default, similar to how singular verbs acted as a default baseline for number prediction. Akin to number agreement the model thus needs to encounter sufficient evidence of an entity being female to prefer a female pronoun. In the next section we show that this male default is encoded in the gate intercepts as well.

Stereotypical referents The intermediate conclusion that the language model performs successful anaphora resolution on our experiment also provides us the opportunity to probe the gender biases of the model. To do so, we repeat the pronoun preference test on an adapted version of the WinoBias corpus (Zhao et al., 2018), in which all referents are only stereotypically considered to be male or female (e.g., *doctor* and *nurse*). The results, plotted in Figure 3b, show that the model is very susceptible to stereotypically male referents; these decomposed scores contain an even stronger male preference than for the unambiguous corpus. The stereotypically female referents, on the other hand, do not lead to a female preference, indicating that their contribution is not considered strong enough evidence by the model to prefer a female pronoun. All the intermediate tokens exhibit a slight male preference, a pattern that is comparable to the singular bias of the NA task. From these results we conclude that the model considers a stereotypically male job occupation to be male ("*doctors* are male"), whereas this does not hold for stereotypically female jobs.

6.2 Pruning information

Following our subject-verb agreement setup, we compare the predictions of our language model when it focuses only on the subject or object of the sentence. In Table 2, we show the percentage of cases in which *he* is assigned a higher decomposed score than *she*, for both unambiguously gendered referents and stereotypically gendered referents.

FULL In the first column of Table 2a, we see that if the sentence contains referents of the same gender (MM & FF), the full model prediction almost always prefers to use a pronoun with that same gender. When both a male and female referent are present, the model has a slight preference for generating a pronoun that matches with the *subject* of the sentence (which, interestingly, is the referent that is the furthest away from the pronoun). In the stereotypical case (Table 2b), the difference between male and female sentences for the FULL scores almost disappears, showing a predominant male pronoun preference. This shows that the model by default prefers a masculine pronoun, and only when it is provided sufficient evidence of a female entity it will consider predicting *she* (similar to number agreement).

Pruning When considering the decompositions with relation to the subject or object we see that the decomposed score of a male entity in all conditions always prefers a male pronoun. For female entities this effect is slightly obscured by the male bias of the decoder intercept: The accuracies without adding this intercept highlight that female contributions lead to a strong female preference. For the stereotypical corpus this female preference is

		GCD		
	FULL	SUBJECT	OBJECT	INTERCEPT*
MM	100	100 (93.2)	100 (97.8)	100 (93.2)
MF	58.6	100 (86.4)	47.2 (0.8)	100 (96.0)
FM	37.0	29.2 (0.6)	100 (97.2)	100 (98.0)
FF	1.2	77.2 (0.8)	88.8 (1.2)	100 (92.2)

(a) *%he>she*, unambiguous referents

		GCD		
	FULL	SUBJECT	OBJECT	INTERCEPT*
MM	100	100 (100)	100 (100)	100 (88.0)
MF	94.6	100 (99.6)	95.4 (84.0)	100 (84.8)
FM	88.8	90.6 (77.4)	100 (100)	100 (91.0)
FF	84.6	92.8 (75.6)	97.4 (84.0)	100 (89.2)

(b) *%he>she*, stereotypical referents

Table 2: Gender preference on the fixed and stereotypical gender corpora. Reported scores are the percentage of times *he* is preferred over *she*. The first column denotes the gender of the subject and object. FULL denotes the full model preference, SUBJECT the decomposed score of the subject phrase (including determiners), and OBJECT the decomposed object score. INTERCEPT* is the decomposed score with relation to the intercepts only. $(\cdot)$ denotes accuracies of scores without decoder bias, i.e. Dh_t vs $Dh_t + b_d$.

far less apparent, which is in line with the results of Section 6.1. When solely considering the intercept contributions it becomes clear once more that a strong male bias is encoded in them, an effect that is further amplified by the decoder intercept.

Corpus frequency For NA the default class turned out to be less frequent in the training corpus. For our gender setup it turns out the male default is in fact the majority class, with *he* being nearly 4 times more frequent than *she*. We conclude that the default class is not directly correlated to training frequency and likely depends on the phenomenon at hand, although an investigation incorporating a wider range of models would be needed to establish this.

7 Conclusion

We propose a generalised version of Contextual Decomposition (Murdoch et al., 2018) – GCD – that allows to study specifically selected interactions of components in an LSTM language model. This enables GCD to extract the contributions of a model's intercepts, or to investigate the interactions of a phrase with other phrases and intercepts.

We analyse two linguistic phenomena in a pretrained language model: subject-verb agreement, in which *number* plays a role, and anaphora resolution for which *gender* is important. Anaphora resolution in the context of language modelling had not been investigated thoroughly before, and our setup enables this at an unprecedented level.

We trace what information the language model uses to make predictions that require gender and number information and find that, in both cases, the model applies a form of *default reasoning*, by falling back on a default class (male, singular) and predicting a female or plural token only when it is provided enough explicit evidence. As such, the decision to predict masculine and singular words can not be traced back evidently to specific information in the network inputs, but is encoded by default in the model's weights.

Our setup and results demonstrate the power of GCD, which can be applied on top of any model without additional training. Our results bear relevance for work on detecting and removing model biases, and may clarify some of the issues that were raised by Gonen and Goldberg (2019), who argue that current bias removal methods only operate on a superficial level. GCD could also be used to aid a model in guiding it towards the right flow of information, which could be applied to a wide range of applications such as the interventions of Giulianelli et al. (2018). In the future, we plan on extending GCD to other types of language models, such as the currently popular attention-based models. Furthermore, we wish to expand the capacities of GCD by improving the gate factorisation with a better Shapley value approximator, such as those proposed by Lundberg and Lee (2017) or Ancona et al. (2019). The axiomatic approach of Montavon (2019) could provide further insight into how GCD relates to other explanation methods, and we are confident that combining the strengths of GCD with that of other frameworks will ultimately lead to a more *robust* and *faithful* insight into deep neural networks.

Abstract

Supertagging is a sequence prediction task where each word is assigned a piece of complex syntactic structure called a supertag. We provide a novel approach to multi-task learning for Tree Adjoining Grammar (TAG) supertagging by deconstructing these complex supertags in order to define a set of related but auxiliary sequence prediction tasks. Our multi-task prediction framework is trained over the exactly same training data used to train the original supertagger where each auxiliary task provides an alternative view on the original prediction task. Our experimental results show that our multi-task approach significantly improves TAG supertagging with a new state-of-the-art accuracy score of 91.39% on the Penn treebank supertagging dataset.

1 Introduction

A treebank for lexicalized tree-adjoining grammar (TAG) (Joshi and Schabes, 1997) consists of annotated sentences where each word is provided a complex tree structure called a supertag and the overall parse of the sentence combines these supertags into a parse tree. Supertagging is a task that learns a sequence prediction task from this annotated data and is able to then assign the most likely sequence of supertags to an input sequence of words (Bangalore and Joshi, 1999). Once the right supertag is assigned then parsing is a much easier task and may not even be needed for many applications where information about syntax is needed but a full parse is unnecessary.

Supertagging has been shown to be useful for both Tree Adjoining Grammar (TAG) (Bangalore and Joshi, 1999) and combinatory categorial grammar (CCG) (Hockenmaier and Steedman, 2007) parsing. In this paper we aim to improve the state-of-the-art for the task of learning a TAG supertagger from an annotated treebank (Kasai et al., 2018). We observe that supertag prediction does not take full advantage of the complex structural information contained within each supertag. Neural models have been used to learn embeddings over these supertags and thereby share weights among similar supertags. Friedman et al. (2017) provide tree-structured neural models over supertags which can learn interesting relationships between supertags but the approach does not lead to higher supertagging accuracy.

Our main contribution is to provide several novel ways to deconstruct supertags to create multiple alternative auxiliary tasks, which we then combine using a multi-task prediction framework and we show that this can lead to a significant improvement in supertagging accuracy.

Multi-task learning (MTL) (Caruana, 1997) learns multiple heterogenous tasks in parallel with a shared representation so that what is learned for one task can be shared for another task. In most cases the improvement is due to weight sharing between different tasks (Collobert and Weston, 2008; Luong et al., 2015). While some combinations may not provide any benefit in MTL (Bingel and Søgaard, 2017) and the improvements might be simply due to training on more data. However, MTL can be effective even when using large pretrained models (Liu et al., 2019).

Unlike most other work in multi-task learning with neural models we do not use different annotated datasets for each task. Similar to the approach to combining different representations for phrase structure parsing in (Vilares et al., 2019) we also construct multiple tasks from exactly the same training data set. Our approach is also distinct in that we take advantage of the structure of the supertags by deconstructing the tree structure implicit in each supertag.

Our experimental results show that our novel multi-task learning framework leads to a new

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 12–21
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

state-of-the-art accuracy score of 91.39% for TAG supertagging on the Penn Treebank dataset (Marcus et al., 1993; Chen et al., 2006) which is a significant improvement over the previous multi-task result for supertagging that combines supertagging with graph-based parsing (Kasai et al., 2018).

2 The Supertagging Task

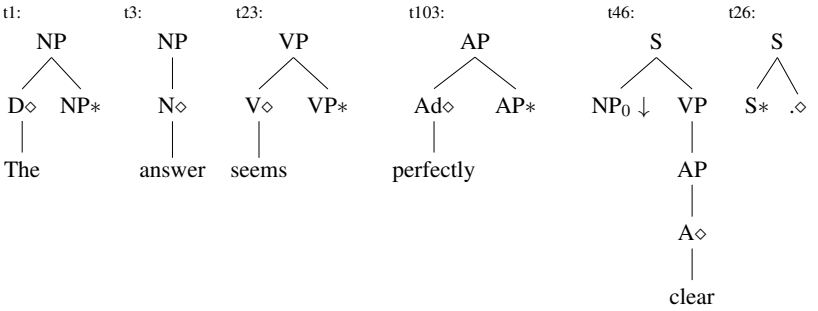
Supertagging assigns complex structural descriptions to each word in the sentence. The complex structural descriptions come from grammar formalisms that are more expressive than context-free grammars for phrase structure trees or dependency trees. In Tree Adjoining Grammar (TAG), the supertags are tree fragments that can express various syntactic facts such as transitive verb, wh- extraction, relative clauses, appositive clauses, light verbs, prepositional phrase attachment and many other syntactic phenomena. In combinatory categorial grammar (CCG) the supertags are types and their type-raised variants which also capture similar syntactic phenomena as in TAG supertags. Supertagging can be viewed as "almost parsing" (Bangalore and Joshi, 1999) and can provide the benefits of syntactic parsing without a full parser.

In this paper we focus on the TAG supertagging task, however, our proposed methods can likely be used to improve CCG supertagging as well. Supertagging is a relatively simple linear time sequence prediction task similar to part of speech tagging. Supertagging can be useful in many applications such as machine translation, grammatical error detection, disfluency prediction, and many others while being a much simpler task than full parsing.

In addition, for both TAG and CCG, supertagging is an essential first step to parsing so any improvements in supertag prediction will benefit parsing as well. For all these reasons, in this paper we focus on the supertagging task. TAG and CCG can be parsed using graph-parsing methods in $O(n^3)$ but the complexity of unrestricted parsing for both formalisms is $O(n^6)$ which is prohibitive on real-world data. Neural linear-time transition based parsers are still not accurate enough to compete with the state-of-the-art supertagging models or parsers that use supertagging as the initial step (Chung et al., 2016; Kasai et al., 2018).

An example of the supertagging task for Tree Adjoining Grammars (TAGs) is shown in Fig. 1. The $\downarrow$ symbol on a leaf node represents a substitution node which can be expanded by a tree rooted in the same label, e.g. t3 rooted in NP substitutes into the NP$\downarrow$ node in t46. The $*$ symbol on the leaf node of a tree t represents an adjunction node (also called a footnode) and signifies that t can be inserted into an internal node of another tree with the same label, e.g. t103 adjoins into the AP node in t46. The $\diamond$ node is called the *head* and represents the node where the word token is inserted into the tree. The table on the right shows how many different supertags are possible for each word in the sentence.

Three factors make supertagging a challenging task for sequence prediction: much more severe token level ambiguity when compared to other like part-of-speech tagging, a large number of distinct supertag types (4727 distinct supertags in our dataset, including an unknown supertag) and a complex internal structure for each supertag.



3 Baseline Supertagging Model

For our baseline supertagging model we use the state-of-the-art model that currently has the highest accuracy on the Penn treebank dataset (Kasai et al., 2018). For the supertagging model the main contribution of Kasai et al. (2018) was two-fold: the first was to add a character CNN for modeling word embeddings using subword features, and the second was to add highway connections to add more layers to a standard bidirectional LSTM. The output layer was a standard multi-layer perceptron that had a softmax output over the set of supertags. Another extension to the standard sequence prediction model in Kasai et al. (2018) was to combine supertagging with graph-based parsing.

In this paper, we focus on the supertagging model and compare only on supertagging accuracy. The neural model for supertagging that we use as a baseline uses graph-based parsing as an auxiliary task and has the current highest accuracy score on the Penn treebank (90.81%). The model has three main components: the input layer, the bidirectional LSTM component, and the output layer which computes a softmax over the set of supertags. The input to the model is a sequence of words and the output is a sequence of supertags, one per word, which makes it a standard tagging aka sequence prediction task.

3.1 Input Layer

Each word in the input sequence is converted into a word embedding in the input layer. Following

Token	#supertags
The	5
answer	14
seems	20
perfectly	5
clear	32
.	16

Figure 1: An example that explains the supertagging task for Tree Adjoining Grammars (TAGs). For the sentence "*The answer seems perfectly clear .*" the correct supertag for each word is shown above. The table on the right shows how many different supertags are possible for each word in the sentence. See Section 2 for more details on the notation used to define the supertags and how the supertags can be combined to form a parse tree.

(Kasai et al., 2018) we use two components in the word embedding:

- a 30-dimensional character level embedding vector computed using a char-CNN which captures the morphological information (Santos and Zadrozny, 2014; Chiu and Nichols, 2016; Ma and Hovy, 2016; Kasai et al., 2018). Each character is encoded as a 30-dimensional vector, and then we apply 30 convolutional filters with a window size of 5. This produces a 30-dimensional character embedding.

- a 100/200/300 size word embedding which is initialized using GloVe (Pennington et al., 2014). For words that do not appear in GloVe, we randomly initialized the word embedding.

A start of sentence token and an end of sentence token is added into the beginning and ending position of each sentence, but is not included in the computation of loss and accuracy.

Unlike (Kasai et al., 2018) we do not use predicted part of speech (POS) tags as part of the input sequence. In our experiments, the improvement was negligible and there was a significant overhead of having to do part of speech predictions at test time.

3.2 BiLSTM Layer

The core of this base model is a bidirectional recurrent neural network, in particular a Long Short-Term Memory neural network (Graves and Schmidhuber, 2005). For the hyperparameters, we use the settings in Kasai et al. (2018) in order to ensure a fair comparison.

Unlike (Kasai et al., 2018) we do not use highway connections in our model. We did experiment with the addition of highway connections but we found no improvement in accuracy over the baseline BiLSTM-only model with a significant increase in training time.

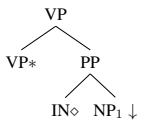
The bidirectional representation has 1024 units, a combination of the 512 forward and backward units each. Dropout layers (Gal and Ghahramani, 2016; Srivastava et al., 2014) are inserted between the input and BiLSTM layer, between BiLSTM layers, and between recurrent time steps. The dropout rate used was 0.5. We used 2-3 BiLSTM layers. Kasai et al. (2018) provide some reasons why > 3 layers do not provide any additional accuracy even with highway connections.

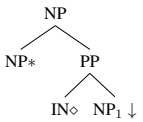
3.3 Output Layer

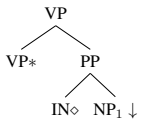
We concatenate hidden vectors from both directions of the last layer of BiLSTM and pass it into a multilayer perceptron (MLP). In practice a single layer perceptron performs just as well in this task. The number of input neurons of the single layer perceptron equals 1024 (2×512) and the output vector size equals the number of labels for each specific task: 4727 for the main supertagging task.

4 Deconstructing Supertags

The error analysis of our baseline BiLSTM model is shown in Fig. 1. We observed some consistent ways in which the baseline model confused the correct supertag with the incorrect one. We also observed that the baseline BiLSTM model can achieve over 97% 3-best accuracy on the supertagging task. This means it should be possible to boost the accuracy by rescoring the alternatives that already exist in the n-best output of the baseline supertagger. Rather than a re-ranking frame-







Prediction	Ground Truth	#times in dev
t2: 	t36: 	194
tCO: CO◇	t13: 	156
t4: 	t13: 	144

Table 1: The top-3 errors made by the state-of-the-art Bi-LSTM supertagger. tCO stands for a co-head in the case where a supertag has multiple heads. One example is a sentence fragment like *pull it from the marketplace* which contains a multi-word predicate *pull ... from*; *pull* is the V◇ head of tree t531 which has a IN^c node where tCO (headed by *from*) is inserted.

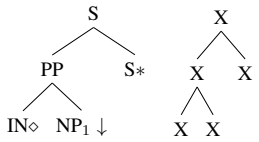
work we used a multi-task learning framework in order to boost the scores of correct supertags over the error-prone supertags. The auxiliary tasks we created based on our error analysis are as follows.

4.1 Auxiliary Tasks

4.1.1 HEAD

Consider the trees t2 and t36 in Table 1. t2 is headed by a noun head N and t36 is headed by an adjective A. The label of the head node is a useful auxiliary task for disambiguation. We define a function HEAD(t) to get the head node (marked by a diamond) of supertag t. There are 29 distinct HEAD labels.

4.1.2 ROOT

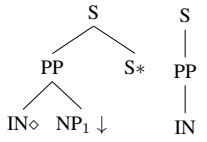


Consider the trees t4 and t13 in Table 1. t4 modifies an NP node while t13 modifies a VP node. This is a case of preposition attachment ambiguity. The label of the root node is a useful auxiliary task for disambiguation. We define a function ROOT(t) to get the root node of supertag t. There are 48 distinct ROOT labels.

4.1.3 TYPE

Consider the trees tCO and t13 in Table 1. tCO is a supertag that does not use adjunction (this type of supertag is called an initial tree). In contrast, t13 modifies an internal VP node in another supertag (this type of supertag is called an auxiliary tree). In addition a left auxiliary tree modifies from the left while a right auxiliary tree modifies from the right. To make this task more sensitive we also include the node label of the root (for initial trees) or footnode which is the node marked with $*$ (for left/right auxiliary trees). We define a function TYPE(t) to obtain the type of each supertag. There are 67 distinct types.

4.1.4 SKETCH



In many cases, the overall shape of the supertag is useful for disambiguation, ignoring the node labels. The following example keeps the tree structure of the supertag but removes the node labels:

Tree sketches help disambiguation (see t81 in Table 5). We define a function SKETCH(t) that returns the sketch. There are 602 distinct supertag sketches.

4.1.5 SPINE

The spine of a supertag is the path from the root node to the head node (marked by ◇). The following example keeps only the path from root to head and produces a spine supertag:

Spine supertags are helpful for disambiguation as well (see t132 in Table 5). We use a function SPINE(t) to return the spine of supertag t. There are 1372 distinct supertag spines.

4.2 Multi-task Framework

Unlike most other work in multi-task learning with neural models we do not use different datasets for each task. We use exactly the same training data set but we construct multiple tasks with alternate output labels by automatically deconstructing the supertags (the output labels in the original task). These alternate output labels are easier to predict than the full set of supertags, and these new output labels are related to the original supertag in a linguistically relevant way. As a result, we train on the same training set but with alternate output labels, each forming a different task. We then combine these multiple tasks in order to improve the performance in the original supertagging task.

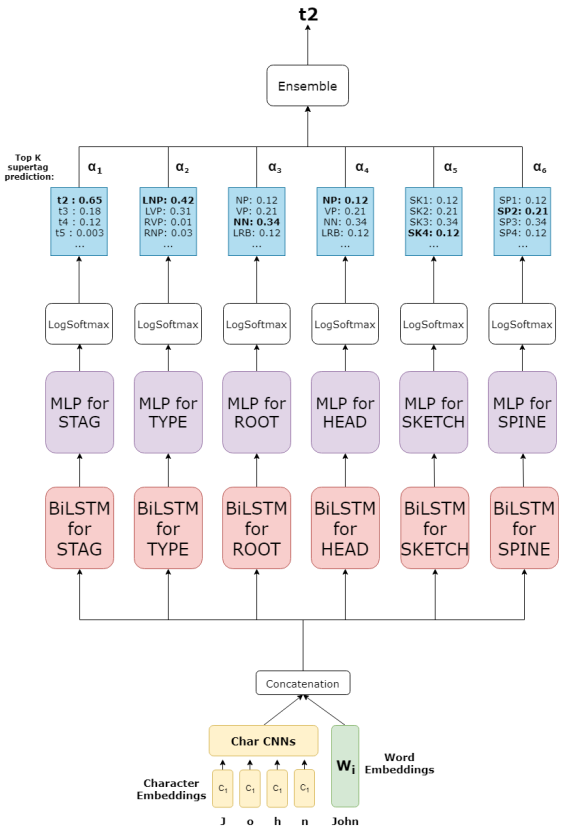


Figure 2: The prediction procedure of combining models trained on separate tasks

The usual criticism of a fair comparison between multi-task and single-task learning is that the multi-task setting simply uses more labeled data instances (typically with different data sources) and as a result a fair comparison between a multi-task and a single-task setting should involve large pre-trained models trained using a language modelling objective (such as ELMO (Peters et al., 2018) or BERT (Devlin et al., 2018)). In our case, because we re-use the same training set for multi-task learning, we have made sure our experimental settings exactly match the previous best state-of-the-art method for supertagging (Kasai et al., 2018) and we use the same pre-trained word embeddings to ensure a fair comparison.

We train six different neural sequence prediction models **independently** on the supertagging task, root node prediction (ROOT), head node prediction (HEAD), tree type prediction (TYPE), tree sketch prediction (SKETCH) and tree spine prediction (SPINE) tasks. For each task, we use the state-of-the-art baseline supertagging model as defined in Section 3. The only change is that the output size for softmax is changed to reflect the number of output labels in each task. We obtain very high accuracies for each of the tasks. For example, on the dev set we obtain the following accuracies: ROOT = 97.04%, HEAD = 93.37%, TYPE = 93.14%, SKETCH = 93.74% and SPINE = 91.00%.

We train the model, including the word embedding (which is initialized using a pre-trained embedding) and character-level CNNs by optimizing the negative log-likelihood of the predicted sequences of output labels. The output labels for each task is different: supertag, root node, head node, tree type, sketch, spine. Training is done using minibatches. The main hyperparameters are as follows: we use the ADAM optimizer with a batch size of 100 and learning rate $\ell = 0.001$ (Kingma and Ba, 2015). After every training epoch, we evaluate the model on the dev set, if the accuracy on dev set has not been improved for five consecutive epochs, training stops. The maximum number of epochs is 70. After obtaining the best model trained with $\ell = 0.001$, we further fine-tune the best model using $\ell = 0.0001$ for at most 10 more epochs. By conducting this step, we have seen 0.1% to 0.2% accuracy improvement depending on the task.

After obtaining the best trained model on each of the multiple tasks we combine the multiple tasks together in order to create a decoder for the supertagging task.

We first run the baseline supertagger to obtain the distribution P_{STAG} and using this distribution we select the top-K output supertags for each word in each sentence in the dev or test data. We experiment with different values of K but we know that even K=3 gives 97% accuracy for the supertagging task. For each dev or test sentence we also compute the output softmax distributions for each task, P_{HEAD}, P_{ROOT}, P_{TYPE}, P_{SKETCH}, P_{SPINE}. Each of these probabilities are defined as a sequence prediction task over the auxiliary tasks using the functions defined in Section 4.1.

$$
\begin{aligned}
P_{\text{HEAD}}(t) &= P(\text{HEAD}(t)) \\
P_{\text{ROOT}}(t) &= P(\text{ROOT}(t)) \\
P_{\text{TYPE}}(t) &= P(\text{TYPE}(t)) \\
P_{\text{SKETCH}}(t) &= P(\text{SKETCH}(t)) \\
P_{\text{SPINE}}(t) &= P(\text{SPINE}(t))
\end{aligned}
$$

We compute the argmax sequence of supertags $t_1^*, t_2^*, \ldots, t_T^*$ by scoring each supertag t_i^* individ-

ually from the top-K list by combining the probabilities from the different tasks as follows:

$$t_i^* = \arg\max_{t_i \in S} \quad (1)$$

$$\alpha_1 P_{\text{STAG}}(t_i) + \alpha_2 P_{\text{HEAD}}(t_i) \quad (2)$$

$$+\alpha_3 P_{\text{ROOT}}(t_i) + \alpha_4 P_{\text{TYPE}}(t_i) \quad (3)$$

$$+\alpha_5 P_{\text{SKETCH}}(t_i) + \alpha_6 P_{\text{SPINE}}(t_i) \quad (4)$$

S is the top-K set of supertags for each word in the input sequence. The hyperparameters α_i can be tuned. However we found in our experiments that the results were not very sensitive to the values, and the uniform distribution over all the tasks performed the best. The model and decoding step for our multi-task model is shown in Fig. 2. We also experiment with a commonly used multi-task model where some or all of the components are shared between the different (unlike our approach)..

5 Dataset

We use the dataset that has been widely used by previous work in supertagging and TAG parsing (Bangalore et al., 2009; Chung et al., 2016; Friedman et al., 2017; Kasai et al., 2017, 2018). We use the grammar and the TAG-annotated WSJ Penn Tree Bank extracted by Chen et al. (2006). As in previous work, we use Sections 01-22 as the training set, Section 00 as the dev set, and Section 23 as the test set. The training, dev, and test sets comprise 39832, 1921, and 2415 sentences; 950028, 46451, 56683 tokens, respectively.

The TAG-annotated version of Penn treebank (Chen and Shankar, 2001) includes 4727 distinct supertags (including an unknown supertag) and the grammar file of all supertags is downloaded from `http://mica.lif.univ-mrs.fr/`. There are 69 auxiliary tree TYPEs, 40 distinct types of ROOT node and 30 different types of HEAD node, 602 tree SKETCHes and 1372 tree SPINEs.

6 Results and Discussion

For our experiments, we implemented all of the models we discussed above in PyTorch (Paszke et al., 2017). We have various hyperparameters and Table 2 shows the results obtained from the different model configurations which were described in Section 3. The table also includes the results from the multi-task model and decoder described in Section 4. We experiment with pretrained GloVe word embeddings of three different sizes: 100, 200 and 300.

With our multi-task approach, all base models gain significant improvements compared to a single supertagging base model between 0.4% to 0.65%. We also varied the parameter K which picks the top-K supertags from the baseline model for use with the multi-task model. Table 3 that increasing K helps up to a point. After K=10 there is no further improvement.

We obtain a new state-of-the-art result of 91.39% which is significantly better than the 90.81% result which combines supertagging with the parsing task and so is using more labeled training information used by our supertagger models.

Table 4 shows the result of task ablation for each task. We can see that adding a new task always improves the results. The best result is obtained by using all five auxiliary tasks.

We computed a significance score on the accuracy of our best model BiLSTM3+CNN+GloVe200 with and without multi-task learning. On the dev set, using McNemar's significance test we found that the multi-task model is significantly better than the baseline model with a p-value of 0.0062; on the test set, the p-value is 0.0064.

We evaluated our own implementation of the baseline BiLSTM-only model and even with highway connections we only obtained 89.25% on the dev set compared to the built-in BiLSTM implementation in Pytorch (without highway connections) which obtains 89.94%.

6.1 Task Contribution

Table 5 shows some examples about how each of auxiliary tasks can help in the correction of supertag prediction. Examples of each task are selected if a considerable number of predictions of each example are corrected after applying the multi-task model.

While the multi-task model can correct many wrong predictions made by the baseline model, the multi-task model may also override some correct predictions.

The first row is an example of the prediction of head node that helps differentiate two similar supertags, t2 and t36. In the dev set, there are 24 words of which ground truth supertags are t2, wrongly predicted as t36 by a single base model; 25 words of which ground truth supertags are t36, wrongly predicted as t2. All of those words are

Model	Multi-task	Dev	Test
BiLSTM3+HW+CNN+POS+GloVe100 (Kasai et al., 2018)	-	90.45	90.81
BiLSTM2+GloVe100	No	89.11	-
	Yes	89.67	-
BiLSTM2+CNN+GloVe100	No	89.45	-
	Yes	90.12	-
BiLSTM3+GloVe100	No	89.41	-
	Yes	90.02	-
BiLSTM3+CNN+GloVe100	No	89.83	-
	Yes	90.41	-
BiLSTM3+CNN+GloVe200	No	89.94	-
	Yes	**90.55**	**91.37**
BiLSTM3+CNN+GloVe300	No	89.91	-
	Yes	90.45	-
Shared BiLSTM layer (BiLSTM3+CNN+Glove200)	No	90.11	90.83
	Yes	90.11	90.83

Table 2: Supertagging task results. The number after BiLSTM represents the number of BiLSTM layers; CNN refers to the word embedding model using character-level CNN; the number immediately after GloVe represents the dimension of pre-trained GloVe word vectors. HW in Kasai et al. (2018) refers to highway connections, and POS refers to the use of predicted part-of-speech tags as inputs. We do not use HW or POS in our models as they do not provide any benefit.

Top-K	Dev	Test
Top-3	90.55	91.37
Top-5	90.58	91.38
Top-10	**90.58**	**91.39**
Top-20	90.58	91.39

Table 3: Change in accuracy as K is increased when choosing Top-K supertags for rescoring. The model used is BiLSTM+CNN+GloVe200.

correctly predicted by the multi-task model. The ROOT, TYPE, SKETCH and SPINE are all the same for t2 and t36, the only difference is the HEAD value, **N** for t2 and **A** for t36. The model for the HEAD task correctly predicts the head node of those words which is further improved using our multi-task approach.

The second row demonstrates how the tree sketch can help discriminate supertags. t81 and t27 have exactly the same ROOT, HEAD, SPINE (S-VP-V) and TYPE (Init), the only difference between these two supertags is the tree structure.

The third to fifth rows are examples of the effect of multiple auxiliary tasks in getting the prediction right. The third row is an example of the prediction of TYPE and SKETCH that can help differentiate supertags. The TYPE of t3 is **Init**, while t38 has TYPE **Left+NP**. They also have different tree sketches. There are 11 words of which supertags are wrongly predicted as t3 by a single supertagging model, but correctly predicted as t38 by the multi-task model; also, 3 words of which supertags are wrongly predicted as t38 by a single supertagging model, but correctly predicted as t3 by the multi-task model.

The forth row is an example of how the prediction of the ROOT can help differentiate supertags. The ROOT of t3 is **NP**, while t18 has ROOT **N** (N is also its head node). For the last row, t132 and t20 have the same root node(S), head node(Punct) and tree type (Right+S) but they are different in the tree spine (**S-Punct** for t20 and **S-PRN-Punct** for t132) and SKETCH. The joint effort of various models plays a significant role in getting the prediction right.

Table 5: Some examples of how the deconstructing of base models correct the prediction made by the supertagging model.

et al., 2015; Lewis et al., 2016; Xu, 2016; Vaswani et al., 2016) have shown substantial improvement in performance, but the supertagging models are all quite similar as they all use a bi-directional RNN feeding into a prediction layer. Structural features of supertags are heavily used in pre-neural statistical parsing methods (Bangalore et al., 2009) and proved to be useful. The use of supertag structure was explored in (Friedman et al., 2017) where they adopt grammar features into a tree-structured neural model over the supertags but this model was unable to beat the state-of-the-art. (Kasai et al., 2018) combines supertagging with parsing which does provide state-of-the-art accuracy but at the expense of computational complexity.

Kasai et al. (2017) extends the BiLSTM model with predicted part-of-speech tags and suffix embeddings as inputs, then Kasai et al. (2018) further extends the BiLSTM model with highway connection as well as character CNN as input, and jointly train the supertagging model with parsing model and this work had the state-of-the-art accuracy before our paper on the Penn treebank dataset. Friedman et al. (2017) investigated a recursive tree-based vector representation of TAG supertags, but while their model can learn useful facts about supertags, about how one can be related to another, there was no performance improvement as a result of their model on the supertagging task. Xu et al. (2015) uses RNN for the CCG supertagging task, Lewis et al. (2016) adopted the LSTM structure into this task, while Vaswani et al. (2016) also introduced another variation of Bi-LSTM into this task. Xu (2016) then proposed an attention-based Bi-LSTM supertagging model.

8 Conclusion

In this paper we have introduced a novel multi-task framework for the TAG supertagging task. The approach involved a novel multi-task learning framework which led to a new state-of-the-art accuracy score of 91.39% for TAG supertagging on the Penn treebank dataset.

Our multi-task prediction framework is trained over the exactly same training data used to train the original supertagger where each auxiliary task provides an alternative view on the original pre-

diction task.

In the future we would like to explore further tasks to integrate into our multi-task sequence prediction framework. We also believe that the idea of our multi-task framework can be applied into similar tasks such as CCG supertagging task of which the labels themselves contains the latent information. We would also like to investigate how to semi-automatically generate new tasks which can be of further help in the multi-task setting.

Abstract

We present a method for applying a neural network trained on one (resource-rich) language for a given task to other (resource-poor) languages. We accomplish this by inducing a mapping from pre-trained cross-lingual word embeddings to the embedding layer of the neural network trained on the resource-rich language. To perform element-wise cross-task embedding projection, we invent locally linear mapping which assumes and preserves the local topology across the semantic spaces before and after the projection. Experimental results on topic classification task and sentiment analysis task showed that the fully task-specific multilingual model obtained using our method outperformed the existing multilingual models with embedding layers fixed to pre-trained cross-lingual word embeddings.[1]

1 Introduction

Deep neural networks have improved the accuracy of various natural language processing (NLP) tasks by performing representation learning with massive annotated datasets. However, the annotations in NLP depend on the target language as well as the task, and it is unrealistic to prepare such extensive annotated datasets for every pair of language and task. As a result, we can only obtain an accurate model for a few resource-rich languages such as English.

To overcome this problem, researchers have attempted to make models trained with massive annotated datasets in a resource-rich language (hereafter, *source language*) applicable to a resource-poor language (*target language*) that have no annotated datasets (Ruder et al., 2019) (§ 2). These methods utilize language-universal word representations, namely cross-lingual word embeddings, to absorb the differences among languages in the vocabularies of neural network models; specifically, these *multilingual models* are trained with embedding layers fixed to pre-trained cross-lingual word embeddings. However, because those embedding layers are not optimized for the target task, the resulting model cannot exploit the true potential of representation learning, as demonstrated by Kim (2014) and our experimental results (§ 5.1).

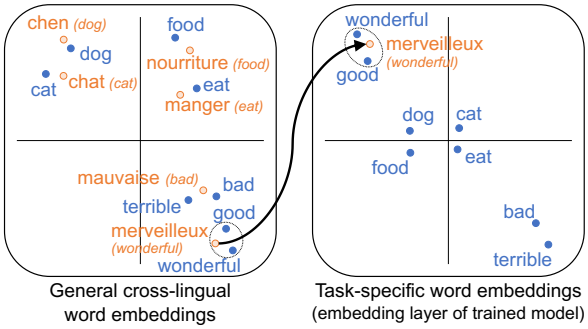

Figure 1: Locally linear mapping for sentiment analysis task. The relationship between "merveilleux (wonderful)" and its neighboring English words, "wonderful" and "good," are preserved after projection.

We propose methods of projecting pre-trained cross-lingual word embeddings to word embeddings of a *fully* task-specific neural network all of whose parameters are optimized to the training data in a source language, to realize *fully task-specific multilingual model* (§ 3). In addition to naive linear projection, we present an element-wise projection method inspired by locally linear embeddings used for dimension reduction (Roweis and Saul, 2000). This method is built on the assumption that local topology is preserved between the semantic spaces of word embeddings in two NLP tasks; that is, *adequately close* words in pre-trained cross-lingual word embeddings will have similar representation even in task-specific semantic space (Figure 1). We first represent the

general cross-lingual word embedding of a word in the target language by weighted linear combinations of general cross-lingual word embeddings of k neighboring words in the source language. We then use the weights to compute a task-specific word embedding of the target word as a linear combination of task-specific word embeddings of the k neighboring source words (§ 3.2).

We evaluate our method on topic classification and sentiment analysis tasks (§ 4). We first obtain a task-specific neural network using annotated corpora in the source language (English) and then induce task-specific cross-lingual word embeddings for the target languages to apply the accurate task-specific neural network to those languages. Experimental results demonstrate that our method has improved the classification accuracy of the multilingual model (Duong et al., 2017) in most of the task-language pairs (§ 5).

Our contributions are as follows:

- We established **a method of obtaining fully task-specific multilingual models** by learning a cross-task embedding projection (§ 3).
- Our **cross-task projection is simple and has an analytical solution** with one hyperparameter; the solution is a global optima (§ 3.2).
- We **confirmed the limitation of the traditional multilingual model** with embedding layers fixed to pre-trained cross-lingual word embeddings (§ 5.1).
- We **showed the effectiveness of our method** over the existing models (§ 5.2).

2 Related work

Lack of resources in resource-poor languages has been a deeply rooted problem in NLP, and there have been many pieces of researches contributed to mitigating this problem by transferring models across languages.

Multilingual models using parallel corpora An intuitive approach to realize the cross-lingual transfer of a model is to utilize machine translation by either translating the training set or the model input (Wan, 2009). Instead of translating, Meng et al. (2012) leverage a parallel corpus of the source and target languages to obtain cross-lingual mixture model to bridge the language gap. Xu and Wan (2017) also utilize parallel corpus with word alignment to train a multilingual model for sentiment analysis task. While some of these methods do not rely on an annotated corpus in the target language, they heavily rely on cross-lingual resources such as parallel corpora, and thus, are not applicable to the resource-poor languages.

Multilingual models with cross-lingual word embeddings Another method to obtain multilingual models is to fix the embedding layer of a neural network to pre-trained cross-lingual word embeddings. Many existing pieces of researches implemented this for various tasks in unsupervised senario (Duong et al., 2017; Can et al., 2018) where no annotated corpus is available in the target language as ours and supervised scenario (Pappas and Popescu-Belis, 2017; Upadhyay et al., 2018) where a small annotated corpus is available in the target language. Another study enhanced this method by employing language-adversarial networks (Chen et al., 2018). These methods do not induce task-specific word embeddings, thereby failing to exert true potential of neural networks, as we confirm in § 5.

Multilingual models with character embeddings Several studies utilize character level embeddings shared across languages to obtain multilingual models (Kim et al., 2017; Yang et al., 2017). An obvious weak point of these methods is that they do not apply to distant language pairs with different alphabets. In contrast, our method only relies on cross-lingual word embeddings which are obtainable regardless of the alphabets of the languages (Artetxe et al., 2018).

Task-specific word embeddings Few efforts have been previously made to obtain cross-lingual task-specific word embeddings. Gouws and Søgaard (2015) obtain task-specific cross-lingual word embeddings by constructing a task-specific bilingual dictionary, which defines "equivalent classes" designed for the given task instead of equivalent semantics. Although they successfully obtained task-specific cross-lingual word embeddings for POS tagging and supersense tagging tasks, the open problems are how to define a task-specific bilingual dictionary for many of other tasks, and cost of developing such resources.

Feng and Wan (2019) exploit multi-task learning to induce cross-lingual task-specific word embeddings for sentiment analysis task. This method is tailored for the sentiment analysis task and thus, not applicable to other tasks.

3 Fully task-specific multilingual model

Our method first learns a neural network model by optimizing to the annotated corpus in the source language. It then induces a projection from the semantic space of general cross-lingual word embeddings to the semantic space of the optimized embedding layer, to make the model applicable to languages other than the source language.

3.1 Framework

The entire framework of obtaining a fully task-specific multilingual model is as follows:

Step 1 (train task-specific neural network) First, we train a neural network $f(\cdot; X^{\text{spec}}, \theta)$ on an annotated corpus in the source language. The embedding layer, X^{spec}, of the resulting neural network consists of task-specific word embeddings of the source language, and θ is the collection of the other parameters. At this point, this neural network is only applicable to the source language since we do not have task-specific word embeddings Y^{spec} of the target language in the same semantic space as X^{spec}.

Step 2 (induce cross-lingual word embeddings) Next, we obtain general cross-lingual word embeddings $\{X^{\text{gen}}, Y^{\text{gen}}\}$ in the same semantic space from raw monolingual corpora where X^{gen} and Y^{gen} are cross-lingual word embeddings of the source and target languages, respectively. Without loss of generality, we assume that X^{gen} and X^{spec} are aligned so that X_i^{gen} and X_i^{spec} represent the same word. We utilize unsupervised cross-lingual word embeddings such as (Artetxe et al., 2018) that do not require any cross-lingual resources to maximize the applicability of our approach.

Step 3 (learn cross-task embedding projection) Then, we induce a cross-task projection ϕ that computes task-specific word embeddings of the target language Y^{spec} from the general cross-lingual word embeddings $\{X^{\text{gen}}, Y^{\text{gen}}\}$ obtained in Step 2 to the task-specific word embeddings of the source language X^{spec} obtained in Step 1. We explain the details of this core part in § 3.2.

Step 4 (obtain task-specific multilingual model) Finally, we replace embedding layer X^{spec} of the neural network $f(\cdot; X^{\text{spec}}, \theta)$ trained in Step 1 with Y^{spec} induced in Step 3 to obtain a task-specific neural network $f(\cdot; Y^{\text{spec}}, \theta)$ applicable to the target language.

3.2 Cross-task embedding projection

Here, we explain the detailed construction of our cross-task projection ϕ for cross-lingual word embeddings used in Step 3 in § 3.1. Given general cross-lingual word embeddings, X^{gen} and Y^{gen}, of the source and target languages and task-specific word embeddings X^{spec} of the source language, we compute task-specific word embeddings Y^{spec} of the target language in the same semantic space with X^{spec}. In what follows, we propose two simple methods to obtain such projection: a linear projection and a locally linear mapping.

Linear projection

One naive approach is to regard general and task-specific word embeddings as embeddings of two distinct languages and to exploit a mapping method developed for cross-lingual word embeddings (Mikolov et al., 2013).[2] Concretely, we train a transformation matrix W that maps general word embeddings Y^{gen} to task-specific word embeddings Y^{spec} by minimizing

$$\hat{W} = \arg\min_{W} \sum_{i=1}^{|V_X|} \left\| W X_i^{\text{gen}} - X_i^{\text{spec}} \right\|^2 \quad (1)$$

where $|V_X|$ is the vocabulary size of the source langauge. Then, we compute the task-specific word embeddings of the target language, $\hat{Y}^{\text{spec}}$;

$$\hat{Y}_i^{\text{spec}} = W Y_i^{\text{gen}}. \quad (2)$$

Locally linear mapping

A possible limitation of the above linear projection method is the lack of representation power. Due to the difference of topologies between the general and task-specific semantic spaces, our experimental results indicate that it fails to obtain precise cross-task embedding projection (§ 5).

Therefore, we introduce an element-wise mapping method inspired by locally linear embeddings (Roweis and Saul, 2000), a dimension reduction technique. Our method assumes that the local topology among nearest neighbors will be consistent between two NLP tasks (here, language modeling and the target task). In other words, synonyms will have a similar role across NLP tasks.

We build the cross-task projection as follows. First, for each word i in the target language, we

[2] Although orthogonal mapping (Xing et al., 2015) is reported to perform better for inducing cross-lingual word embeddings, it performed worse for our purpose in preliminary experiments probably due to the strong constraint.

take k nearest neighbors (words) in the source language, $\mathcal{N}_i^{\text{gen}}$, in the semantic space of the general cross-lingual word embeddings where k is a hyperparameter, and the cosine similarity is the metric. We next obtain the reconstruction weights, $\hat{\alpha}_{ij} \in \mathbb{R}$, that restore Y_i^{gen} as a linear combination of $X_j^{\text{gen}} \in \mathcal{N}_i^{\text{gen}}$ by optimizing

$$\hat{\boldsymbol{\alpha}}_i = \arg\min_{\boldsymbol{\alpha}_i} \left\| Y_i^{\text{gen}} - \sum_{j \in \mathcal{N}_i^{\text{gen}}} \alpha_{ij} X_j^{\text{gen}} \right\|^2 \quad (3)$$

with constraint of $\sum_j \alpha_{ij} = 1$. The solution to this optimization problem can be analytically given by using the method of Lagrange multipliers as:

$$\hat{\alpha}_{ij} = \frac{\sum_l (C_i^{-1})_{jl}}{\sum_j \sum_l (C_i^{-1})_{jl}} \quad (4)$$

where

$$C_{ijl} = \left(Y_i^{\text{gen}} - X_j^{\text{gen}}\right) \cdot \left(Y_i^{\text{gen}} - X_l^{\text{gen}}\right) \quad (5)$$

(see Appendix A for the detailed derivation). We can thereby find the global optima by this analytical solution with simple computation.

We then compute Y_i^{spec} using $\hat{\boldsymbol{\alpha}}_i$ by

$$Y_i^{\text{spec}} = \sum_{j \in \mathcal{N}_i^{\text{gen}}} \hat{\alpha}_{ij} X_j^{\text{spec}}, \quad (6)$$

assuming that the local topology among $\mathcal{N}_i^{\text{gen}}$ is preserved before and after the projection. The resulting Y^{spec} is in the same semantic space with X^{spec}. Setting a large $k = |\mathcal{N}_i^{\text{gen}}|$ in the projection, we can handle words in the target language that have no direct translations in the source language (*e.g.*, *amiga*, female friend in Spanish).

Hyperparameter search In general, we choose a hyperparameter that performs best on development data in the target task and language. However, since we assume that no annotated data is available in the target language, we cannot exploit development data in the target language.

To address this issue, we apply our cross-task projection to the *source* language with various hyperparameter k; namely, represent X_i^{gen} considering k nearest neighbors $X_j^{\text{gen}} (j \neq i)$. We then choose k with the best model performance with the resulting embeddings on the development data of the target task in the source language. In § 5.2, we report results with this language-universal, yet the task-specific method of tuning. We also report results of a language- and task-specific tuning method assuming a minimal development data in the target language in addition to a naive method of fixing $k = 1$, which is equivalent to the word-by-word translation. Furthermore, we investigate the effect of value k in details in § 5.3.

Language	train	dev.	test

4 Experimental setup

We conduct a series of experiments to evaluate our fully task-specific multilingual models (§ 3) obtained by our cross-task projections of cross-lingual word embeddings (§ 3.2). Our method is language- and task-independent and is applicable to various tasks where existing multilingual models are applicable. We adopted a topic classification task and a sentiment analysis task as the target tasks for evaluation in various languages.

Topic classification is the task of predicting the topic of a given document. For this task, we use English (en) as the source language, and Spanish (es), German (de), Danish (da), French (fr), Italian (it), Dutch (nl), Portuguese (pt), and Swedish (sv) as the target languages. We use the RCV1/RCV2 dataset (Lewis et al., 2004) for this task, following Duong et al. (2017). This dataset contains news articles in various languages with labels of four categories: Corporate/Industrial, Economics, Government/Social, and Markets.

For English dataset, we randomly chose 10,000 examples as test data, another 10,000 examples as development data, and the rest as training data. For the other languages, we randomly selected 1000 examples as test data, and another 1000 examples (for Danish, 100 examples) as development data, and the rest as training data. Among the development data, we randomly chose 100 samples as the development data for an alternative, language-specific tuning of k (§ 3.2). The summary of the resulting dataset is shown in Table 1.

Sentiment analysis is a task of predicting a polarity label of the writer's attitude for a given text. We design this task to be a three-class classification of positive, negative, and neutral labels. We use datasets from two domains of restaurant review and product review to conduct this experiment. In both domains, we consider the most resource-rich language, English (en), as the source language and other languages (Spanish (es), Dutch (nl), and Turkish (tr) for restaurant review domain, and German (de), French (fr), and Japanese (ja) for product review domain) as the target languages.

To train models in restaurant review domain, we use Yelp Review dataset[3] which consists of a set of restaurant reviews with numerical ratings in the range of 1-5 given by the reviewers. We label the reviews with ratings of 1 or 2 as negative, those with ratings of 4 or 5 as positive, and the rest with ratings of 3 as neutral. Then, we randomly chose 100,000 examples as test data, another 100,000 examples as development data, and the rest as training data. For evaluation in the target languages, we use a subset of ABSA dataset (Pontiki et al., 2016), which consists of restaurant reviews in English, Spanish, Dutch, and Turkish with annotation of a polarity label of positive, negative, or neutral to each sentence. For each language, we randomly chose 100 sentences as development data for the alternative, language-specific tuning of k (§ 3.2) and the rest as test data.

For experiments in the product review domain, we use Amazon Multilingual Review dataset[4] which consists of a set of product reviews in English, German, French, Japanese with numerical ratings given in the same manner as the Yelp Review dataset. We label the reviews in the same manner as the Yelp Review dataset. For English dataset, we randomly sample 100,000 examples as development data, other 100,000 examples as test data, and the remaining 6,731,166 examples as training data. For the other languages, we randomly chose 10,000 examples as development data, another 10,000 examples as test data, and the rest as training data. Among the development data, we randomly chose 100 examples as development data for the alternative, language-specific tuning of k. The summary of the resulting datasets is shown in Table 2.

Table 2: Number of examples for sentiment analysis.

General cross-lingual word embeddings were obtained using a state-of-the-art unsupervised method with self-learning framework (Artetxe et al., 2018).[5] This method takes monolingual word embeddings of two languages and learns a mapping between them to obtain cross-lingual word embeddings. For monolingual word embeddings, we used pre-trained word embeddings available online (Grave et al., 2018).[6] They are word embeddings with 300 dimensions obtained by applying subword-information skip-gram (Bojanowski et al., 2017) to the Wikipedia corpus.

Preprocessing We use the tokenizer of Europarl tools[7] to tokenize all datasets except for Japanese. For Japanese, we use MeCab v0.996[8] with IPA dictionary v2.7.0. After tokenization, the tokens are lowercased to match vocabularies of the pre-trained word embeddings.

Models To evaluate the impact of our task-specific word embeddings on multilingual models and to compare the two methods for the cross-task embeddings projections we proposed in § 3, we compare the following five models.

CLWE fixed trains a bag-of-embeddings model in the target language with its embedding layers fixed to the pre-trained cross-lingual word embedding. The model takes the dimension-wise average of all embeddings of input tokens into a feedforward neural network with one hidden layer. This model is analogous to (Duong et al., 2017) except that they use the summation weighted by $\texttt{tf} \cdot \texttt{idf}$.

Monolingual	0.879	0.857	0.838	-	-	-

Table 4: Classification accuracy of sentiment analysis task in cross-lingual settings. The underlined values indicate that, among the three trials, the worst model of **CLWE opt (LLM)** outperforms the best model of **CLWE fixed**.

CLWE fixed + NNmap adds two embedding-wise hidden layers to the original feedforward neural network in **CLWE fixed**. This is aimed at giving the network the capability of acquiring task-specific word embeddings by enhancing the representation of the network.

CLWE opt (LP) is **CLWE fixed** with embedding layer updated; we made this model cross-lingual by the linear projection (§ 3.2).

CLWE opt (LLM) is **CLWE fixed** with the embedding layer updated; we made this model cross-lingual by the locally linear mapping (§ 3.2). We report results with the three strategies to tune the hyperparameter k for cross-task projection.

Monolingual has the same network as **CLWE fixed** with the embedding layer updated; we trained the model with datasets in the same languages as testing. We present this result to show the upper bound of model accuracy.

The dimensions of all the layers of the above five models are 300, and they are all optimized by Adam optimizer (Kingma and Ba, 2014) for training. We conduct all experiments three times with different initialization of the model parameters and report the average accuracy, and hyperparameter tuning is conducted independently to each model.

5 Results

We evaluate the models in cross-lingual settings to confirm how well our method produces task-specific cross-lingual word embeddings (Table 3 and Table 4). Prior to reporting the results, we confirm the impact of task-specific word embeddings in neural networks through experiments in a monolingual setting in English (Table 5).

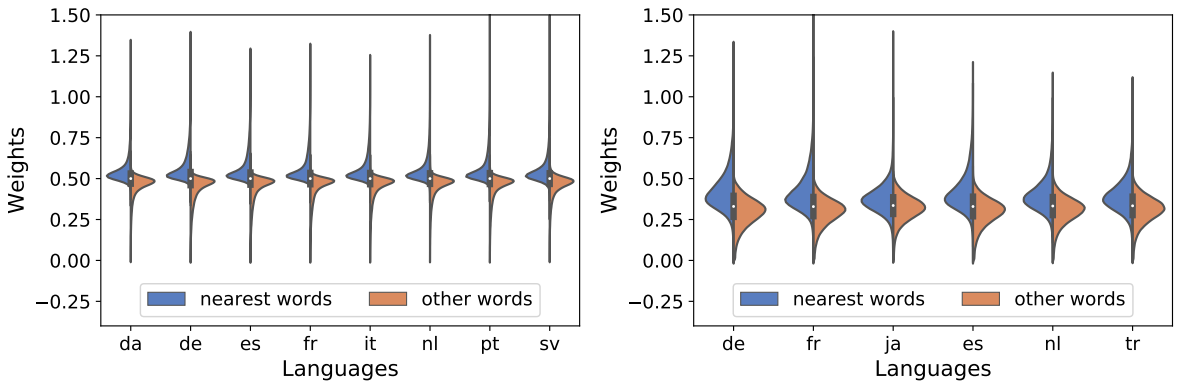
Table 6: Nearest neighbors of some **words** in the semantic space of general and task-specific word embeddings.

English by comparing **Monolingual** to **Monolingual fixed** which is the same network as **Monolingual** with the embedding layer fixed to general words embeddings. We show the results of topic classification and sentiment analysis tasks in Table 5. In both tasks, **Monolingual** outperformed **Monolingual fixed** with a wide margin, which indicates that task-specific word embeddings are indeed crucial to obtain better model performance. This result motivates us to learn task-specific cross-lingual word embeddings to exploit the fully task-specific neural network.



5.2 Performance of multilingual models

Table 3 and Table 4 report the classification accuracy of the models on topic classification and sentiment analysis, respectively. All models are trained in English and evaluated in the target languages. **CLWE opt** with hyperparameter k tuned on the source language successfully outperformed the two baselines, **CLWE fixed** and **CLWE fixed + NNmap**, in all task-language pairs except for English-German in the topic classification task and English-Japanese in the sentiment analysis task. This result indicates the importance of task-specific word representation in the multilingual model and that our projection successfully induced task-specific cross-lingual word embeddings. Although we gained some improvements by tuning k to the target language using the minimal development set in some configurations, the gains are smaller than the gains over the two baselines. This implies that k is more sensitive to the target task rather than the target language, which we discuss further in § 5.3.

In some languages, **CLWE fixed + NNmap** has even lower classification accuracy than **CLWE fixed**. We hypothesize that by having more layers, the model becomes more sensitive to the small difference in word representation, which means that the noise in pre-trained cross-lingual word embeddings affects on the model accuracy.

Comparing **CLWE opt (LLM)** to **CLWE opt (LP)**, we found that our locally linear mapping outperforms the linear projection method for a cross-task embedding projection. For some configurations, the performance of **CLWE opt (LP)** degrades significantly. These results indicate that the topology of the general and task-specific embedding spaces are so apart from each other that simple projection methods such as the linear projection are inappropriate. We will further discuss the difference in the topologies of the general and task-specific embedding spaces in § 5.3 by looking into nearest neighbors of some target words in the semantic space of general and task-specific cross-lingual word embeddings (Table 6).

In all configurations where sufficient dataset is available in the target languages, **monolingual** outperformed cross-lingual models with a wide margin. This indicates that there is still space for improvements in cross-lingual models.

(b) Sentiment analysis ($k = 3$)

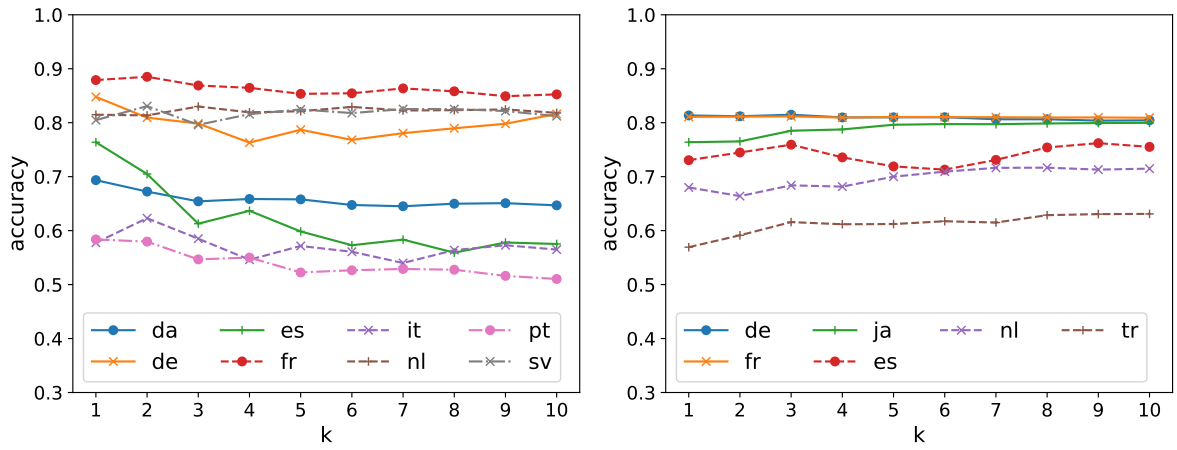
Figure 2: Distribution of the reconstruction weights $\hat{\alpha}$ for the nearest words of the target words and the other nearest neighbors.

5.3 Analysis

We conduct further investigation to gain a profound understanding of our method and the resulting task-specific cross-lingual word embeddings. We first analyze the task-specific cross-lingual word embeddings through nearest neighbors of some words. We next investigate the distribution of the reconstruction weights to see the impact of k nearest neighbors other than the nearest one. We then evaluate the sensitivity of the model accuracy to the value of k.

Properties of task-specific embeddings Here, we examine the properties of task-specific word embeddings obtained using our cross-task projection. For this purpose, we present nearest neighbors of frequent words in the tasks in various embeddings in English and French.

Table 6a shows nearest neighbors of "excellent," "terrible," and "economic" in the general word embeddings, and the embedding layer of the models optimized for the training data in English. In the general embeddings, the words are close to words that have similar semantic or syntactic while the task-specific word embeddings show different properties specific to the target tasks.



In the embedding layer optimized for topic classification, we found "economic" to be close to "imf (International Monetary Fund)" or "wto (World Trade Organization)." Even though they are semantically distinct, they all strongly indicate the Economy label. In contrast, the nearest neighbors of "excellent" and "terrible" are noisy since they do not contribute to the topic classification task.

The embedding layers optimized for sentiment analysis exhibit different properties. While the nearest neighbors of "excellent" and "terrible" are not semantically close, they all indicate positive and negative polarities in the respective domains. However, the nearest neighbors of "economic" are noisy as they do not contribute to the task.

Table 6b shows nearest neighbors of "excellent (*excellent*)," "terrible (*terrible*)," and "économie (*economy*)" in French; the general word embeddings (**General**) and the task-specific word embeddings obtained using our cross-task projection (**LLM**). **General** embeddings exhibit similar properties as English ones.

LLM embeddings of topic classification task have "fmi (*IMF; International Monetary Fund*)" and "conjoncture (*conjuncture*)" as nearest neighbors of "économie." This indicates that our cross-task projection successfully obtains word embeddings optimized for the task since they are strong signals of the Economy label. For sentiment analysis, the word embeddings obtained by our cross-task projection of Amazon dataset captures "extraordinary" and "parfaite," which strongly indicate positive polarity, as the nearest neighbors of "excellent" In contrast, the words strongly associated with negative polarity, "débile" and "stupide," are the nearest neighbors of "terrible" in the embedding space. These properties suggest that our cross-task projection successfully obtains task-specific cross-lingual word embeddings.

Distribution of the reconstruction weights To see how much the nearest neighbors for the target words contribute to the projection, we investigate the distribution of $\hat{\alpha}$ induced by Eq. 3. Figure 2

(a) Topic classification

(b) Sentiment analysis

Figure 3: Classification accuracy as a function of k in cross-task embedding projection.

shows the distribution of the absolute value of $\hat{\alpha}$ for the nearest neighbors of the target word and the other nearest neighbors. For this experiment, we used k tuned on the source language.

Even though the nearest words tend to have a slightly higher value of $\hat{\alpha}$ compared to the other nearest neighbor words, the difference is not so significant for most of the configuration. This observation indicates that all of the k-nearest neighbors contribute to the projection.

Sensitivity to hyperparameter k We proposed three strategies to tune the hyperparameter k of our locally linear mapping for cross-task embedding projection of cross-lingual word embeddings: tuning on the development data in the source language as described in § 3.2, preparing small development data (100 samples) in the target languages, or fixing $k = 1$. Revisiting results in Table 3 and Table 4, for the topic classification task, the classification accuracy of the models are consistent among all of the tuning methods (Table 3), while for the sentiment analysis task, fixing $k = 1$ yields lower classification acuracy (Table 4). Here, we conduct further analysis to gain a profound understanding of the effect of the value of k.

Figure 3 depicts the classification accuracy of the models on the test set while varying k in the topic classification task and sentiment analysis task. Across languages, a smaller value of k yields better performance for the topic classification task, while a larger value of k yields better performance for the sentiment analysis task. These results indicate that the best value of k is language-independent and thus, the tuning k for the development set of source language suffices to achieve good results.

6 Conclusions

We proposed a method to obtain a fully task-specific multilingual model without relying on any cross-lingual resources or annotated corpora in the target language by a cross-task embedding projection. Because a naive linear projection puts too strong assumption on the topologies of two embedding spaces, we present an effective method for the cross-task embedding projection named locally linear mapping. The locally linear mapping assumes and preserves the local topology across the semantic spaces before and after the projection. Experimental results demonstrated that the locally linear mapping successfully obtains task-specific word embeddings of the target language, and the resulting fully task-specific multilingual model exhibited better model accuracy than the existing multilingual model that fixes its embedding layer to general word embeddings.

We plan to evaluate our method on various NLP tasks, languages, and neural network models, and investigate the results to devise an adaptive method to tune k for individual words.

A Derivation of the locally linear mapping

Recall that X^{gen} and Y^{gen} represent general cross-lingual word embeddings of the source and target languages, respectively. Also, for each word i in the target language, we denote the set of its k nearest neighbors in the target language in the semantic space of the general cross-lingual word embeddings as $\mathcal{N}_i^{\text{gen}}$.

We reconstruct Y_i^{gen} as a linear combination,

$$\sum_{j \in \mathcal{N}_i^{\text{gen}}} \alpha_{ij} X_j^{\text{gen}}$$

where $\boldsymbol{\alpha}_i$ is the weight vector which we optimize. The reconstruction error is given as

$$\begin{aligned}
\epsilon &= \left\| Y_i^{\text{gen}} - \sum_{j \in \mathcal{N}_i^{\text{gen}}} \alpha_{ij} X_j^{\text{gen}} \right\|^2 \\
&= \left\| \sum_{j \in \mathcal{N}_i^{\text{gen}}} \alpha_{ij} \left(Y_i^{\text{gen}} - X_j^{\text{gen}} \right) \right\|^2 \\
&= \sum_{j \in \mathcal{N}_i^{\text{gen}}} \sum_{i \in \mathcal{N}_i^{\text{gen}}} \alpha_{ij} \alpha_{il} C_{ijl}
\end{aligned}$$

where $C_i \in \mathcal{R}^{k \times k}$ is the covariance matrix,

$$C_{ijl} = \left(Y_i^{\text{gen}} - X_j^{\text{gen}} \right) \left(Y_i^{\text{gen}} - X_l^{\text{gen}} \right).$$

We minimize this reconstruction error ϵ under the constraint of $\sum_{j \in \mathcal{N}_i^{\text{gen}}} \alpha_{ij} = 1$. Applying the method of Lagrange multiplier, we have

$$L = \sum_{j \in \mathcal{N}_i^{\text{gen}}} \sum_{i \in \mathcal{N}_i^{\text{gen}}} \alpha_{ij} \alpha_{il} C_{ijl} - \lambda \left(\sum_{j \in \mathcal{N}_i^{\text{gen}}} \alpha_{ij} - 1 \right).$$

We then solve $\frac{\partial L}{\partial \alpha_{ij}} = \frac{\partial L}{\partial \lambda} = 0$ to obtain

$$\hat{\alpha}_{ij} = \frac{\sum_l (C_i^{-1})_{jl}}{\sum_j \sum_l (C_i^{-1})_{jl}}.$$

The resulting value of $\hat{\boldsymbol{\alpha}}_i$ is then used to compute the task-specific word embedding of i as

$$Y_i^{\text{spec}} = \sum_{j \in \mathcal{N}_i^{\text{gen}}} \hat{\alpha}_{ij} X_j^{\text{spec}}$$

where X^{spec} is the tast-specific word embeddings of the source language.

Investigating Cross-lingual Alignment Methods for Contextualized Embeddings with Token-Level Evaluation

Abstract

In this paper, we present a thorough investigation on methods that align pre-trained contextualized embeddings into shared cross-lingual context-aware embedding space, providing strong reference benchmarks for future context-aware crosslingual models. We propose a novel and challenging task, Bilingual Token-level Sense Retrieval (BTSR). It specifically evaluates the accurate alignment of words with the same meaning in cross-lingual non-parallel contexts, currently not evaluated by existing tasks such as Bilingual Contextual Word Similarity and Sentence Retrieval. We show how the proposed BTSR task highlights the merits of different alignment methods. In particular, we find that using context average type-level alignment is effective in transferring monolingual contextualized embeddings cross-lingually especially in non-parallel contexts, and at the same time improves the monolingual space. Furthermore, aligning independently trained models yields better performance than aligning multilingual embeddings with shared vocabulary.

1 Introduction

Contextualized embeddings have been shown to achieve superior performance compared to static word embeddings in English (Peters et al., 2018; Devlin et al., 2019). Despite recent efforts to better understand their multilingual variants (Pires et al., 2019), leveraging these available pretrained contextualized embeddings to learn cross-lingual contextualized embeddings is still an under-explored area: past cross-lingual embedding alignment methods have mainly focused on static embeddings (Ruder et al., 2019). In this paper, we introduce a first study that investigates and compares different ways of aligning the pretrained contextualized embeddings. In particular, we make the comparisons focused on the following properties: (1) aligning contextualized embeddings at the level of word tokens versus word types; (2) different training signals: static dictionaries, word alignment, or sentence alignment from parallel data; and (3) aligning different model variants: aligning from independently trained models versus aligning embeddings from a multilingual model with shared vocabulary.

We evaluate the methods on a variety of context-aware tasks. Besides two previously established evaluation tasks (1) Bilingual Contextual Word Similarity (Chi and Chen, 2018) and (2) Sentence Retrieval (Conneau et al., 2017), we introduce a new task: Bilingual Token-level Sense Retrieval (BTSR). It is more challenging than the alternatives as it requires the accurate cross-lingual retrieval of contextualized words on the token level which are disambiguated both in the source and the target language using non-parallel contexts. We provide BTSR task data and run evaluations on two language pairs: English–Chinese (EN–ZH) and English–Spanish (EN–ES). The data and guidelines can be found at: https://github.com/qianchu/BTSR

Our main findings are as follows. (1) Using the average of the contextualized word representations as type-level anchors is effective and robust for aligning pre-trained contextualized embeddings cross-lingually, and can also improve the monolingual contextualized space as it brings the largest gains in English context-aware evaluation compared to results from aligning on other levels. (2) Using a dictionary with a few thousand entries is able to yield performance comparable to leveraging training signals from parallel corpora. (3) Aligning independently trained models performs better than aligning embeddings from a multilingual model trained with shared vocabulary.

2 Related Work

Cross-lingual Word Embeddings. We conduct our experiments using a popular projection-based approach that learns an orthogonal mapping between pretrained embeddings (Xing et al., 2015; Artetxe et al., 2016). The orthogonality of the mapping is crucial as it preserves monolingual invariance and is empirically proven to be more robust (Smith et al., 2017; Xing et al., 2015). This projection-based method can be applied post-hoc on pretrained monolingual embeddings with an exact analytical solution. Moreover, its performance is often competitive to that of jointly trained cross-lingual models using additional bilingual signals in the form of parallel or comparable corpora (Ruder et al., 2019; Glavaš et al., 2019).

However, projection-based cross-lingual embeddings are still predominantly concerned with static word embeddings (Glavaš et al., 2019; Vulić et al., 2019; Mohiuddin and Joty, 2019). Learning cross-lingual contextualized embeddings is still a large unexplored area with only two concurrent papers at the moment. First, Aldarmaki and Diab (2019) adopt the same projection-based approach as our paper to align contextualized embeddings on the token-level using parallel data. They find that context-aware mapping using parallel data outperforms context-independent mappings from static dictionaries on a parallel Sentence Retrieval task. Second, Schuster et al. (2019) introduce anchor embeddings as the average of contextualized embeddings of a word to perform alignment for contextualized models, and show its effectiveness in cross-lingual dependency parsing. These two studies are not directly comparable, whereas our paper provides a comprehensive and systematic comparison of various methods for learning cross-lingual contextualized embeddings and introduces a new and more challenging evaluation task.

Evaluation of (Contextualized) Cross-lingual Embeddings. The traditional task to evaluate cross-lingual embeddings is Bilingual Dictionary Induction (BDI) (Vulić and Moens, 2013; Mikolov et al., 2013a; Gouws et al., 2015): given a source query word, the task is to retrieve the translation word in the target language. The test words in BDI are out-of-context and polysemy cannot be addressed properly. The same issue is found in another relevant lexical task, Cross-lingual Semantic Similarity. (Camacho-Collados et al., 2017).

The only context-aware dataset for evaluating cross-lingual embeddings on the word level is Bilingual Contextual Word Similarity (BCWS) (Chi and Chen, 2018). It challenges a system to predict similarity scores between cross-lingual word pairs with sentential context provided in both languages. However, BCWS does not explicitly test for the retrieval of meaning-equivalent cross-lingual contextualized embeddings, which is explicitly tested in our test. Also, BCWS is only available for one language pair: English-Chinese.

Another task used for evaluating contextualized embeddings is Sentence Retrieval (Aldarmaki and Diab, 2019): given a query source sentence, the task is to retrieve the corresponding parallel sentence in the target language. Sentences can be represented as averages of contextualized embeddings of their constituent words. As the task does not explicitly evaluate at the word level, even if a system cannot accurately capture polysemy, it can rely on other words in the sentence to retrieve the correct parallel sentence. Therefore, Sentence Retrieval may lead to superficially high scores.

Cross-lingual Word Sense Disambiguation. Our new task is also related to Cross-lingual Word Sense Disambiguation (Lefever and Hoste, 2009): given a source language word in context, a system needs to provide the correct sense labels as clustered translation words in a number of target languages. Another related task is Cross-lingual Lexical Substitution (Sinha et al., 2009): the model must provide plausible target language translations for the source language lexical item in the source language context. In contrast, our BTSR task: (1) directly evaluates token-level word representations without the need to predict sense labels from a sense inventory and (2) it contextualizes both the source query and the target candidates ensuring full sense disambiguation. The core differences between the three tasks are illustrated in the following examples below:

(1) Cross-lingual Word Sense Disambigution:
source query: the national [coach] of the Irish teams ...
answer: allenatore (Italian); Fußbaltrainer; Nationaltrainer; Trainer (German); entrenador(Spanish) ...

(2) Cross-lingual Lexical Substitution :
source query: She looked as [severely] as she could muster at Draco.
answer: rigurosamente, seriamente

(3) BTSR:
source query: The reflections included in this document are linked to discussions with many colleagues and friends, in the present [tense].

answer: Scott Peterson metió la pata elfondo y usó el [tiempo] pasado mientras afirmaba que su esposa asesinada estaba viva , lanzando una búsqueda (...)

3 Methods

3.1 Monolingual Contextualized Embeddings

Compared to static word embeddings (Mikolov et al., 2013b; Bojanowski et al., 2017), more recent contextualized embeddings provide dynamic representations for a word in context as hidden layers in a deep neural network. They are typically obtained by unsupervised pretraining based on language modeling objectives (Devlin et al., 2019; Yang et al., 2019). The underlying contextualized method in our study is the pretrained $BERT_{base}$ cased model[1] (Devlin et al., 2019). BERT is trained using a transformer architecture (Vaswani et al., 2017) with masked language modelling (MLM) and next sentence prediction (NSP) tasks. MLM predicts the vocabulary id of a randomly masked word in a sentence based on the word's context. NSP trains text-pair representations to predict whether the text-pair contains consecutive sentences from a monolingual corpus.[2]

We work with two BERT variants. First, we explore aligning independently trained BERT models, that is, models with separate model parameters for each language. For English and Chinese, we align independently trained Chinese and English monolingual models. For Spanish and English, since there is no pretrained BERT Spanish model, we take the Spanish embeddings from the BERT multilingual model and align it with the monolingual English model. We take this alignment as an approximation to aligning two independently trained models. We have also experimented with directly aligning embeddings obtained from the BERT multilingual model, which is a joint model trained with the same model parameters with shared subword vocabulary (Devlin et al., 2019). This means that identical words in two different languages will obtain the same embeddings.

[1]To produce the contextualized representation for a word in context, we average the 12 hidden layers of the word's subword representations in BERT and then average the subword representations as input for the cross-lingual alignment. We leave other ways to extract the representations for future work.

[2]We have also experimented with ELMo in lieu of BERT (Peters et al., 2018; Che et al., 2018). However, as we reach similar conclusions in terms of relative performance, while BERT-based cross-lingual embeddings outperform their ELMo-based counterparts in absolute terms, we do not report ELMo's results for brevity. It should be noted that these pretrained models used different training data.

3.2 Orthogonal Mapping and MIM

Given a dictionary with item pairs from source and target languages (s_i, t_i), and matrices S and T that contain the vector representations corresponding to the item pairs in the columns, we follow the standard practice (Glavaš et al., 2019) to find an orthogonal alignment matrix W that minimizes the distance between the transformed matrix WS and T. For improved performance, following Artetxe et al. (2016), we normalize and mean center the embeddings in S and T. The mapping is as follows:

$$W = \arg\min_{W} \|WS - T\|^2 \quad s.t. \quad W^T W = I. \qquad (1)$$

The closed-form solution can be found by solving the orthogonal Procrustes problem (Schönemann, 1966) as follows:

$$TS^T = U\Sigma V^T; W = UV^T \qquad (2)$$

We also optionally apply a post-processing *Meeting-in-the-Middle* (MIM) technique, recently proposed by Doval et al. (2018). It first calculates the average of each dictionary item representation in a pair after the orthogonal mapping: we denote the matrix U as the matrix where each column is such an average vector. Then, it finds a linear mapping M from both the source language (denoted as M_s) and the target language (M_t) after the previous step of orthogonal mapping to minimize the distance to U via a closed-form solution. Equation (3) formulates how to find M_s, and we do the same from target to source.

$$M_s = \arg\min_{M_s} \|M_s WS - U\|^2 \qquad (3)$$

We apply the orthogonal mapping and MIM both on static embeddings (for baselines) and contextualized embeddings. For mapping the contextualized embeddings, we either extract type-level embeddings from the contextualized models to serve as anchors for the alignment using static dictionaries, or we use parallel sentences as dictionary items to directly align contextualized word representations on the token level. We discuss this in what follows.

3.3 Alignment Levels

We explore aligning contextualized models on two levels: *type-level* and *token-level*. Type-level word representation refers to static word representation that assigns one fixed embedding to a word. All the traditional word embedding models (e.g., skip-gram, CBOW, fastText) provide such embeddings, and cross-lingual alignment is typically applied on

these type-level embeddings (Ruder et al., 2019). Token-level word representation refers to dynamic representations for words *in context*, i.e., contextualized word representations.

Contextualized models such as BERT provide token-level embeddings by default: a natural way to align these embeddings is token-level alignment. This has been proposed concurrently to our work by Aldarmaki and Diab (2019). This method requires token-level training data , e.g., from a word-aligned parallel corpus.

As an alternative, we obtain static type-level representations in the same space as our contextualized embeddings and use these type-level representations as anchors to learn the crosslingual mapping. The type-level anchors can be seen as taking a representative sample of the infinite space of the contextualized embeddings. The mapping learned via the anchors will hopefully be generalizable to align the dynamic token-level contextualized embeddings as well. The advantage of this approach is that we can align the contextualized embeddings with a standard dictionary now that we have one representation per word.

We experiment with two different kinds of anchor type-level embeddings: iso_type and avg_type. The iso_type refers to type-level embeddings that are produced by simply inputting the word in isolation to the contextualized model. Avg_type embeddings are obtained by taking the average of the contextualized representations of a word.[3] The context-average avg_type embeddings has been proposed recently by Schuster et al. (2019). In this work, we provide a systematic comparison of embeddings aligned on the token level, and on the two kinds of type-level alignments.

3.4 Alignment Training Signal

We explore a number of different supervision signals for learning the alignment between monolingual embeddings. First, we evaluate traditional methods that exploit word-level training signals (Ruder et al., 2019). We use (1) a static manually created (i.e., external) dictionary to obtain the alignment, and (2) we rely on word alignments from a parallel corpus as the source of the training signal. For word alignments, we either treat them as a large dictionary to perform type-level alignment or we additionally leverage the context in the aligned sentences to extract a dynamic contextualized dictionary to perform token-level alignment.

We also exploit the training signal coming from the aligned parallel sentences alone without word alignments. We first create sentence representations by averaging type-level or token-level embeddings, and then align the parallel sentence representations from source to target language.

The configurations for learning cross-lingual contextualized word embeddings explored in this work are summarized in Table 1, and we rely on the configuration labels from the table throughout the paper. Type-level configurations which ignore context are treated as baselines.

4 Bilingual Token-level Sense Retrieval Task (BTSR)

Task Description. In §2, we already discussed the main properties of the two other tasks that can be used to evaluate cross-lingual context-aware embeddings: BCWS and parallel Sentence Retrieval. In short, BCWS only measures similarity between cross-lingual word pairs in context, and it does not evaluate the translation capacity of different methods. The Sentence Retrieval task does not evaluate on the word level and can be solved by relying on the context alone.

To bridge this gap in evaluation, we introduce a new task: Bilingual Token-level Sense Retrieval (BTSR). It tests for the retrieval of meaning-equivalent cross-lingual contextualized word embeddings relying on non-parallel context information. Our task can be seen as a contextualized variant of the BDI task. Its comparison to the traditional BDI task is provided in Table 2.

In what follows, we define the BTSR task formally and provide details on how the task data is created. To build a representative sample of contextualized words in the source and target languages, we collect translation pairs and contextualize the word pairs into token-level representations. Then we manually check a sample of the contextualized word pairs to ensure correspondence of sense on the token-level. To understand the effect of the size of the search space, we experiment with 20k and 200k candidates respectively.

Formal Definition. In BTSR, we define S : $s^1_{tk,1}, s^1_{tk,2}, s^2_{tk,1}, \ldots, s^n_{tk,m}$ as a set of queries from the source language. A query $s^i_{tk,j}$ is a token-level contextualized representation of the ith source

[3] In practice, we take 1000 random samples for a word from the training data of the parallel corpora used in our experiments.

Component	Options	Label
Alignment Signal	Word alignment from parallel data	wa
	Sentence alignment from parallel data	sa
	MUSE training dictionary	dict
Alignment Level	Token-level alignment	token
	Type-level alignment from context average	avg_type
	Type-level alignment from inputting the word in isolation	iso_type
	Type-level alignment in static embeddings (eg. Fasttext)	type
Models	monolingual English BERT model	mono_en
	monolingual Chinese BERT model	mono_zh
	BERT multilingual English model	multi_en
	BERT multilingual Spanish model	multi_es
	Fasttext baseline	fasttext
Alignment techniques	the original orthogonal linear transformation	orig
	post-processing linear transformation after the orthogonal transformation	mim
Evaluation level	Evaluated on token-level representations	[token]
	Evaluated on type-level representations	[type]

Table 1: Different components used for the model configurations in our evaluation.

BDI		BTSR

subdue	制服	..mosquito was [subdued]..	..[制服]刺客.. (...[subdue] the assassin...)
uniform	一致	the [uniform] convergence of the regular solution	...[一致] 漸近穩定...定理 (the theorem of [uniform] asymptotic stability...)

Table 2: BTSR: examples and a comparison with traditional (non-contextualized) BDI.

word that corresponds to the word's jth sense. Similarly, we define $T : t^1_{tk,1}, t^1_{tk,2}, \ldots, t^p_{tk,q}$ as a set of candidates in the target language where each candidate is a contextualized token-level word that represents a specific sense of a word in the target language. For each query s_{tk}, the task is to find a target contextualized token-level word t_{tk} that has the same word sense as in the query. $Sim(s_{tk}, t_{tk})$ is a function that computes the similarity of s_{tk} and t_{tk}. In our experiments, we use cosine similarity. Using $Sim(s_{tk}, t_{tk})$, for each query, we retrieve $t_{tk,i^1}, \ldots, t_{tk,i^K}$: the top K most similar token-level contextualized words from the target set T in the cross-lingual space as the nearest neighbours. We report *Precision@K*, i.e. precision of finding the gold t_{tk} in the top K retrieved candidates.

Collecting Translation Pairs. We select a representative set of query words from WordNet (Miller, 1998) (one unique word per WordNet synset). For each source word, we retrieve its WordNet senses and the corresponding translations in the target language from Multilingual WordNet (Bond and Foster, 2013). As WordNet senses are too fine-grained, we collapse senses into clusters if they contain the same translation for the source word. For example, "uniform" has five WordNet senses which are translated into four distinct Chinese words: 制服(the clothes worn by a particular group), 一致(the translation of two senses: consistent and undifferentiated)[4], 不變(unchanged) and 相同(the same) . We take these four Chinese words to form four translation pairs with "uniform".

Word Pair Contextualization. For each word in a word pair, we "contextualize" the word by selecting a sentence in which the word appears, and ensure that the resulting contextualized word can be translated into the other word. Therefore, if a polysemous word occurs in multiple word pairs with distinct translations, it will be accompanied with different contexts that correspond to each translation. We achieve this by selecting a pair of parallel sentences in which the source word and the target word from the word pair are aligned after we run word alignment. The context in the source language in this parallel sentence pair is used to "contextualize" the source word. When we select context for the target word, we choose a different parallel sentence in which the two words in the pair are aligned. Therefore, the final contexts for the source and target word in the word pair are indeed non-parallel.

The use of non-parallel contexts here is crucial because when we perform the token retrieval task, parallel contexts can be superficially retrieved by simply matching the contexts rather than repre-

[4]Notice the senses are different thus contexts are needed to find the pair corresponding to the same meaning.

senting the words in context appropriately. We empirically verified that a simplistic context average baseline outperforms contextualized word embeddings in a variant of our task which relies on parallel contexts.

We set aside 1M parallel sentences from the UMCorpus (Tian et al., 2014) (EN–ZH) and the WMT13 news dataset (Bojar et al., 2013) (EN–ES) for extracting the sentence contexts. We end up with 14,604 distinct word pairs with contexts extracted for EN–ZH, and 9,623 pairs for EN–ES.

Creation of Test Data. As the contexts are non-parallel in a word pair, we need to check if the contextualized words in a word pair genuinely represent the same meaning. We manually checked a sample of the word pairs extracted in the previous step to produce the final test set for BTSR. To produce the sample, we selected the translation pairs that satisfy any of the following constraints: 1) target or source word belongs to the top 250 frequent words in each language, 2) target or source word belongs to the top 250 most ambiguous words in each language. We take the number of sense clusters as introduced above as a measure of ambiguity for each word.

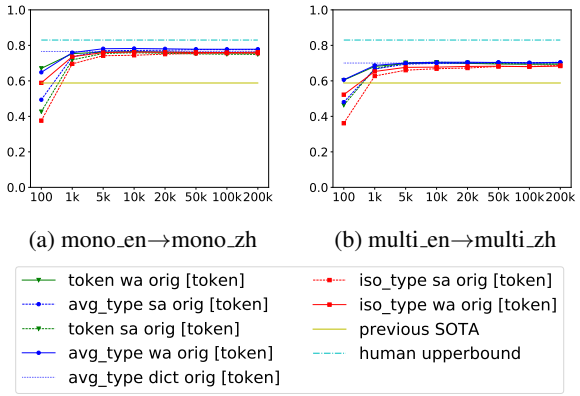
The first author then provided an initial manual annotation of the samples for both EN–ES and EN–ZH on whether the contextualized words in a pair correspond to the same meaning. The samples from the two language pairs were subsequently annotated by one native Chinese speaker and one native Spanish speaker respectively. The final agreement rate calculated as pairwise inter-annotator agreement on a binary choice[5] for EN–ZH is 94.5%, and 94.7% for EN–ES. Finally, we take the subsets where all annotators agree as the test sets for EN–ZH (1,181 pairs) and EN–ZH (994 pairs).

Target Candidates. We treat the token-level representations of the target words from all words pairs in the contextualization process described above as our candidate space. To make the target candidate space more representative of the language, we supplement the space with words outside of the WordNet inventory from monolingual Wikipedia dumps in the target language. For each of these words, we randomly select a sentence in which it occurs to contextualize the word into a token-level target candidate. We experiment with 20k target candidates and 200k target candidates.

[5]For each language pair, it is calculated as the percentage of token pairs marked correct by both annotators (the first author and one native speaker of the language) divided by the number of all the token pairs.

5 Experiments

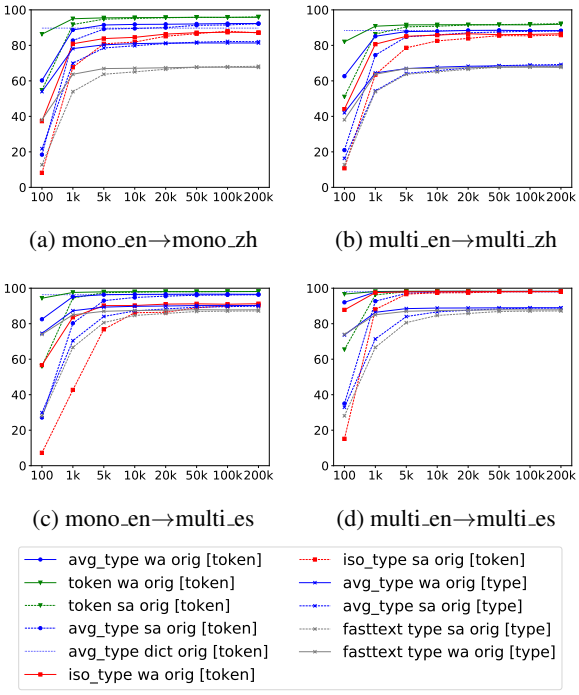
Training Setup. To test the effects of corpora size on the induction of the cross-lingual alignment, we vary the size of the parallel corpus from 100 up to 200k parallel sentences in the UMCorpus and the WMT13 corpus. Word alignment was produced by IBM Model 2 using Fastalign (Dyer et al., 2013). We also induce cross-lingual alignments relying on static dictionaries provided by MUSE (Conneau et al., 2017). BERT variants (see §3.1) are taken from Devlin et al. (2019). For comparison with BERT, we also run fasttext (Bojanowski et al., 2017) to produce baseline static embeddings using the same training Wikipedia corpora for English, Chinese and Spanish.



5.1 Bilingual Contextual Word Similarity

We first evaluate the models on two previous evaluation tasks: BCWS and Sentence Retrieval. For both tasks, we compute cosine similarity to measure the distance between representations. For BCWS, we evaluate embedding distance against human annotations via Spearman correlation. Results on the BCWS task for EN–ZH are shown in Figure 1. The main finding is that all cross-lingual contextualized embeddings in our comparison surpass the previous state-of-the-art (SOTA) based on a cross-lingual multi-sense model (Chi and Chen, 2018) as soon as they are fed 5K or more parallel sentences. Note that the previous SOTA model was trained on the full EN–ZH parallel corpus of around 2M sentences. Although BERT was pretrained on a corpus comprising 3.3B words , it is reasonable to assume that it is easier to procure abundant monolingual data than parallel data. Therefore, aligning pretrained monolingual embeddings using only a small amount of parallel data rather than training on a large parallel corpus is a more favorable choice.

Alignment based on independent monolingual models (mono_en→mono_zh) is particularly effective, achieving human-level performance. While different methods achieve comparable results, avg_type consistently takes the lead.



5.2 Sentence Retrieval

For the Sentence Retrieval task, we compute cosine similarity between the query sentence representation and sentence representations in the tar-

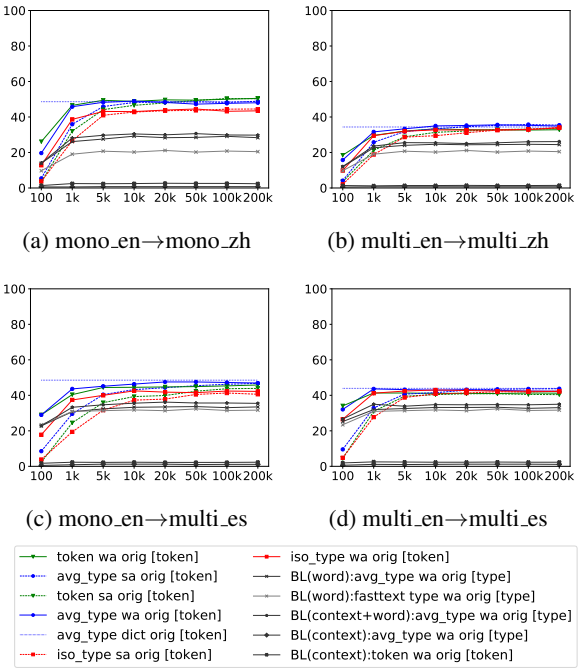
get language in the test set of UMcorpus (English-Chinese) and WMT13 corpus (English-Spanish). Precision results for finding the parallel sentence in the top 5 candidates are reported in Figure 2. We find that evaluating with contextualized embeddings on the token-level (all the *[token]* lines) performs consistently better than type embedding baselines. Among the different ways to transfer the contextualized embeddings, aligning directly on the token level with parallel data outperforms aligning via type-level anchoring. Concerning the alignment training signal, sentence alignment starts low but is able to yield comparable results with word alignment after 50K sentences. For the EN–ZH Sentence Retrieval, aligning independently trained BERT models outperforms aligning embeddings with shared vocabulary. For the EN–ES Sentence Retrieval task, aligning from both independent models and from shared embeddings achieves ceiling performance.

5.3 Bilingual Token-level Sense Retrieval

We report *Precision@5* scores for 20k target words in Figure 3. We also report the results from aligning using 200k parallel sentences on BTSR with 200k target words and applying the additional MIM technique in Table 3.



Baselines. We evaluate four baselines that help us better understand the models' performance in this task. For *BL(word)* methods, we discard the contexts and use only the query and target word's type representations. Therefore, polysemous words in the dataset will have only one static representation. We implement both a fasttext baseline and a context-average type embedding baseline for each contextualized model. We also provide baselines which use context but ignore the word in focus (*BL(context)*). These baselines take an average of the context embeddings both at the token level and at the type level of the contextualized models. Instead of finding the best translation word in context, these baselines retrieve the target sentence with the best translation of the source context.[6] Finally, we evaluate a simple baseline that combines both word and context as an average of the two representations. Context representation here is the average of the context embeddings. Both word and context embeddings here are calculated using the avg_type embeddings.

Discussion. The low performance of all the baselines suggest that the proposed task is more challenging than the alternatives: it can not be easily

[6] On our trivial parallel variant of the task, this context baseline gives the best performance.

	token		avg_type		iso_type	
	wa	sa	wa	sa	wa	sa

tackled by looking at word in isolation (i.e., at type-level representations) or the context alone, or a simple combination of context and the query word.

Regarding the alignment level, compared to the Sentence Retrieval task, the benefit of dynamic token-level alignment from parallel corpora now disappears. Aligning the contextualized embeddings via context-average anchor type embeddings, i.e. avg_type alignment, (which consistently outperform iso_type embeddings) is the best model in most cases, or yields comparable performance with token-level alignment. Their advantage becomes more pronounced in the experiments with 200K target candidates, see Table 3. We suspect that this method is particularly robust when generalizing to words in non-parallel contexts: we find the same pattern in the BCWS task which is also constructed with nonparallel sentences.

Applying MIM brings consistent improvement for the best (avg_type) alignment method. Such improvements for the other methods are less stable. This suggests MIM is only effective when the alignment methods already learn a high-quality cross-lingual space before applying MIM.

As for training signals, relying only on a small dictionary (5K word pairs) yields comparable results with the methods that are trained on large amounts of parallel data. This suggests that a small seed dictionary may be enough to transfer the contextualized embeddings cross-lingually and be able to disambiguate words in context cross-lingually.

When comparing model variants, we see an advantage of aligning independent models over aligning shared models as we increase the training data. This advantage becomes more obvious with 200K target candidates, see Table 3. For EN–ES results in Figure 3, we observe that all alignment methods which use the shared model (i.e., multi_en→multi_es) start higher than results from aligning independently trained mono_en→multi_es. With the 'avg_type wa orig' method for example, aligning mono_en→multi_es starts at 29.04(%) whereas multi_en→multi_es starts at 34.07(%) given 100 parallel sentences. This is intuitive as English and Spanish share a larger portion of their vocabulary compared to English and Chinese: this gives the multilingual model a head start, but it is quickly surpassed by aligning from independently-trained models, especially via the avg_type alignment, as we increase training data.

In sum, we show that (1) BTSR is a challenging task; (2) unlike in Sentence Retrieval, context

	English original		token		avg_type		iso_type

Table 4: Evaluating alignment methods and model variants on the monolingual SCWS dataset which measures word similarity in context (in English). Spearman's ρ ($\times$ 100%). Previous best reported score is 69.3 (Neelakantan et al., 2014). Please refer to Table 1 for the explanations of the acronyms.

average type-level alignment performs the best in our task and in the BCWS task where the contexts are non-parallel, and can be further improved with the MIM technique. (3) Using a small dictionary is sufficient to transfer the contextualized embeddings via type-level alignment. (4) Aligning from a shared model gives a head start when two languages contain some shared vocabulary, but aligning from independently trained monolingual embeddings is able to achieve better performance given sufficient training data (5) Overall, increasing the search space from 20K to 200K target words results in a decrease of 10% in precision in BTSR, but the relative performance of different methods is more consistent and more pronounced.

Monolingual Contextual Evaluation. We also examine whether the cross-lingual alignment with MIM post-processing can improve the monolingual contextualized embeddings by evaluating the EN models on the Stanford Contextualized Word Similarity Task which measures similarity of word pairs with context in English. We evaluate the alignments learned from using 200K parallel sentences. The results are in Table 4. It seems that aligning independently trained models, which have better monolingual performance, outperforms aligning from shared models as found in BTSR. Also, we see consistent improvement over the original monolingual space after MIM, especially with avg_type alignment level. This indicates that the avg_type alignment level is effective not only in transferring the contextualized embeddings to the target language, but it can also improve the context-aware monolingual space.

We also observe that the EN contextualized models in their original space (both mono_en and multi_en) outperform SOTA (69.3%), a multi-sense static embedding model (Neelakantan et al., 2014). This indicates that the present contextualized embeddings are already capturing context effect including sense-level information without explicitly assigning embeddings to discrete sense categories.

6 Conclusion

We have conducted novel comparisons and analyses of various alignment methods for aligning contextualized embeddings cross-lingually. We have also introduced a novel task, Bilingual Token-level Sense Retrieval, which directly evaluates the retrieval of meaning-equivalent cross-lingual contextualized embeddings. The proposed task is challenging and enables a finer-grained analysis of different cross-lingual alignment methods. We have found that using context-average type-level alignment (avg_type) is effective and robust in transferring monolingual contextualized embeddings cross-lingually and at the same time improves the monolingual space. Using a small static dictionary as the alignment signal provides comparable results to word alignment methods relying on parallel corpora. We have also found that aligning independently trained monolingual embeddings yields better performance than aligning embeddings from a shared model. As our paper focuses only on the projection-based alignment methods, future work may explore other ways to learn the cross-lingual contextualized embeddings, e.g., based on joint training (Mulcaire et al., 2019).

Acknowledgments

We thank the anonymous reviewers for their helpful feedback on this work. We acknowledge Peterhouse College at University of Cambridge for funding Qianchu Liu's PhD research. The work was also supported by the ERC Consolidator Grant LEXICAL: Lexical Acquisition Across Languages (no 648909) awarded to Anna Korhonen. We also appreciate many helpful discussions and feedback from our colleagues in the Language Technology Lab, in particular Victor Prokhorov, Yi Zhu, Edoardo Ponti, Dr Haim Dubossarsky, and Dr Ehsan Shareghi.

Large-scale, Diverse, Paraphrastic Bitexts via Sampling and Clustering

Abstract

Producing diverse paraphrases of a sentence is a challenging task. Natural paraphrase corpora are scarce and limited, while existing large-scale resources are automatically generated via back-translation and rely on beam search, which tends to lack diversity. We describe PARABANK 2, a new resource that contains multiple *diverse* sentential paraphrases, produced from a bilingual corpus using negative constraints, inference sampling, and clustering. We show that PARABANK 2 significantly surpasses prior work in both lexical and syntactic diversity while being meaning-preserving, as measured by human judgments and standardized metrics. Further, we illustrate how such paraphrastic resources may be used to refine contextualized encoders, leading to improvements in downstream tasks.

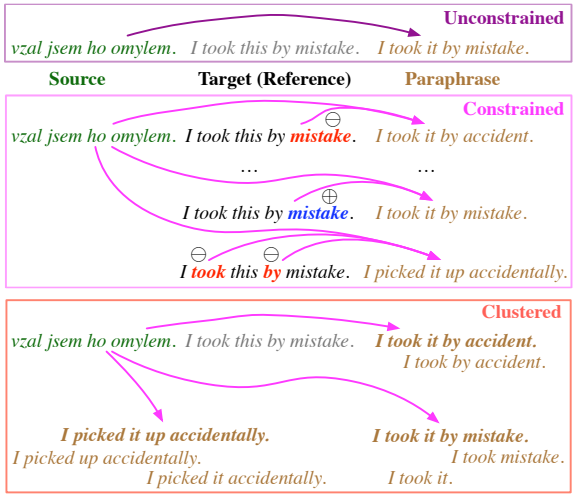

Figure 1: Contrived example paraphrases from previous work (unconstrained and constrained—used with permission) and ours (clustered).

1 Introduction

The ability to understand and produce paraphrases is a basic competency task, one that is often used as a teaching aid to validate if a student *understands* a statement or a concept. Current deep learning systems struggle with this task, exhibiting brittleness to both understanding and producing paraphrastic expressions (Iyyer et al., 2018).

One crucial factor behind this incompetence is the dearth of sentential paraphrastic data. Many works have sought to leverage the relative abundance of sub-sentential paraphrastic resources in paraphrase detection or generation (Napoles et al., 2016). Yet, they fail to capture contextualized word choices or syntactical variations, as word- or phrase-level resources cannot incorporate information from the whole input sentence.

Recent works have focused on leveraging bilingual resources to create large sentence-level paraphrastic collections using translation-based methods (Wieting and Gimpel, 2018; Hu et al., 2019). However, these works are confined to using beam search in decoding, which tend not to produce diverse candidates. One approach to force diverse translations is the use of hard lexical constraints at inference time (Hu et al., 2019). While effective in some cases, current approaches to automatic selection of such constraints is based on heuristics and task-oriented trial-and-error.

We present a novel resource with accurate and *collectively diverse* paraphrases, generated using stochastic decoding and clustering. By *collectively diverse*, we mean that the paraphrases of a given sentence cover a wide lexical and syntactic spectrum. Given a bilingual input pair, our core idea is to *sample* a large space of outputs from a translation system, cluster the results according to a notion of token-sequence similarity, score them with two translation models (one in each direction), and then select the best item from each cluster. We believe that sampling from the word distribution at each decoder time-step bet-

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 44–54
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

ter preserves the decoder's level of uncertainty, which is intrinsic to the goals of paraphrasing. We also sample *ancillary* lexical constraints to discourage, instead of explicitly prohibiting (Hu et al., 2019), certain words from being used by the decoder. While our experiment produces a large-scale English resource, our approach is dependent only on the availability of large bitexts and so is language-agnostic. We chose to build an English resource from CzEng to enable a direct comparison with Wieting and Gimpel (2018) and Hu et al. (2019).

Our contributions include:

- A large, high quality paraphrase collection[1] with up to 5 paraphrases per reference, close to 100 million pairs in total, which are more diverse than prior work in two distinct ways, as measured by standardized metrics;
- An evaluation of semantic similarity, lexical and syntactic diversity, compared against prior works, along with results on Sentence Textual Similarity (STS) Benchmark;
- Experiments on how our resource can be leveraged to improve performance on a set of language tasks.

2 Paraphrase generation pipeline

Prior works in constructing sentential paraphrastic resources have worked from large collections of bitext, producing translations of the foreign language sentence which, when paired with the target-language reference, constitute a set of paraphrases. Working from the very large CzEng parallel corpus, Wieting and Gimpel (2018) produced a single paraphrase for each English sentence by translating from the Czech source. Hu et al. (2019) expanded on this by translating the Czech sentence several times, using positive or negative constraints obtained from the English reference.

In terms of producing diverse paraphrases, both approaches are limited because they rely on beam search. There are potentially billions of paraphrases of a sentence (Dreyer and Marcu, 2012), yet beam search with recurrent models can only search a constant subset of them (in the beam size). There are techniques for producing more diverse paraphrases, such as the use of positive and negative constraints (Hu et al., 2019) or syntactic fragments (Iyyer et al., 2018), but these require the user to manually specify them, which can be cumbersome and unreliable.

We follow these prior works in working with the CzEng, a Czech–English dataset (Bojar et al., 2016b), due to its size, diverse domain coverage, and rich syntactic variations (Wieting and Gimpel, 2018), and to allow for a direct comparison in methodologies. However, we propose a new approach to paraphrase generation designed to increase paraphrastic diversity, using a multi-step process: the first part of the pipeline generates a large number of candidate paraphrases through a random process, and the second part whittles them down to a much shorter list. For each {source, target} input pair, we run the following pipeline:

1. *Constrained sampling*. We sample translations using a source→target translation model with lexical constraints. We obtain negative constraints by randomly selecting a set of tokens from the "source", so that they are not allowed to appear in the translations. Then, we decode each translation by sampling from only the top-k most probable tokens at each time step, after excluding constrained tokens (§2.1).
2. *Dual scoring*. The set of samples is then scored against the original source input using a target→source translation model. The scores from the forward and backward models are summed (§2.2).
3. *Clustering*. The samples are then clustered. The best item from each cluster (according to the summed score) is then returned (§2.3).

2.1 Constrained sampling

Sampling is a more effective way to explore model search space than beam search, particularly in auto-regressive models that do not permit dynamic programming. We introduce two means by which we can expand the hypothesis space, and produce a more diverse set of paraphrases, relative to straightforward beam search.

Top-k sampling In auto-regressive neural MT, the standard sampling approach would be to choose a word w_t at each decoder timestep t by sampling from the distribution $P(w_t \mid w_{1\ldots t-1})$. This approach has been found effective over 1-best beam search in generating source sentences in

[1] Available at http://nlp.jhu.edu/parabank2

back-translation (Edunov et al., 2018). However, for paraphrasing, this is not ideal, since words that are not semantically licensed by the source may be selected. Instead, we propose top-k sampling, in which we choose w_t from the top k most-probable tokens at each time step. This way, we allow the model to sample flexibly, vastly opening up the hypothesis space, without creating a large risk of producing nonsensical translations.

Randomized negative constraints Negative constraints are tokens that are not permitted in the decoder output. They are not formally described in the literature, but an implementation was provided with the associated positive constraints (Post and Vilar, 2018). Negative constraints can be provided as tokens or phrases; the decoder tracks the progress of generation through each constraint and adds an infinite cost to the final word of any constraints, precluding its selection in both sampling and beam search.

In order to further increase sample diversity when generating the hypotheses (§2.1), we obtain negative constraints from the source by randomly choosing a subset of tokens. We do this independently multiple times for each input sentence. This provides new sets of constraints for the inputs, independent of the decoding.

Note that we use subword regularization (Kudo, 2018) during training, causing different subword segmentations to be applied to training data types each time they are encountered and helping to build more robust models. We only constrain on the Viterbi segmentation, effectively discouraging negatively constrained words from appearing in the output, instead of prohibiting them, since there are often ways for the model to produce a word by generating a different decomposition.

2.2 Back-translation likelihoods

Some semantic changes during paraphrasing, especially omission, are not well-reflected by the (forward) probability $p_{generate}$ from the generating model. However, a model running in the other direction can penalize this omission, as found by Goto and Tanaka (2017). Thus, we obtain the back-translation probability p_{back} of each sampled candidate paraphrase, and define the final score for each candidate paraphrase as the joint probability $p^* = p_{generate} * p_{back}$, which is the sum of negative log-likelihood.

2.3 Edit-distance-based clustering

The above process produces a large set of translations of the source sentence. Many of them will be minor variants of one another, but we expect that there will be a lot of variety in the large pool. The task now is to reduce this pool to a small set of *collectively diverse* paraphrastic candidates.

We address this problem with k-means clustering via Levenshtein (or edit) distance (Miller et al., 2009). We compute this on lowercased, segmented candidates, after striping punctuation. Clusters are initialized with the k furthest candidates measured by edit-distance. We also add the reference sentence as the centroid of an additional cluster and skip the re-centering for that cluster. This improves the chance of the k clusters congregating candidates different from the reference in different ways. When the clustering has converged, we take the candidate with the best score from each cluster (except for the one with the reference sentence), rank them by score, and take the best n as the final output.

3 Evaluations

3.1 Data

All of our experiments are based on the CzEng 1.7 corpus, a subset of CzEng 1.6 (Bojar et al., 2016b) that has been chosen for higher quality. Based on experience with data quality issues in neural MT (Ott et al., 2018; Junczys-Dowmunt, 2018), we decided to further clean the corpus. First, we normalize Unicode punctuation, and keep only bilingual pairs whose English side can be encoded with `latin-1` and Czech side with `latin-2`. We then filter the data with dual cross-entropy filtering (Junczys-Dowmunt, 2018). We use Sockeye (Hieber et al., 2017) to train two NMT models, CS–EN and EN-CS, on a relatively clean subset of the data provided for WMT 2018 (Bojar et al., 2016a): Europarl, Wiki titles, and news commentary. We use 4 layer Transformer models (Vaswani et al., 2017) trained to convergence, with held-out likelihood evaluated on a random 500-sentence subset of the WMT16 and WMT17 news test data. These models are then used to score all the remaining CzEng data after deduplication. We kept all sentences with a model score (negative log-likelihood) of less than 3.5. After applying the above two filters, we keep $19,723,003$ out of the $57,065,358$ pairs in CzEng 1.7.

3.2 Translation models

We train two new translation models on the filtered data, the CS–EN *generation model* (for generating English candidates via sampling) and the EN–CS *scoring model* (for providing backwards scores of the candidates). Both are Transformer models built with AWS SOCKEYE. The generation model is a 12 layer Transformer with a model and embedding size of 768, 12 attention heads, a feed-forward layer size of 3072. The scoring model has 6 layers, model and embedding size of 512, 8 attention heads, and a feed-forward layer size of 2048.

All training data is pre-processed with subword sampling using SentencePiece[2] (Kudo, 2018) with a vocabulary size of 20k and character coverage of 0.9999. We used separate models for Czech and English. At inference time, we use the Viterbi segmentation of each input sentence, for both the generation and scoring models.

3.3 Parameters

There are a few parameters involved in the sample-score-cluster pipeline. For each Czech input sentence, we generate 5 sets of random constraints (§2.1), creating 5 variants of the input. From each of these inputs, we generate 30 samples using top-k sampling with $k = 10$ (i.e., at each timestep, the model randomly chooses from the top 10 most probable words, according to their scaled distribution, and excluding negatively constrained words). The resulting 150 sentences are scored, and anything with a combined score greater than 3.5 is thrown out. The remaining sentences are clustered into 8 clusters, one of them centered on the English reference. The reference cluster is thrown out, and a list of the best-scoring translation from the remaining 7 clusters is constructed. From this list, the top 5 translations are returned as hypotheses.

3.4 Setup

We follow the evaluation framework of Hu et al. (2019), which judged semantic similarity between paraphrases and their reference through human evaluation, and lexical diversity via automatic metrics. We use the evaluation result made public by Hu et al. (2019) to enable a direct comparison. Rather than focusing on improving semantic similarity, which is limited by the quality of the bilingual resource, we seek to build a resource that contains both more lexical and syntactical diversity.

We obtained the evaluation set from Hu et al. (2019), which contains 400 English sentences from CzEng. Due to additional filtering, 24 out of 400 (6%) reference sentences aren't in PARABANK 2 and therefore excluded in this evaluation.

We set the output size $n = 5$. After sorting the candidates by negative log-likelihood for each reference, we treat candidates at each rank as an individual system to investigate the expected quality of paraphrases under our approach. For references that produce fewer than 5 paraphrases, the paraphrase with the highest negative log-likelihood is duplicated to fill in ranks that otherwise would be empty. We also artificially pick the paraphrase with the maximum, minimum, and median human semantic similarity judgment under each reference as three additional oracle systems.

3.5 Semantic similarity via human judgments

For a fair comparison, we used the evaluation setup released by Hu et al. (2019), which uses the interface from EASL (Sakaguchi and Van Durme, 2018) to collect semantic similarity and gammaticality judgments. Each human annotator is presented with a reference sentence and five paraphrases from different sources. Annotators use a slider bar under each paraphrase to rate the semantic similarity from 0 (Opposite/Irrelevant) to 100 (Identical Meaning). Annotators are also asked to comment on whether the paraphrase is ungrammatical or nonsensical. The reference sentence is repeated next to the paraphrase for easier visual comparison.

Each paraphrase receives at least 3 independent judgments. Following Hu et al. (2019), we randomly add in the reference sentence as a paraphrase and filter out annotators who fail to score them 100 more than 10% of such encounters. The result includes only annotators who contributed at least 25 judgments and is shown in Tab. 1.

3.6 Paraphrastic diversity

BLEU has been a successful metric in evaluating MT systems. However, as noted earlier, monolingual paraphrasing has inherently different objectives than cross-lingual translation. BLEU, in tandem with human evaluation in semantic similarity, makes a good metric for paraphrastic diversity.

Table 1: Paraphrastic diversity measured by (1-BLEU)×100, bag-of-word intersection/union score×100, and Tree edit-distance. Systems from this work that receive the best human judgments, worst human judgments, and the median, are included in the table. A higher 1-BLEU suggests higher paraphrastic diversity; a higher Intersection/Union score suggests a higher lexical diversity; a higher Tree edit-distance suggests a higher syntactic diversity. Best in each column, excluding oracle systems, is in bold. * denotes best oracle systems.

Here, we use 1-BLEU to measure how different the paraphrases are to the references.

We generate 5 paraphrases for each reference sentence using the approach outlined in this work. To account for randomness, we average over two independent runs in the result, shown in Tab. 1.

We consider two sources of paraphrastic diversity: 1) lexical diversity, the use of different words; and 2) syntactic diversity, the change of sentence or phrasal structure. We separately measure them using bag-of-word Intersection/Union scores and parse-tree edit-distances, respectively.

Lexical diversity A sentence is lexically different from the reference when it uses lexical paraphrases (e.g., synonyms) to convey similar meanings. We calculate the case-insensitive piece Intersection/Union score after striping punctuation and the SentencePiece white space symbol. All pieces are put to lowercase and into a set. The more pieces the two sentences share, the higher the score will be. The Intersection/Union scores between the reference and the paraphrases are shown in Tab. 1.

Syntactic diversity We consider the edit-distance between the parse trees of the reference and the paraphrase as a metric of syntactic diversity. Parse tree edit-distance is considered a useful feature in NLP tasks (Yao et al., 2013). The more syntactic variations there are between two sentences, the larger the tree edit-distance will be. We consider only the top 3 levels of the parse trees, excluding any terminals. Sentences are parsed with Stanford CoreNLP (Manning et al., 2014); the tree edit-distance is calculated with the APTED (Pawlik and Augsten, 2015a,b) algorithm. The average tree edit-distance for each system is shown in Tab. 1.

Diversity among paraphrases Hu et al. (2019) produced multiple paraphrases for each reference. While shown to be diverse compared to the reference, the authors did not investigate whether these paraphrases are trivial rewrites of one another, as it is likely the case with beam search under a few lexical constraints. Our clustering step is specifically designed to retrieve collectively diverse paraphrases.

We use the same metrics to evaluate pairs of systems from our work and compare them against PARABANK (Hu et al., 2019), as shown in Tab. 2. The max/min/median systems are oracle systems derived from human semantic similarity judgment scores. The human judgments from Tab. 1 show our paraphrases are of comparable quality to PARABANK, while maintaining a much higher degree of diversity among paraphrases of the same reference, as shown by automatic metrics.

3.7 Semantic similarity on STS Benchmark

In addition to evaluating via human judgments, we consider the same evaluation mechanism as PARANMT (Wieting and Gimpel, 2018): the use

Systems Compared	1-BLEU↑	∩/∪ ↓	Tree ED↑
PARABANK$_{17}$/PARABANK$_{34}$	20.58	80.93	2.26
Our work$_1$/Our work$_3$	64.16±.21	52.77±.48	5.51±.01
Our work$_3$/Our work$_5$	**71.05±.22**	**45.00±.51**	**6.40±.19**
Our work$_1$/Our work$_5$	69.46±.27	46.79±.12	6.25±.18
Our work$_{max}$/Our work$_{min}$	66.03±.86	49.10±.16	5.84±.33

Table 2: Collective diversity within our work compared to PARABANK, as measured by (1-BLEU)×100, intersection/union score×100, and parse tree edit-distance.

of paraphrase corpora as training data for the Semantic Textual Similarity (STS) task. STS aims to measure the degree of equivalence in meaning or semantics between a pair of sentences. Notably, Agirre et al. (2016) having been a part of the SemEval workshop (2012 -2017). The evaluation consists of human annotated English sentence pairs, scored on a scale of 0 to 5 to quantify similarity of meaning, with 0 being the least, and 5 the most similar.

Wieting and Gimpel (Wieting and Gimpel, 2018) compared three encoding mechanisms: WORD, TRIGRAM and LSTM. The WORD model (Wieting et al., 2016) averages the embedding for each word in the sentence into a fixed length vector embedding for the sentence; the TRIGRAM model (Huang et al., 2013) averages over character trigrams; and the LSTM (Hochreiter and Schmidhuber, 1997) approach averages over the final hidden states to obtain the sentence embedding.

Encoders are trained on paraphrase pairs (s, s') with a margin based loss function $l(s, s', t, t') =$

$$\max(0, \delta - \cos[g(s), g(s')] + \cos[g(s), g(t)]) + \max(0, \delta - \cos[g(s), g(s')] + \cos[g(s'), g(t')])$$

where g is one of (WORD, TRIGRAM, LSTM) and (t, t') is a negative sample selected from a *megabatch*, an aggregation of m mini-batches (Wieting and Gimpel, 2018).[3]

We evaluate the WORD model trained[4] on PARANMT, PARABANK and PARABANK 2 (our work). We retrieved the paraphrases from PARABANK and our work that share the same references as PARANMT-5M. Our work is evaluated as 5 systems, based on the rank in the output; the last available paraphrase is used when lower ranks are empty. We also include a system that uses a pair of paraphrases, instead of a reference and a paraphrase. We keep PARABANK paraphrases that have a bag-of-word intersection/union score of 0.7 or less, and use the 1-best based on regression scores. In Tab. 3, we report Pearson's r and Spearman's r on the STS'16 test set. Sentence embeddings trained on our work exhibit higher correlation with human judgments, which reflects the superior paraphrastic diversity of the corpus.

System	Pearson's r	Spearman's r
PARANMT	75.378	76.322
PARABANK	76.006	76.961
Our work$_1$	**76.546**	77.528
Our work$_2$	76.143	77.240
Our work$_3$	76.397	77.500
Our work$_4$	76.414	**77.612**
Our work$_5$	75.882	77.075
Our work$_{1/5}$	75.680	76.882

Table 3: Pearson's r × 100 and Spearman's r × 100 computed on STS 2016 task. Our work$_{1/5}$ contains paraphrase pairs from system$_1$ paired with system$_5$, while all other systems are paired with the reference sentence.

3.8 Improving contextualized encoders with paraphrastic data

Paraphrastic data can be used to fine-tune contextualized encoders such as BERT (Devlin et al., 2018). We frame the fine-tuning task as paraphrase identification (Das and Smith, 2009), where given a pair of sentences, the task is to classify them as paraphrases or non-paraphrases. To generate the training data, we extract, for each

[3] We confirmed this loss with Wieting and Gimpel, that it captures their open implementation, which we employ. Wieting and Gimpel (2018) described their loss as: $\max(0, \delta - \cos(g(s), g(s')) + \cos(g(s), g(t)))$, which is equivalent under their assumption the paraphrases are equivalent.

	Total	74.12	**74.58**
Exact Match	HasAns	**70.34**	68.00
	NoAns	71.44	**74.95**
	Total	70.89	**71.48**

Table 5: SQuAD 2.0 results on dev set.

sentence in PARANMT-5M, the sentence embeddings generated by the WORD model trained in §3.7. For each sentence s, we then find the (approximate) nearest neighbour n which is not s', among all of the sentences. We thus obtain two pairs, where (s, s') is a paraphrase pair, and (s, n) is a non-paraphrase pair. We use these to train a binary classifier with cross-entropy loss.

We then use this BERT fine-tuned on paraphrases (henceforth pBERT) for fine-tuning on SQuAD 2.0 (Rajpurkar et al., 2018) and 4 NLP tasks present in the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2019): Quora Question Pairs (QQP) (Chen et al., 2017), Multi-Genre Natural Language Inference (MNLI) (Williams et al., 2018), the Semantic Textual Similarity Benchmark (STS-B) (Agirre et al., 2016), and the Microsoft Research Paraphrase Corpus (MRPC) (Dolan et al., 2004). Following the model formulation, hyper-parameter selection and training procedure specified in Devlin et al. (2018), we add a single task-specific, randomly initialized output layer for the classifier.

We present our results in Tab. 4 and Tab. 5. We observe gains for STS-B, MRPC and QQP, tasks strongly related to paraphrase identification. Fine-tuning on our paraphrase corpus also improves performance on SQuAD, a question-answering task, while slightly degrading performance on MNLI. Overall, simple fine-tuning of BERT on our corpus leads to improvements on downstream tasks, in particular when the task is related to paraphrase detection.

4 Related works

4.1 Paraphrastic resources

Paraphrastic resources exist across different scopes (i.e., lexical, phrasal, sentential) and different creation strategies (i.e., manually curated, automatically generated). For a more comprehensive survey on data-driven approaches to paraphrasing, please refer to Madnani and Dorr (2010).

Sub-sentential resources WordNet (Miller, 1995), FrameNet (Baker et al., 1998), and VerbNet (Schuler, 2006) can be used to extract paraphrastic expressions at lexical levels. They contain the grouping of words or phrases that share similar semantics and sometimes entailment relations. While FrameNet and VerbNet do have example sentences or frames where lexical units are put into contexts, there is no explicit paraphrastic relations among these examples. Also, these datasets tend to be small, as they were curated manually. There have been efforts to augment such resources with automatic methods (Snow et al., 2006; Pavlick et al., 2015b), but they are still confined to lexical level and sometimes require the use of other paraphrastic resources (Pavlick et al., 2015b).

PPDB (Ganitkevitch et al., 2013; Pavlick et al., 2015a) automated the generation of lexical paraphrases via bilingual pivoting, taking advantage of the relative abundance of bilingual corpora. While significantly larger and more informative (e.g., ranking, entailment relations, etc.) than the above manually curated resources, PPDB suffers from ambiguity as words or phrases are removed from their sentential contexts.

Sentential resources There exists multiple human translations in the same language for some classic readings. Barzilay and McKeown (2001) sought to extract lexical paraphrastic expression from such sources. Unfortunately such resources – along with those manually constructed for text generation research (Robin, 1995; Pang et al., 2003) – are small and limited in domain.

PARANMT and PARABANK are two much larger sentential paraphrastic resources created through back-translation.

Reference:		
	Real life is sometimes thoughtless and mean.	Hey, stop right there!
PARANMT:		
	real life is sometimes reckless and cruel .	hey , stop .
PARABANK:		
	The real life is occasionally ruthless and cruel.	Stay where you are!
	The real world is occasionally ruthless and cruel.	
	The real life is sometimes reckless and cruel.	
Our work:		
	True life is sometimes ruthless and cruel.	Hold your position!
	Actual life is sometimes ruthless and cruel.	Stay where you are!
	Sometimes real life is ruthless and cruel.	Stay in position!
	Real life can be inconsiderate, cruel sometimes.	Remain where you are!
	Real living is a harsh and unscrupulous one, at times.	Stay put!

Table 6: Selected examples from our work, compared to paraphrastic resources with prior approaches. Our work has paraphrases that are not only different from the reference, but also diverse among themselves.

4.2 Translation-based Approaches

PARANMT is an automatically generated sentential paraphrastic resource through back-translating bilingual resources. It leveraged the imperfect ability of Neural Machine Translation (NMT) to recreate the translation target by conditioning on the source side of the bitext.

PARABANK took a similar approach but with the inclusion of lexical constraints from the target side of the bitext. This step allows for multiple translations from one bilingual sentence pair and promotes lexical diversity. Their work, despite being larger and shown to be less noisy than PARANMT, relies on heuristics to produce *hard* constraints on the decoder, which often causes unintended changes in semantics or grammar.

Both works largely follow standard approaches in NMT, generating 1-best hypotheses given a source text and a set of constraints using beam search. Sentential paraphrasing, nevertheless, has fundamentally different objectives than MT. The latter strives to find the best elicitation that is both fluent and semantically close to the **foreign** text to convey information across languages. The former, on the other hand, seeks syntactically and lexically diverse expressions that convey the same meaning, with the goal of capturing the **intrinsic flexibility and uncertainty** of human communications. This work attempts to adapt the methodology to these objectives of monolingual paraphrasing.

4.3 Leveraging paraphrases in NLP

In the context of semantic parsing, Berant and Liang (2014) use a paraphrase classification module to determine the match between a canonical utterance and a logical form, both using a phrase table and distributed representations. To improve question answering (QA), Duboue and Chu-Carroll (2006) generate paraphrases of a given question using back-translation, and optionally replace the original question with the most relevant paraphrase. Dong et al. (2017) tackle QA by marginalizing the probability of an answer over a set of paraphrases, generated using rule-based and NMT-based methods. Fader et al. (2013) use a corpus of questions with paraphrases, to construct a corpus of semantically equivalent queries.

The task of paraphrase identification, which we use as a fine-tuning objective, has been studied as a task in itself. Das and Smith (2009) use grammars to perform generative modeling of paraphrases. Madnani et al. (2012) identify paraphrases by relying only on MT metrics as features. Ferreira et al. (2018) feed sentence similarity measured with hand-crafted features to machine learning algorithms. Convolutional neural networks have been introduced by Yin and Schütze (2015) and Chen et al. (2018), and further augmented with LSTMs (Kubal and Nimkar, 2018) and attention mechanisms (Fan et al., 2018).

5 Conclusions and future work

A presumed goal for building a sentential paraphrase resource is to capture *different* ways of expressing the same thing: *diversity matters*. Previous work on paraphrastic resource creation relied on decoding techniques from NMT using bilingual corpora, with limited success in promoting diverse expressions. We have presented a new community resource produced by sampling and clustering. We evaluated our method against prior works (Wieting and Gimpel, 2018; Hu et al., 2019) and found significant gains in both lexical and syntactic diversity. Further, we've shown how straightforward fine-tuning of a state-of-the-art contextual encoder on our resource can improve performance on a variety of language tasks.

Large-scale representation learning from visually grounded untranscribed speech

Abstract

Systems that can associate images with their spoken audio captions are an important step towards visually grounded language learning. We describe a scalable method to automatically generate diverse audio for image captioning datasets. This supports pretraining deep networks for encoding both audio and images, which we do via a dual encoder that learns to align latent representations from both modalities. We show that a masked margin softmax loss for such models is superior to the standard triplet loss. We fine-tune these models on the Flickr8k Audio Captions Corpus and obtain state-of-the-art results—improving recall in the top 10 from 29.6% to 49.5%. We also obtain human ratings on retrieval outputs to better assess the impact of incidentally matching image-caption pairs that were not associated in the data, finding that automatic evaluation substantially underestimates the quality of the retrieved results.

1 Introduction

Natural language learning in people starts with speech, not text. Text is tidy: it comes in convenient symbolic units that vary little from one writer to another. Speech is continuous and messy: the sounds used to convey a given word are modified by those of surrounding words, and the rate of speech, its pitch, and more vary across speakers and even for the same speaker in different contexts. As such, problems involving speech provide distinct challenges and opportunities for learning language representations that text-based work—which represents the vast majority—gets a free pass on.

Recent work has explored various means to transform raw speech into symbolic forms with little or no supervision (Park and Glass, 2007; Varadarajan et al., 2008; Ondel et al., 2016; Kamper et al., 2017a; Bhati et al., 2018). However, learning natural language starts with grounded, contextualized speech. While infants as young as 8-months-old can segment word-like units without non-linguistic information (Jusczyk and Aslin, 1995) and adults can learn to segment words in artificial languages (Saffran et al., 1996), a learner must ultimately ground their representations of linguistic sequences (Harnad, 1990) to effectively use them to refer to objects, events and more. Furthermore, learning from rich perceptual data and interactions can be more efficient as it provides additional cues to the identities of words and their meaning in context.

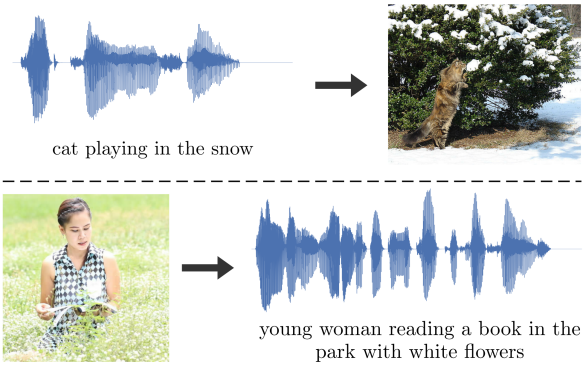

Figure 1: Models that encode speech segments and images into a shared latent space enable images to be retrieved using their audio descriptions (top) and to associate images with spoken captions (bottom). Text captions are provided for clarity; only speech and images are used by the models.

We address the problem of relating images to audio captions that describe them (Figure 1), building on previous research into learning from visually grounded, untranscribed speech (Harwath and Glass, 2015; Sun et al., 2016; Harwath et al., 2016; Chrupała et al., 2017; Kamper et al., 2017b; Chrupała, 2019; Harwath and Glass, 2019). Such problem settings provide opportunities both to improve our theoretical understanding of language

as well as to realize gains on practical problems—including voice interaction with virtual assistants, image retrieval based on speech, and generally better supporting people with visual impairments.

Our contribution is to improve performance on bidirectional speech/image retrieval through better data and better models for learning fixed dimensional latent representations of both modalities. We construct a synthetic speech caption dataset for pretraining by applying text-to-speech (TTS) on Conceptual Captions (Sharma et al., 2018), a dataset with 3.3 million diverse image-caption pairs. Unlike Chrupała et al. (2017), who similarly applied TTS to MS-COCO (Chen et al., 2015), we inject diversity by varying the voice, speech rate, pitch and volume gain on every synthetically produced audio caption. We refer to the resulting dataset as Conceptual Spoken Captions (CSC). CSC's scale allows us to train deeper models than previous work. We use Inception-ResNet-v2 (Szegedy et al., 2017) to encode both the audio and visual modalities in a dual encoder model, pretraining on CSC and then fine-tuning and evaluating on human speech in the smaller Flickr Audio Caption Corpus (FACC) (Harwath and Glass, 2015). Using an adapted batch loss function rather than the triplet loss used in previous work, we substantially improve on the previous state-of-the-art for the standard FACC retrieval tasks.

Image captioning datasets contain positively paired items—but that does not imply that a random image and caption cannot also be a valid match. For instance, in FACC there are many spoken captions about beaches and sunsets and plenty of images that match these captions; two different images with descriptions *"A surfer is riding a wave."* and *"A man surfs the wave"* are likely compatible. It is of course not feasible to exhaustively annotate all pairwise associations, so we have human raters judge the top five retrieved results for two models to assess the impact of this aspect of the data on automatic retrieval metrics used thus far. Unsurprisingly, models retrieve many compatible results that are unpaired in FACC: with the human evaluations, we find consistent increases in recall.

2 Data

Larger training datasets support better performance and generalization (Banko and Brill, 2001; Halevy et al., 2009; Sun et al., 2017), especially for deep models. Collecting labels from people has become easier via crowd computing (Buhrmester et al., 2011), but is still expensive and remains a bottleneck for creating broad and representative datasets. This motivates the case for exploiting incidental annotation (Roth, 2017) and automating some aspects of dataset creation. The current trend of using machine translation systems to produce augmented datasets for machine translation itself (Sennrich et al., 2016) and for monolingual tasks like classification (Yu et al., 2018) and paraphrasing (Wieting and Gimpel, 2018) is a good example of this.

For speech image captioning, Chrupała et al. (2017) used a Text-to-Speech (TTS) system to create audio from the textual captions given in the MS-COCO dataset, resulting in 300k unique images with 5 spoken captions each. We scale this idea to the larger and more diverse textual Conceptual Captions dataset with 3.3 million unique image and captions, additionally modifying the produced speech by using multiple voices and random perturbations to the rate, pitch and audio. Our goal is to make the resulting data more effective for pretraining models so they can learn more efficiently on smaller amounts of human speech.

2.1 Conceptual Captions

Image captioning datasets have ignited a great deal of research at the intersection of the computer vision and natural language processing communities (Lin et al., 2014; Vinyals et al., 2015; Bernardi et al., 2016; Anderson et al., 2018). Getting annotators to provide captions works well with crowd computing, but Sharma et al. (2018) exploit incidental supervision for this task to obtain greater scale with their Conceptual Captions dataset. It contains 3.3 million pairs of image and textual captions, where pairs are extracted from HTML web pages using the *alt-text* field of images as a starting point for their descriptions.

The textual captions are processed in a hypernymization stage. Named entities and syntactic dependency annotations are obtained using Google Cloud Natural Language APIs, which are matched to hypernym terms using the Google Knowledge Graph Search API. Proper nouns, numbers, units, dates, durations and locations are removed; identified named-entities are substituted with their hypernym, merging together analogous terms when possible. For example, the original alt-text (1) is converted to the conceptual caption (2).

(1) **alt-text**: *Musician Justin Timberlake per-*

forms at the 2017 Pilgrimage Music & Cultural Festival on September 23, 2017 in Franklin, Tennessee.

(2) **conceptual caption**: *pop artist performs at the festival in a city.*

There are many sequential filtering steps for improving the quality of the captions—see Sharma et al. (2018) for a thorough description. As quality control, a random sample of 4K conceptual captions were rated by human annotators, and 90.3% were judged "good" by at least 2 out of 3 raters.

2.2 Conceptual Spoken Captions

We use TTS to generate a high-fidelity spoken sentence for each of the 3.3 million textual captions in the Conceptual Captions dataset.[1] We use the Google Cloud Speech API[2] for TTS. Internally, the service uses a WaveNet model (Van Den Oord et al., 2016) to generate audio. For diversity, the speech is synthesized using parameter variations, as follows:

- *Voice*, which is sampled uniformly from a set of 6 different voices generated using a WaveNet model for American English.
- *Speaking rate* controls the speed of the synthesized audio. A speaking rate of 1.0 means the normal speed of a given voice, while a speaking rate of 2.0 means twice as fast. When synthesizing the data, we draw this parameter from a Gaussian distribution $\sim \mathcal{N}(1.0, 0.1^2)$.
- *Pitch* controls how high/deep the voice is. For example, if set to 1, this means the voice will be synthesized 1 semitones above the original pitch. This parameter is drawn from a Gaussian distribution $\sim \mathcal{N}(0.0, 1.0^2)$.
- *Volume gain* controls a gain in dB with respect to the normal native signal amplitude. If set to 0, the voice is synthesized without alterations in volume. This parameter is drawn from a Gaussian distribution $\sim \mathcal{N}(0.0, 2.0^2)$.

To avoid degenerate cases, we clip the values sampled from the Gaussian distributions described above such that they are never more than 2 times the standard deviation from the mean. All spoken captions are generated in 16000 Hz.

[1]The alt-text does not come with the dataset and cannot be redistributed, so we focus on the conceptual captions for ease of experimentation and reproducibility.

[2]https://cloud.google.com/text-to-speech/

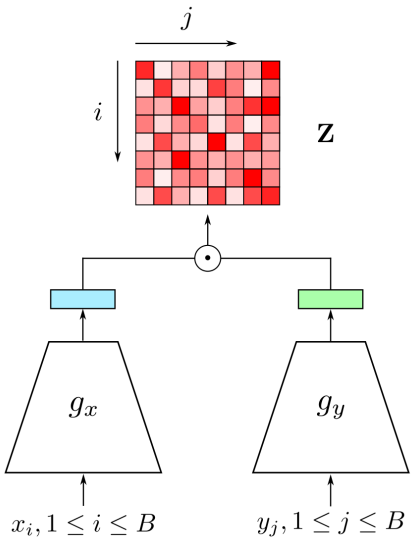

Figure 2: Dual-encoder model architecture.

2.3 Flickr Audio Caption Corpus

The Flickr Audio Caption Corpus (FACC) (Harwath and Glass, 2015) consists of 40,000 pairs of images and spoken captions, with 8000 unique images, of which 1000 are held for validation and 1000 for testing. The spoken captions are generated from humans reading the textual captions from the Flickr8k dataset (Hodosh et al., 2013), originally crowd-sourced and based on images from Flickr.

We use FACC for evaluation, both when pretraining on Conceptual Spoken Captions and when training on FACC from scratch. Like previous work, the core evaluation considered is retrieval of the known paired image given an audio caption within some top-k set of retrieved items (e.g. R@1 for whether the first item retrieved is the paired one and R@10 for whether it is in the top ten results). We also conduct human evaluations on retrieval outputs to detect the presence of unpaired but matching image-caption pairs identified by the models and thereby better assess their impact on performance.

3 Model

Dual encoders are used in a wide range of applications, including signature verification (Bromley et al., 1994), object tracking (Bertinetto et al., 2016), sentence similarity (Mueller and Thyagarajan, 2016), improving neural machine translation (Yang et al., 2019) and many others. The core of this set of architectures is a simple two-tower model illustrated in Figure 2, where inputs $x \in \mathcal{X}$ are processed by an encoder g_x and inputs $y \in \mathcal{Y}$ by a second encoder g_y. The inputs may come

from the same distribution—or they may be from entirely different sources or modalities. The towers may share the same architecture and weights—or they can be completely unlike and disconnected.

These models are standard in audiovisual image captioning (Harwath and Glass, 2015; Chrupała, 2019; Harwath et al., 2018). In this setting, the dual encoder model, is composed by a visual tower, g_{vis}, processing the images, and an audio tower, g_{aud}, processing the spoken captions. The model is trained to map both modalities into a joint latent space. Here, we extend previous work to consider a batched margin loss, which we show to be superior for learning dense representations for retrieval.

Notation. The inputs are processed in batches of size B. For each input x_k and y_k in the batch, $1 \leq k \leq B$, let $g_x(x_k)$ and $g_y(y_k)$ be their latent representations extracted by the corresponding tower. We define the $B \times B$ matrix $\mathbf{Z}$ as the similarity between the latent representations for each pair of elements in the batch. A natural choice for that similarity is the dot product between the latent representations:

$$\mathbf{Z}_{ij} = g_x(x_i) \cdot g_y(y_j) \tag{1}$$

As shown in Figure 2, $\mathbf{Z}$ encodes all pairwise associations in the batch. However, an additional aspect of some datasets must be taken into account: often times the same input x can match multiple inputs y or vice-versa—for instance, both Flickr8k and MS-COCO have multiple captions for the each image. To respect these pairs when they land in the same batch—and thus not penalize models for (correctly) associating them—we define a $B \times B$ masking matrix $\mathbf{M}$:

$$\mathbf{M}_{ij} = \begin{cases} 0, & \text{if } x_i \text{ matches } y_j \\ 1, & \text{otherwise} \end{cases} \tag{2}$$

All pairs (x_k, y_k) match and this equivalence is transitive, so $\mathbf{M}$ is symmetric and all diagonal elements $\mathbf{M}_{kk}$, $1 \leq k \leq B$ are zero.

Triplet Loss. Both Chrupała (2019) and Harwath et al. (2018) (and their previous work) employ the triplet loss function given in Equation 3.

$$\mathcal{L}_{\text{T}} = \sum_{k=1}^{B} \big(\max(0, \mathbf{Z}_{km} - \mathbf{Z}_{kk} + \delta) + \max(0, \mathbf{Z}_{nk} - \mathbf{Z}_{kk} + \delta) \big) \tag{3}$$

For each value k, m is randomly drawn from a uniform distribution over indices j such that $M_{kj} = 1$, and n over indices i such that $M_{ik} = 1$.

Masked Margin Softmax Loss. The triplet loss (3) used previously misses opportunities to learn against a wider set of negative examples, namely all those in the batch that are not known to be positively associated (i.e., $\mathbf{M}_{ij} = 1$). To exploit these additional negatives, we minimize the Masked Margin Softmax (MMS) loss function, inspired by Henderson et al. (2017) and Yang et al. (2019). MMS simulates x-to-y and y-to-x retrievals inside the batch. It is defined at a high level as:

$$\mathcal{L}_{\text{MMS}} = \mathcal{L}_{xy} + \mathcal{L}_{yx} \tag{4}$$

$\mathcal{L}_{\text{MMS}}$ is the sum of losses defined over x-to-y (Eq. 5) and y-to-x (Eq. 6) in-batch retrievals.

$$\mathcal{L}_{xy} = -\frac{1}{B} \sum_{i=1}^{B} \log \frac{e^{\mathbf{Z}_{ii} - \delta}}{e^{\mathbf{Z}_{ii} - \delta} + \sum_{j=1}^{B} \mathbf{M}_{ij} e^{\mathbf{Z}_{ij}}} \tag{5}$$

$$\mathcal{L}_{yx} = -\frac{1}{B} \sum_{j=1}^{B} \log \frac{e^{\mathbf{Z}_{jj} - \delta}}{e^{\mathbf{Z}_{jj} - \delta} + \sum_{i=1}^{B} \mathbf{M}_{ij} e^{\mathbf{Z}_{ij}}} \tag{6}$$

These are equivalent to a cross-entropy loss after a column-wise or row-wise softmax on the matrix $\mathbf{Z}$, subject to the masking constraints in $\mathbf{M}$ and margin δ.

The margin hyperparameter δ is gradually increased as training progresses. Empirically, we found that, with a fixed δ, large values lead to unstable performance in early training, while small values lead to negligible results in final performance. Starting with a small δ and increasing it does not hurt early training and forces the model to learn from a harder task later on. There many ways to increase δ along training—e.g. linearly, quadratically, and exponentially. The latter is used in this work.

Contrasting Equations 3 and 4, the former chooses a negative sample randomly, while the latter takes advantage of all negative pairs in the batch and thus improves sample efficiency. $\mathcal{L}_{\text{MMS}}$ has three main differences with Yang et al. (2019): (1) a masking term that accounts for the fact that there might be multiple positive choices in the batch for a given input; (2) a varying margin term δ, which is increased during training; (3) a log term that makes MMS more closely resemble a cross-entropy loss.

		Speech to Image					Image to Speech

Table 1: Performance on the validation set of Conceptual Spoken Captions, comparing different loss functions and batch sizes.

4 Experiments

4.1 Experimental settings

Image preprocessing. During training, data augmentation is performed by randomly distorting the brightness and saturation of images. Each image is also randomly cropped or padded such that at least 67% of the area of the original image is covered, and re-scaled if necessary to 299×299. During evaluation, we do not perform color distortions, and we crop/pad the central portion of the images.

Audio preprocessing. We extract 128 Mel-Frequency Cepstral Coefficients (MFCCs) from the raw audio signals using a window size of 20ms. The audio signals have a sampling rate of 16000Hz. We compute features every 10ms, such that each window has a 50% overlap with its neighbors. During training, we randomly crop/pad the MFCCs in the temporal dimension, and perform data augmentation as in Park et al. (2019), using one mask with a frequency mask parameter of 20 and a time mask parameter of 40. We do not perform time warping.

Encoders. Both audio and image encoders are Inception-ResNet-v2 networks (Szegedy et al., 2017), allowing the model to reap the benefits of relatively low computational cost, fast training and and strong performance when combining the Inception architecture with residual connections.[3] Related to our setting for audio processing, Li et al. (2019) also uses residual convolutional neural networks for state of the art results on LibriSpeech dataset (Panayotov et al., 2015). For the audio tower, we stack 3 replicas of the MFCCs and treat them as images. For each modality, a 1536-dimensional latent space representation is extracted. Despite using the same architecture for both encoders, their weights are not shared. Unless specified otherwise, the models are *not* pretrained.

[3] See Bianco et al. (2018) for an extensive benchmark analysis of popular convolutional neural network architectures.

Optimization. Models are trained using Adam (Kingma and Ba, 2014), with an initial learning rate of 0.001 and an exponential decay of 0.999 every 1000 training steps, $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 1\text{e}{-8}$. We use a weight decay of $4\text{e}{-5}$, and train on 32 GPUs until convergence. Unless specified otherwise, the optimization objective is minimizing the loss $\mathcal{L}_{\text{MMS}}$ (Eq. 4) with a margin term initially set to $\delta = 0.001$ exponentially and increased by a factor of 1.002 every 1000 steps.

4.2 Retrieval: Conceptual Spoken Captions

Our primary aim with CSC is to use it for pretraining for later fine-tuning and evaluation on datasets with human speech instead of TTS. Nevertheless, we can compare different loss functions and different batch sizes on the CSC validation set to better understand the impact of these parameters.

We train models on CSC for 3 million steps, cropping/padding spoken captions to a duration of 3.5 seconds and using the loss functions $\mathcal{L}_{\text{T}}$ (Eq. 3) and $\mathcal{L}_{\text{MMS}}$ (Eq. 4). We find continuing improvements as batch size increases from 12 to 24 to 48. Furthermore, with the same batch size of 48, models optimized for minimizing $\mathcal{L}_{\text{MMS}}$ perform substantially better than those using $\mathcal{L}_{\text{T}}$, as summarized in Table 1. Of particular note is that R@1 scores for $\mathcal{L}_{\text{MMS}}$ (batch size 48) are more than double those of $\mathcal{L}_{\text{T}}$ in both directions.

4.3 Retrieval: Flickr Audio Caption Corpus

Table 2 compares previous results on the FACC dataset with those obtained by variations of our model. As a pre-processing step, spoken captions are cropped/padded to a duration of 8 seconds. After pretraining the model in CSC, we explore all possible combinations of using or not the pretrained weights for each of the branches g_{aud} and g_{vis} as a warm-starting point, training until convergence on FACC. Warm-starting each of the branches in the dual-encoder leads to substantial improvements

	Model	Caption to Image					Image to Caption

Table 2: Retrieval scores on the test set of FACC.

over the baseline, and combining both branches leads to the best overall performance.

In particular, we improve R@10 for caption-to-image from the .296 obtained by Chrupała (2019) by 20% absolute to .495, without using multitask training or pretraining g_{vis} on ImageNet (Deng et al., 2009). The multitask training approach of Chrupała (2019) is complementary to our improvements, so further gains might be obtained by combining these strategies. Furthermore, very deep, residual convolutional neural networks over characters have been shown to perform well for text-based tasks (Conneau et al., 2017). We expect that our strategy of using the same basic architecture across different input types (speech, text and image) can be fruitfully extended to that setting. A related observation: while our results exceed previous results reported on text/image retrieval settings for FACC, we expect that recent advances in text encoding could easily beat those reported numbers.

We also explore very low-data regimes using our pretrained model (see Fig. 3). Using small training subsets randomly drawn from FACC, we report performance as a function of how much data the model sees. With as little as 10% of the original training data (3000 image/spoken caption pairs), the warm-started model performs competitively with a model trained on all training data.

Qualitative evaluation. Once a model is trained, any input (image or spoken caption) can be be used to query the corpus of images and spoken captions for nearest neighbors in the latent space. Figure 4 shows some examples of retrieved nearest neighbors in FACC's test set. Given a spoken caption or

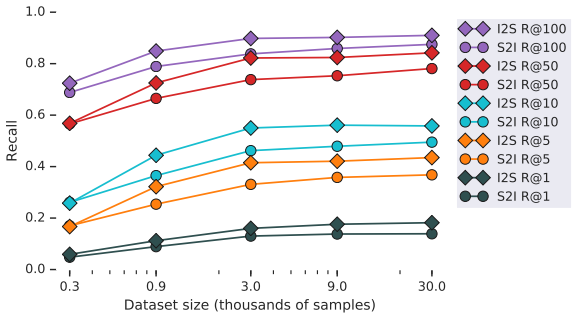

Figure 3: Ablations on low-data regime on FACC: chart shows recall scores for image-to-speech (I2S) and speech-to-image (S2I) retrieval, as a function of the amount of training data used for fine-tuning.

an image we show the five nearest image neighbors and five nearest caption neighbors. From these, it is clear that the representations capture many semantically salient attributes of the inputs. The retrieved items correctly share many thematic elements and many are clearly good matches even though the particular image-caption pairs are not associated in the data. This serves to reinforce our observation that R@k evaluations using only the known paired items is likely to underestimate the actual performance of the models—which we show to be the case with human evaluations in Section 4.4.

Only some items are substantially incompatible: e.g. an image of a car for a caption about a woman in a river (they share water spraying), a picture of three adults for a caption about children raising their hands, and a caption about a boy climbing a wall for an image of children playing leapfrog). That said, many details are poor matches, such as the count of objects (one ball versus many), colors

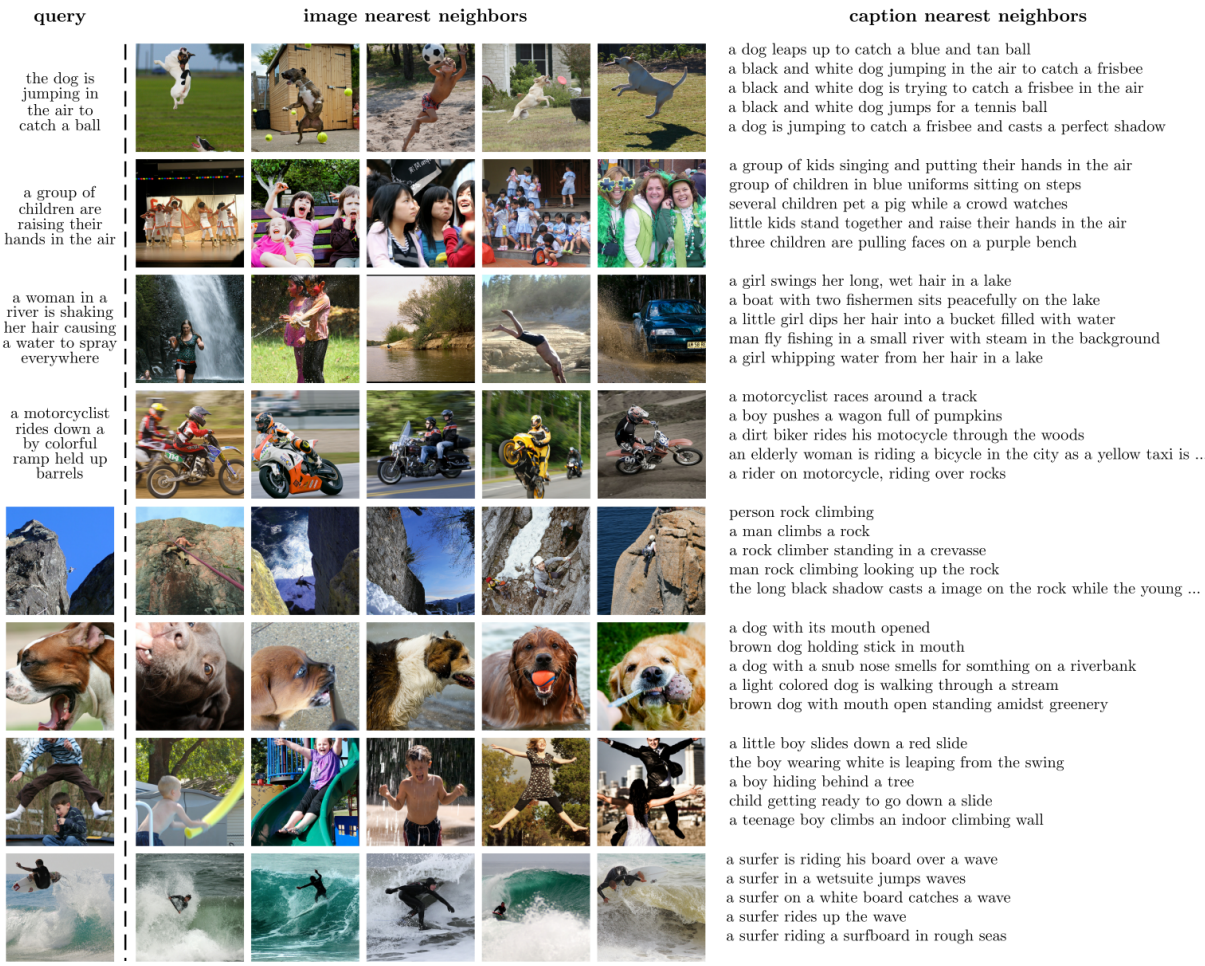

Figure 4: Nearest neighbors in the joint visual and acoustic latent space, best viewed with zoom: using 4 spoken captions and 4 images as queries, we extract from FACC's test set the closest 5 images and 5 spoken captions in the latent space for each of them. For simplicity, we show the text associated with each spoken caption.

(brown dogs versus multicolored ones), people descriptions (elderly woman versus male dirt biker), object identification (e.g. a yellow pool noodle viewed as similar to slides), processes (jumping versus sliding) and perspective (man looking up versus viewed from behind and climbing). As such, there is clearly significant headroom for better, more fine-grained modeling of both captions and images. Additionally, cross-modal attention mechanisms (Xu et al., 2015) and other explainability techniques (Ribeiro et al., 2016) could help better inspect and understand a model's predictions.

Furthermore, as noted by Chrupała et al. (2017), text-based retrieval models often handle misspellings poorly. In contrast, speech-based models are unlikely to suffer from similar problems because they inherently must deal with variation in the expression of words and utterances. For instance, the caption *"a dirt biker rides his **motocycle** through the woods"* (fourth row of Figure 4) is highly correlated with the correctly spelled sentences.

4.4 Human evaluation

We ran human evaluations to answer two questions: (1) how much does cropping limit model performance? and (2) how much do retrieval evaluations based only on positive associations underestimate model performance? Hints about both questions can be seen in the qualitative evaluation (Fig. 4).

To answer the first question, Table 3 shows the ratings for ground truth image/caption pairs in the FACC test set. The *uncropped* row shows that overall the captions are high quality and do match the full images. However, human ratings on images *cropped* at the center (which is what is provided to the models) show that there is considerable loss from cropping—only 62.5% of cropped images are rated as good matches by all five raters. Inspection makes it clear why cropping hurts: for example an

	"good" ratings (out of 5)				
	1+	2+	3+	4+	5
Cropped	.949	.918	.874	.800	.625
Uncropped	.995	.994	.989	.971	.891

Table 3: Human evaluation results on ground truth pairs on the test set of FACC, using either center cropped (which the models receive) or uncropped versions of the images.

image of a snowboarder in the air next to another on a ski lift is cropped such that the snowboarder is missing, and thus a poor match to captions mentioning the snowboarder. This clearly indicates that standard cropping (which we follow) inherently limits model performance and that strategies that use the full image should be explored.

Standard retrieval evaluations are blind to pairs that match but are not associated in the data. To address this and answer the second question posed above, we present the top-5 retrieved captions for each image and the top-5 retrieved images for each caption in FACC's test set to human raters. To increase speed and decrease costs, we show raters the original Flickr8k textual captions instead of the spoken ones. Each pair is judged by five raters as "good" or not. This gives a soft measure of the compatibility of each pair based on fast binary judgments from each rater. For retrieval evaluations of a model, we compute recall based on the majority of human raters approving each image-caption pair: R@1 is the percentage of top-1 results and R@5 the percentage of top-5 results that are evaluated as a match by at least 3 of the 5 raters.

Table 4 shows these metrics computed on retrieval outputs from two settings: FACC training from scratch and FACC fine-tuning after CSC pretraining. It also shows the corresponding automatic evaluations from Table 2 for easy comparison. These results make it clear that evaluation based only on positive associations is too rigid: speech-to-image retrieval based on human evaluations shows that a good matching item is returned in 52.2% of cases rather than just the 36.8% indicated by strict corpus matches. For image-to-speech retrieval the 55.8% strict measure goes up to 63.8%. That said, the results also show that the strict measure is nevertheless a useful indicator for comparing relative model performance: the model pretrained on CSC beats the corresponding one trained on FACC from scratch, on both human and automatic evaluations.

		S2I		I2S	
Eval	Pretrain	R@1	R@5	R@1	R@5
Auto		.018	.063	.024	.072

Humans		.056	.154	.070	.196
Humans	✓	.229	.522	.306	.638

Table 4: Comparison of human rater scores (majority agreement) versus using only corpus-known pairs on all metrics for speech-to-image (S2I) and image-to-speech (I2S) retrieval. Rows with *Auto* evaluation correspond to *Ours (from scratch)* and *Ours (warm-starting all)* scores in Table 2.

5 Conclusion

Large-scale datasets are essential for training deep networks from scratch. In this paper, we present a scalable method for generating an audio caption dataset taking advantage of TTS systems to create millions of data pairs. Using the MMS loss, we demonstrate that pretraining on this dataset greatly improves performance on a human-generated audio caption dataset. As TTS models continue to improve and be developed for more languages, this data augmentation strategy will only become more robust and helpful over time. Finally, using human evaluations, we show evidence that corpus-based retrieval scores underestimate actual performance.

This present work is focused on the here and now since captions describe a snapshot in time and focus on the visual entities and events involved in them. We thus have little hope to learn representations for words like *visit*, *career* and *justice*, for example. Videos can help with process oriented words like *visit* and could get significant components of words like *career* (such as the visual contexts, but not the overall path with intermediate goals involved in careers). They are likely to be hopeless for abstract words like *justice*. To address problems of this sort, there are likely many opportunities to combine ideas from unsupervised term discovery (Kamper et al., 2016; Bansal et al., 2017) with audiovisual word learning (Harwath et al., 2018) and models of visual grounding that have been applied to text (Kiros et al., 2018). Being able to learn effective representations from raw audio associated with images could provide new possibilities for work that learns from videos and text (transcribed speech) (Chen et al., 2018), and in particular open up such techniques to new languages and domains.

Abstract

Neural language models (LMs) perform well on tasks that require sensitivity to syntactic structure. Drawing on the syntactic priming paradigm from psycholinguistics, we propose a novel technique to analyze the representations that enable such success. By establishing a gradient similarity metric between structures, this technique allows us to reconstruct the organization of the LMs' syntactic representational space. We use this technique to demonstrate that LSTM LMs' representations of different types of sentences with relative clauses are organized hierarchically in a linguistically interpretable manner, suggesting that the LMs track abstract properties of the sentence.

1 Introduction

Neural networks trained on text alone, without explicit syntactic supervision, have been surprisingly successful in tasks that require sensitivity to sentence structure. The difficulty of interpreting the learned neural representations that underlie this success has motivated a range of analysis techniques, including diagnostic classifiers (Giulianelli et al., 2018; Conneau et al., 2018; Shi et al., 2016), visualization of individual neuron activations (Kádár et al., 2017; Qian et al., 2016), ablation of individual neurons or sets of neurons (Lakretz et al., 2019) and behavioral tests of generalization to infrequent or held out syntactic structures (Linzen et al., 2016; Weber et al., 2018; McCoy et al., 2018); for reviews, see Belinkov and Glass (2019) and Alishahi et al. (2019).

This paper expands the toolkit of neural network analysis techniques by drawing on the **syntactic priming** paradigm, a central tool in psycholinguistics for analyzing human syntactic representations (Bock, 1986). This paradigm is based on the empirical finding that people tend to reuse syntactic structures that they have recently produced or encountered. For example, English provides two roughly equivalent ways to express a transfer event:

(1) a. The boy threw the ball to the dog.
b. The boy threw the dog the ball.

When readers encounter one of these variants in the text more frequently than the other, they expect that future transfer events will more likely be expressed using the frequent construction than the infrequent one. For example, after reading sentences like (1a) (the **prime**), readers expect sentences like (2a), which shares syntactic structure with the prime, to occur with a greater likelihood than the alternative variant like (2b) which does not (Wells et al., 2009).[1]

(2) a. The lawyer sent the letter to the client.
b. The lawyer sent the client the letter.

We use the priming paradigm to analyze neural network language models (LMs), systems that define a probability distribution over the n^{th} word of a sentence given its first $n-1$ words. Building on paradigms that determine whether the LM's expectations are consistent with the syntactic structure of the sentence (Linzen et al., 2016), we measure the extent to which a LM's expectation for a specific syntactic structure is affected by recent experience with related structures. We prime a fully trained model with a structure by adapting it to a small number of sentences containing that structure (van Schijndel and Linzen, 2018). We then measure the change in surprisal (negative log probability) after adaptation when the LM is tested either on sentences with the same struc-

[1] Wells et al. (2009) measured priming effects for relative clauses, not dative constructions. For work on priming in production with dative constructions, see Kaschak et al. (2011).

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 66–76
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

ture or sentences with different but related structures. The degree to which one structure primes another provides a graded similarity metric between the model's representations of those structures (cf. Branigan and Pickering 2017), which allows us to investigate how the representations of sentences with these structures are organized.

As a case study, we applied this technique to investigate how recurrent neural network (RNN) LMs represent sentences with relative clauses (RCs). We found that the representations of these sentences are organized in a linguistically interpretable manner: sentences with a particular type of RC were most similar to other sentences with the same type of RC in the LMs' representation space. Furthermore, sentences with different types of RCs were more similar to each other than sentences without RCs. We demonstrate that the similarity between sentences was not driven merely by specific words that appeared in the sentence, suggesting that the LMs tracked abstract properties of the sentence. This ability to track abstract properties decreased as the training corpus size increased. Finally, we tested the hypothesis that LMs' accuracy on agreement prediction (Marvin and Linzen, 2018) would increase with the LMs' ability to track more abstract properties of the sentence, but did not find evidence for this hypothesis.

2 Background

2.1 Syntactic predictions in neural LMs

We build on paradigms that use LM probability estimates for words in a given context as a measure of the model's sensitivity to the syntactic structure of the sentence (Linzen et al., 2016; Gulordava et al., 2018; Marvin and Linzen, 2018). If a language model assigns a higher probability to a verb form that agrees in number with the subject (*the boy... writes*) than a verb form that does not (*the boy... write*), we can infer that the model encodes information about the agreement features of nouns and verbs (that is, the difference between singular and plural) and has correctly identified the subject that corresponds to this verb. This reasoning has been extended beyond subject-verb agreement to study whether the predictions of neural LMs are sensitive to a range of other syntactic dependencies, including negative polarity items (Jumelet and Hupkes, 2018), filler-gap dependencies (Wilcox et al., 2018) and reflexive pronoun binding (Futrell et al., 2019).

2.2 Syntactic priming in humans

Syntactic priming has been used to study whether the representations of two sentences have shared structure. For example, (1a) (repeated below as (3)) shares the structure VP → V NP PP with (4a) but not (4b).

(3) The boy threw the ball to the dog.

(4) a. The renowned chef made some wonderful pasta for the guest.
b. The renowned chef made the guest some wonderful pasta.

If (3) primes (4a) more than it primes (4b), we can infer that the representations of (3) are more similar to that of (4a) than to that of (4b). Since (4b) and (4a) differ only in their structure, this difference in similarity must be driven by structural information in the representations of the sentences (for reviews, see Mahowald et al. 2016 and Tooley and Traxler 2010).

Although priming studies have traditionally measured the priming effect on the sentence immediately following the prime, more recent studies have demonstrated that the effects of syntactic priming can be cumulative and long-lasting: sentences with a shared structure S_X become progressively easier to process when preceded by n sentences with the same structure S_X than when preceded by n sentences with a different structure S_Y (Kaschak et al., 2011; Wells et al., 2009).[2] In conjunction with the finding that words that are consistent with a probable syntactic parse are easier to process than words consistent with less probable parses (Hale, 2001; Levy, 2008), the increased ease of processing in cumulative priming studies can be interpreted as evidence that, with increased exposure to a structure, participants begin to expect that structure with a greater probability (Chang et al., 2006).

Cumulative priming allows us to study how sentences are related to each other in the human (or LM) representation space in the same way that non-cumulative priming does: when participants (or LMs) are exposed to sentences with structure S_X, if there is a greater decrease in surprisal when they are tested on other sentences with S_X than when they are tested on other sentences with S_Y, we can infer that the representations of sentences with S_X are more similar to each other than to the

[2] In studies looking at non-cumulative priming, $n = 1$.

Abstract structure	Example
Unreduced Object RC	The conspiracy that the employee welcomed divided the beautiful country.

Unreduced Passive RC	The conspiracy that was welcomed by the employee divided the beautiful country.
Reduced Passive RC	The conspiracy welcomed by the employee divided the beautiful country.
Active Subject RC	The employee that welcomed the conspiracy quickly searched the buildings.
PS/ORC-matched Coordination	The conspiracy welcomed the employee and divided the beautiful country.
ASRC-matched Coordination	The employee welcomed the conspiracy and quickly searched the buildings.

Table 1: Examples of sentences generated using templates containing the seven abstract structures we analyzed (optional elements, which only occur in a subset of the examples, are indicated in grey).

representations of sentences with S_Y.

2.3 LM adaptation as cumulative priming

Van Schijndel and Linzen (2018) modeled cumulative priming in recurrent neural networks (RNNs) by adapting fully trained RNN LMs to new stimuli — i.e. taking a fully trained RNN LM and continuing to train it on a small set of sentences (cf. Grave et al. 2017; Krause et al. 2017; Chowdhury and Zamparelli 2019). They demonstrated that when an RNN LM was adapted to a small number of sentences with a shared syntactic structure, the surprisal for novel sentences with that structure decreased, enabling them to infer that the LM's representations of sentences contained information about that structure.

3 Similarity between syntactic structures in RNN LM representational space

Following the assumptions in Section 2.2, we define a similarity metric between two structures S_X and S_Y in an LM's representation space by adapting the LM to sentences with S_X and measuring the change in surprisal for sentences with S_Y — i.e. measuring to what extent sentences with S_X prime sentences with S_Y. We use the notation $\mathbb{A}(Y \mid X)$ to refer to this change in surprisal[3], where X and Y are non-lexically-overlapping sets of sentences whose members share the structures S_X and S_Y respectively. If we assume that S_X and S_Y are similar to each other in the LM's representation space, then $\mathbb{A}(Y \mid X) > 0$ — i.e., encountering sentences with S_X causes the LM to assign a higher probability to sentences with S_Y. On the other hand, if we assume that S_X and S_Y are unrelated to each other, then $\mathbb{A}(Y \mid X) = 0$ — i.e., encountering sentences with S_X does not cause the LM to change its probability for sentences with S_Y.

[3] $\mathbb{A}$ is shorthand for adaptation.

4 Experimental setup

4.1 Syntactic structures

We analyzed five types of RCs. In an active subject RC, the gap is in the subject position of the embedded clause:[4]

(5) My cousin that _ liked the book ...

In a passive subject RC (*passive RCs*), the gap is in the subject position of the embedded clause, and the embedded verb is passive. In English, passive RCs can be unreduced (6a) or reduced (6b):

(6) a. The book that _ was liked by my cousin ...
b. The book _ liked by my cousin ...

In an object RC the gap is in the object position of the embedded clause. In English, object RCs can be unreduced (7a) or reduced (7b):

(7) a. The book that my cousin liked _ ...
b. The book my cousin liked _ ...

Finally, we also included two additional conditions with verb coordination: one with nearly identical word order and lexical content as active subject RCs ((8); ASRC-matched Coordination), and another with nearly identical word order and lexical content as passive RCs and object RCs ((9); PS/ORC-matched Coordination).[5]

(8) My cousin liked the book and ...

(9) The book liked my cousin and ...

[4] We illustrate the location of the gap with underscores here, but the underscores were not included in the LM's input.

[5] In order to maintain the same word order as in object and passive RCs, the subject of the coordinated verb phrases is an NP that tends to fill the object position in other sentences (e.g, "the equation"). Therefore, many of the sentences in this condition are implausible (e.g., "The equation reviewed the physicists and challenged the method.")

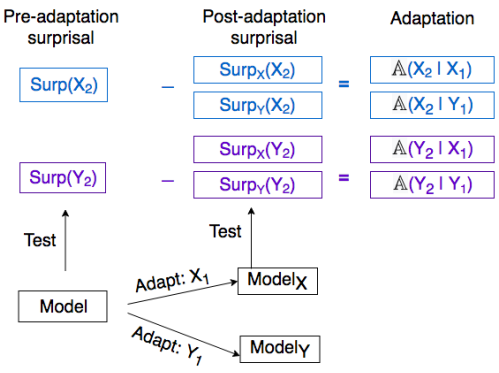

Figure 1: A schematic for calculating the similarity between two structures S_X and S_Y in an LM's representation space. X_1, X_2 and Y_1, Y_2 are non-lexically-overlapping sets of sentences with S_X and S_Y respectively. $Model_X$ and $Model_Y$ refer to versions of a fully trained model that have been adapted to either X_1 or Y_1 respectively. $Surp_X()$ and $Surp_Y()$ are functions that return the surprisal of sentences for $Model_X$ and $Model_Y$.

These conditions enable us to measure whether sentences with different types of RCs are more similar to each other in an LM's representation space than they are to lexically matched sentences without RCs.

4.2 Adaptation and test sets

We generated sentences from seven templates, one for each of the syntactic structures of interest. The slots were filled with 223 verbs, 164 nouns, 24 adverbs and 78 adjectives such that the semantic plausibility of the combination of nouns, verbs, adverbs and adjectives was ensured. The seven variants of every sentence had nearly identical lexical items (see Table 1).[6] We used these templates to generate five experimental lists — each list comprised of a pair of adaptation and test sets with minimal lexical overlap between them (only function words and some modifiers were shared). Each adaptation set contained 20 sentences and each test set contained 50.

In order to infer that any decrease in surprisal is caused by adaptation to an abstract syntactic structure, we need to ensure that the models are not adapting to properties of the sentence that are unrelated to the abstract structure of interest. Consider a LM adapted to (10) and tested on (11):

(10) The conspiracy that the employee welcomed divided the country.

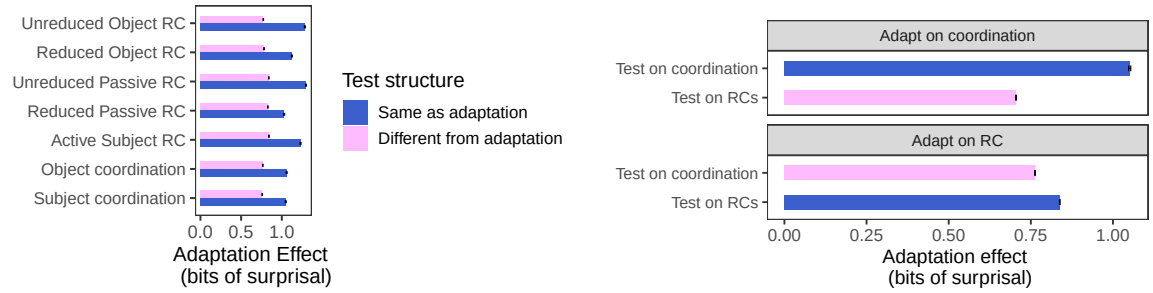
(11) The proposal that the receptionist managed shocked the CEO.

When the LM is adapted to sentences such as (10), it could adjust its expectations about several properties of the sentence, some more linguistically interesting than others. For instance, it could learn that there are three determiners in the sentence, that the third word of the sentence is *that*, that sentences have nine words, that every verb is preceded by a noun, and so on and so forth. If there is a decrease in surprisal when a model is adapted to (10) and tested on (11), it is unclear if this is because the model learned to expect object relative clauses or if it learned to expect any of the other mentioned properties.

To minimize the likelihood that the adaptation effects are driven by irrelevant properties of the sentence, we introduced several sources of variability to our templates: nouns could either be singular or plural, noun phrases could be optionally modified by an adjective, adjectives were optionally modified with an intensifier and verb phrases were optionally modified with adverbs which could occur either pre-verbally or post-verbally (details in the Supplementary Materials).[7]

4.3 Models

We used 75 of the LSTM language models trained by van Schijndel et al. (2019); these LMs varied in the number of hidden units per layer (100, 200, 400, 800, 1600) and the number of tokens they were trained on (2 million, 10 million or 20 million). For each training corpus size, van Schijndel and Linzen trained models on five disjoint subsets of the WikiText-103 corpus, to ensure that the results generalized across different training sets.



4.4 Calculating the adaptation effect (AE)

For every structure, we computed the similarity between that structure and every other structure (including itself) as described in Section 3. This process is schematized in Figure 1. The surprisal values were averaged across the entire sentence.[8]

[6] Since the main verb of the sentence was constrained to be semantically plausible with the subject of the sentence, it often varied between active subject RC and ASRC-matched coordination on the one had and all other conditions on the other.

[7] The Supplementary Materials, the templates and and code for all the analyses along with the data can be found on GitHub: https://github.com/grushaprasad/RNN-Priming

[8] Unknown words were excluded from this average.

(a) (b)

Figure 2: The adaptation effect averaged across all 75 models when (a) they were adapted to each of the structures and tested on either the same structure (blue, bottom) or different structure (pink, top) and (b) they were adapted to RCs and tested on non-RCs or vice versa (pink bars); or when they were adapted to RCs or non-RCs and tested on other RCs or and non-RCs respectively (blue bars). Greater values indicate more similarity between adaptation and test structures. Error bars reflect 95% CIs.

We found that $\mathbb{A}(B \mid A)$ was proportional to the surprisal of B prior to adaptation (see Supplementary Materials). As a consequence, for three structures X, Y and Z, $\mathbb{A}(Y \mid X)$ could be greater than $\mathbb{A}(Z \mid X)$ merely because Y was a more surprising structure to begin with than Z. In order to remove this confound, we first fit a linear regression model predicting $\mathbb{A}(Y \mid X)$ from the surprisal of Y prior to adaptation ($\mathit{Surp}(Y)$):

$$\mathbb{A}(Y \mid X) = \beta_0 + \beta_1 \mathit{Surp}(Y) + \epsilon$$

We then regressed out the linear relationship between $\mathbb{A}(Y \mid X)$ and $\mathit{Surp}(Y)$ as follows:

$$\begin{aligned} \mathit{AE}(Y \mid X) &= \mathbb{A}(Y \mid X) - \beta_1 \mathit{Surp}(Y) \\ &= \beta_0 + \epsilon \end{aligned}$$

Since $\mathit{Surp}(Y)$ was centered around its mean, β_0 reflects the mean of $\mathbb{A}(Y \mid X)$ when $\mathit{Surp}(Y)$ is equal to the mean surprisal of all sentences prior to adaptation. The term ϵ reflects any variance in $\mathbb{A}(Y \mid X)$ that is not predicted by $\mathit{Surp}(Y)$. By summing these two terms together, $\mathit{AE}(Y \mid X)$ reflects the change in surprisal for Y after adapting to X that is independent of $\mathit{Surp}(Y)$.

4.5 Statistical analyses

We used linear mixed effects models (Pinheiro et al., 2000) to test for statistical significance; all of the results reported below were highly significant. Details about the statistical analyses can be found in the Supplementary Materials.

5 Results

5.1 Validating AE as a similarity metric

As discussed in Section 2.3, under the adaptation-as-priming paradigm, we would expect sentences that share the same specific structure to be more similar to each other than lexically matched sentences that do not share the structure.[9] In other words, if X_1 and X_2 are non-lexically-overlapping sets of sentences with shared structure S_X, and Y_2 is a set of sentences with structure S_Y, but is lexically matched with X_2, then we would expect $AE(X_2 \mid X_1) > AE(Y_2 \mid X_1)$. We found this prediction to be true for all of our seven structures (Figure 2a), thus validating our similarity metric.

5.2 Similarity between sentences with different types of VP coordination

Our two coordination conditions were structurally identical to each other but varied in their semantic plausibility — the sentences in PS/ORC-matched coordination condition were often semantically implausible whereas sentences in ASRC-matched condition were always semantically plausible (see footnote 5). If sentences that were structurally similar were close together irrespective of semantic plausibility, then we expect sentences with coordination to be more similar to each other than lexically matched sentences with RCs. Consistent with this prediction, the adaptation effect for models adapted to one type of coordination was greater when the models were tested on sentences with the other type of coordination than when they were tested on sentences with RCs (top panel of Figure 2b).

[9] By lexically matched we mean that all content words were shared between sentences.

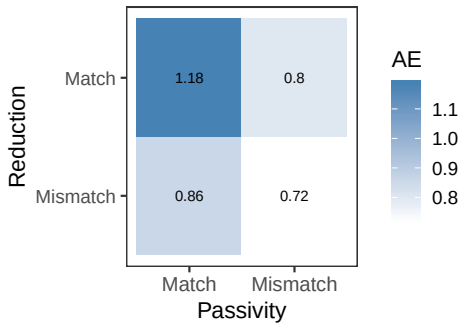


Figure 3: The adaptation effect when models adapted to sentences with reduced and unreduced RCs are tested on sentences that match only in reduction (top right), match only in passivity (bottom right), match in both reduction and passivity (top left) or sentences that match in neither (bottom right).

5.3 Similarity between sentences with different types of RCs

Unlike sentences with coordination, sentences with different types of RCs differ from each other at a surface level (see Table 1). However, at a more abstract level they all share a common property: a gap. If the RNN LMs were keeping track of whether or not a sentence contained a gap, we would expect sentences with different types of RCs to be more similar to each other in the RNN LMs' representation space than lexically matched sentences without a gap. In other words, if RC_X and RC_Y are two different types of RCs and $Coord_Y$ is a sentence with verb coordination lexically matched with RC_Y, then we would expect $AE(RC_Y \mid RC_X) > AE(Coord_Y \mid RC_X)$.

Consistent with this prediction, the adaptation effect for models adapted to RCs was greater when they were tested on sentences with other types of RCs than when they were tested on sentences with coordination (bottom panel of Figure 2b). This suggests that the LMs do keep track of whether or not a sentence contains a gap, even though this property is not overtly indicated by a lexical item that is shared across all types of RCs.

5.4 Similarity between sentences belonging to different sub-classes of RCs

The different types of RCs we tested can be divided into sub-classes based on at least two linguistically interpretable features: reduction and passivity. Reduction distinguishes reduced passive and object RCs on the one hand from unreduced passive and object RCs on the other. Passivity distinguishes reduced and unreduced passive RCs on the one hand from reduced and unreduced object RCs on the other. The LMs could be tracking either, both or none of these features.

We probed whether the LMs track these features by comparing the similarity between sentences that share one feature but not the other, with the similarity between sentences that share neither feature. If the adaptation effect is greater when there is a match in one feature than when there is a match in neither of the features, we can infer that the LMs track whether sentences have that feature. We found that the LMs track both of these features (Figure 3).

Additionally, we probed which of the features contributes more towards the similarity between sentences by comparing the similarity between sentences that match only in passivity with sentences that match only in reduction. When the adaptation and test sets matched only in passivity, the adaptation effect was slightly (but significantly) greater than when the adaptation and test sets matched only in reduction (Figure 3). In other words, in the LMs' representation space, (12) is more similar to (13) than it is to (14), suggesting that passivity contributes more towards the similarity between sentences than reduction.

(12) The conspiracy the employee welcomed divided the country.

(13) The conspiracy that the employee welcomed divided the country.

(14) The conspiracy welcomed by the employee divided the country.

This result is both intuitive and linguistically interpretable — the edit distance between reduced and unreduced RCs is smaller than the that between object and passive RCs; the syntax tree for (12) is also more similar to (13) than it is to (14).

5.5 What properties of sentences drive the similarity between them?

Our analyses so far have demonstrated that sentences that belong to linguistically interpretable classes (e.g., sentences that match in reduction) are more similar to each other in the LMs' representation space than they are to sentences that do not belong to those classes (e.g., sentences that do not match in reduction). However, it is unclear what properties of the sentences are driving this similarity between members of the class. For al-

most all of the linguistically interpretable classes we considered, all sentences belonging to a class shared at least some, if not all, function words. The only exception was the class of all RCs, where the property shared by all sentences in this class (the presence of a gap) was not overtly observable. Therefore, it is possible that the similarity between members of most of the classes we tested was being driven entirely by the presence of these function words.

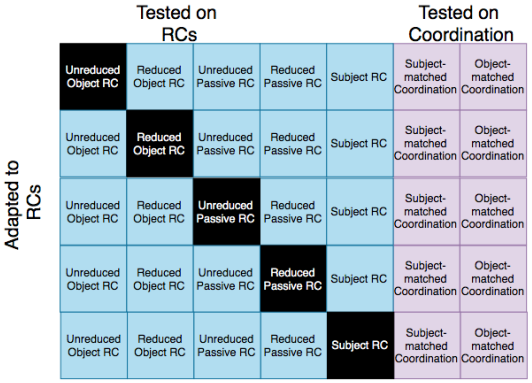
In order to test whether the similarity between members of classes was indeed being driven by the presence of shared function words, we compared the representation space of the models we tested in the previous sections (henceforth *trained models*) with the representation space of models trained on no data (henceforth *baseline models*). Since the baseline models were only ever exposed to the 20 sentences in the adaptation set and there was no lexical overlap in content words between adaptation and test sets, any similarity between sentences in the representation space of these models would be driven by the presence of function words. If the similarity between sentences in the representation space of the trained models was being driven by factors other than the presence of function words, we would expect this similarity to be greater than the similarity between these sentences in the representation space of the baseline models.

We cannot directly use adaptation effect to compare the similarity between sentences in the representation spaces of trained models and baseline models, however: models trained on more data are likely to have stronger priors and are therefore less likely to drastically change their representations after 20 sentences than models trained on less data. In order to mitigate this issue, we defined a distance measure between sentences that belong to a class and sentences that do not belong to a class S_X as follows (see Figure 4 for a schematic):

$$\mathbb{D}(S_X, \neg S_X) = \frac{AE(X_2 \mid X_1)}{AE(\neg X_2 \mid X_1)}$$

This value would be greater than one if sentences that belonged to a class were more similar to each other than they were to sentences that did not belong to the class. Since the strength of prior belief would affect sentences that belong to the class the same way it would affect sentences that do not belong to the class, the effect would cancel out.

We measured the distance between members and non-members for three linguistically inter-



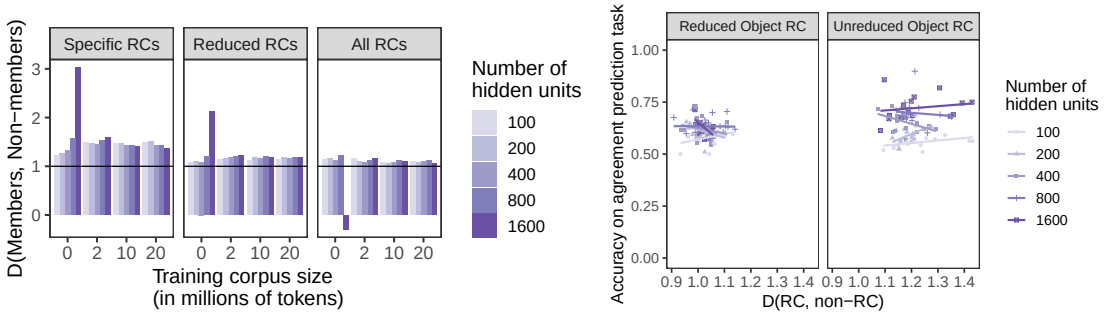


Figure 4: A schematic of how $\mathbb{D}(RC, \neg RC)$ is calculated. For any given row, the black square indicates the specific structure the models were adapted to, the blue squares indicate other structures that belong to the same linguistically defined class as the black square and the pink squares indicate the structures that do not belong to this linguistically defined class. In calculating the distance, we first calculated the proportion between the mean adaptation effect for the blue squares and the mean adaptation effect for pink squares for each row. We then averaged across the proportion for each row to arrive at one number.

pretable classes: sentences which contained the same type of RC, sentences that matched in their reduction or sentences that contained any type of RC. In our baseline models, for all three classes, sentences that belonged to one of these classes were more similar to each other than sentences that did not belong to that class (Figure 5a). This was surprising for the class of sentences that contained any type of RC because there was no function word that was shared by all sentences in this class. We hypothesize that this is because sentences without RCs always contained the word *and*, whereas sentences with RCs never did.

In cases where members of the class shared at least some function words, the distance between sentences that belonged to the class and sentences that did not for the trained models was greater than that for the baseline models. This suggests that the similarity between sentences in the representation space of trained models was being driven by factors other than the mere presence of function words. However, somewhat surprisingly, as the number of training tokens increased, the distance between members and non-members decreased.

In the case where the members of the class did not share any function words, the distance between sentences that belonged to the class and sentences that did not belong to the class did not differ be-

(a) (b)

Figure 5: (a) Effect of hidden layer size and corpus size on the distance between sentences with specific RCs and sentences without (left), between sentences that match in reduction and sentences that do not (middle) and between sentences with RCs and sentences without (right). The solid black line indicates the point at which sentences that belong to a particular class are equally similar to other sentences that belong to that class and sentences that do not. (b) Agreement prediction accuracy on reduced object RCs and unreduced object RCs as a function of $\mathbb{D}(RC, \neg RC)$

tween the trained models and the baseline models. This suggests that any similarity between sentences in the representation space of trained models was driven purely by the presence (or in this case absence) of lexical items.

5.6 Does $\mathbb{D}(RC, \neg RC)$ predict agreement prediction accuracy?

Marvin and Linzen (2018) created a dataset that evaluated the grammaticality of the predictions of language models. Using this dataset, they showed that LSTM LMs could not accurately predict the number of the main verb if the main clause subject was modified by an object RCs (either reduced or unreduced). However, the models had better performance if the main clause was modified by an active subject RC. For example, the models were at near chance levels in predicting that (15a) should have higher probability than (15b), but were slightly better at predicting that (16a) should have higher probability than (16b):

(15) a. The farmer that the parents love swims.
b. *The farmer that the parents love swim.

(16) a. The farmer that loves the parents swims.
b. *The farmer that loves the parents swim.

One possible explanation for this poor performance is that object RCs, either reduced or unreduced, are quite infrequent (Roland et al., 2007). If the LM treats object RCs as unrelated to other RCs, there are likely very few training examples from which the models can learn about subject-verb agreement when the subject is modified by an object RC. If the LM had instead treated object RCs as belonging to the same class as other RCs, it could learn to generalize from training examples of subject-verb agreement when the subject is modified by other RCs. This suggests the hypothesis that agreement prediction accuracy on object RCs will be higher in LMs in which the representation of object RCs is more similar to the representation of other RCs.

The similarity between object RCs and other RCs was defined as in the previous section (the proportion of blue squares to pink squares of the top two rows in Figure 4). There was an increase in accuracy as the number of hidden units increased (see Figure 5b). However, the similarity between object RCs and other types of RCs did not significantly correlate with agreement prediction; we therefore did not find any evidence for the hypothesis mentioned above.[10]

6 Discussion

Drawing on the syntactic priming paradigm from psycholinguistics, we proposed a new technique to analyze how the representations of sentences in neural language models (LMs) are organized. Applying this paradigm to sentences with relative clauses (RCs), we found that the representations of these sentences were organized in a linguistically interpretable hierarchical manner (summarized in Figure 6).

We investigated whether this hierarchical organization was driven by function words that are shared among sentences sentences or whether there was evidence that LMs were tracking more

[10] Similar patterns were observed for the other constructions in the dataset. See Supplementary Materials.

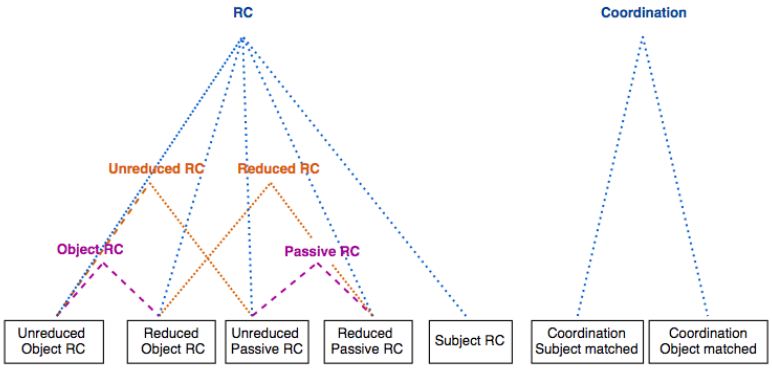

Figure 6: A schematic of how sentences belonging to different linguistically defined classes are related to each other in the LMs' representation space. Each colour indicates a different level of hierarchy.

abstract properties of the sentence. We found that for at least some linguistically interpretable classes, sentences that belonged to these classes were more similar to each other in the representation space of the LMs we tested than in the representation space of baseline LMs that were not trained on any data. This suggests that the trained LMs were capable of tracking abstract properties of the sentence.

However, for linguistically interpretable classes in which sentences shared a non-lexically observable property (e.g. presence of a gap), sentences were as similar to each other in the representation space of the LMs we tested as in the representation space of baseline LMs. Taken together, these results suggest that LMs might be able to track abstract properties of classes of sentences only if these classes also share a lexically observable property.

Additionally, we found that the sentences belonging to linguistically interpretable classes were more similar to each other in the representation spaces of models trained on 2 million tokens than in the representation spaces for models trained on 20 million tokens. We infer from this that LMs' ability to track abstract properties of sentences decreases with an increase in the training corpus size. This suggests that if we want these LMs to track more abstract linguistic properties, training them on more data from the same distribution is unlikely to help (cf. van Schijndel et al. 2019). Future work can explore how to bias these models to track linguistically useful properties through architectural biases (Dyer et al., 2016), training on auxiliary tasks (Enguehard et al., 2017) or data augmentation (Perez and Wang, 2017).

We hypothesized that models' accuracy on subject verb agreement when preceded by object RCs would increase as the similarity between object RCs and the other types of RCs increased. However, we did not find evidence for this. This could either be because the similarity between object RCs and the other types of RCs was too weak to be useful (see Figure 5a) or because the LMs do not use this property when predicting verb agreement. Future work can disambiguate these reasons by testing models that are biased to treat sentences with object RCs and other RCs as being similar.

Finally, our method allows us to generate a similarity matrix in the LMs representation space for any given set of structures. In the future, generating a similar matrix for human representations using priming experiments and comparing these two matrices using analysis methods from cognitive neuroscience (Kriegeskorte et al., 2008) may enable us to gain insight into how human-like the LM representations are and vice versa.

7 Conclusion

We proposed a novel technique to analyze how the representations of various syntactic structures are organized in neural language models. As a case study, we applied this technique to gain insight into the representations of sentences with relative clauses in RNN language models and found that the representations of sentences were organized in a linguistically interpretable manner.

Abstract

Computational research on error detection in second language speakers has mainly addressed clear grammatical anomalies typical to learners at the beginner-to-intermediate level. We focus instead on acquisition of subtle semantic nuances of English indefinite pronouns by non-native speakers at varying levels of proficiency. We first lay out theoretical, linguistically motivated hypotheses, and supporting empirical evidence on the nature of the challenges posed by indefinite pronouns to English learners. We then suggest and evaluate an automatic approach for detection of atypical usage patterns, demonstrating that deep learning architectures are promising for this task involving nuanced semantic anomalies.

1 Introduction

The ubiquity of English as an online lingua franca offers a rich opportunity for computational research on second language acquisition and on tools for aiding non-native speakers. Most computational research in second language (L2) has focused on spelling and grammar errors, and has been conducted on learners with beginner-to-intermediate proficiency level (henceforth, "learners") (e.g. Ji et al., 2017; Sakaguchi et al., 2017; Rozovskaya et al., 2017; Lo et al., 2018). Little empirical work has looked at *semantic* errors, with existing research mostly focusing on collocations (e.g., Dahlmeier and Ng, 2011; Vecchi et al., 2011; Kochmar and Briscoe, 2013). Also, highly proficient, advanced L2 speakers (henceforth, "advanced L2s") have received little attention (though see Daudaravicius et al., 2016). In contrast to learners, these speakers rarely violate grammatical norms of the L2, but rather deviate from native usage in much more nuanced ways, often exhibiting mild infelicities rather than outright errors.

We aim to explore an elusive aspect of mastering the subtle contours of a word's meaning that are shaped by its context. Specifically, we investigate patterns of acquisition of English indefinite pronouns by L2 speakers. *Indefinite pronouns* (IPs) are linguistic devices that refer to an entity (such as a person or thing) that has not yet been introduced in discourse. In English, examples are words like *someone*, *anything*, and *nobody*. Consider the following sentences, taken verbatim from corpora of L2 speakers (original pronoun is boldfaced; less felicitous usages marked with '?').[1]

1. *Do you know* ***someone****/anyone who was discriminated based on gender?*
2. *It was a little amazing, because they didn't stole* ***?something****/anything.*
3. ***??Anyone****/Someone told me the company has millions in debts and isn't able to pay it.*

Clearly, mastery of IPs in English relies on recognizing subtle factors that determine their appropriate usage in various contexts.

Here, in Section 2, we develop a linguistic analysis with detailed hypotheses on precisely how the tangled relations between *some-* and *any-* pronouns, exemplified above, pose a challenge for L2 learners. In Sections 3 and 4, we perform a large-scale investigation of these linguistic predictions using productions of both learners and advanced L2s, and find that the predicted infelicities occur not only in the language of the former but also the latter, albeit (as expected) to a lesser extent.

A practical goal of this work is to gain predictive power regarding the nuanced semantic difficulties that L2 speakers face. As a first step in that direction, in Section 5 we consider the ability of deep learning language models (LMs) – shown to be adept at capturing grammatical phenomena (Ji

[1]We refer to either less preferred or unacceptable occurrences of an IP, as in (2) and (3), as infelicitous usages.

Usage class	*some*-?	*any*-?	Example
specific (SP)	✓		I had to reevaluate things when **someone** pointed that out.
non-specific (NS)	✓		**Someone** please make me a GIF of that Wade dunk.
question (QU)	✓	✓	**Anyone** know what the issue might be?
conditional (CD)	✓	✓	I would love it if **someone** could explain it in a more precise way.
indirect negation (IN)	✓	✓	I don't understand how **anyone** can really hate on him.
direct negation (DN)	✓	✓	I don't have **anything** to add other than to say thanks for typing this out.
comparison (CP)	✓	✓	If you work harder you deserve to earn more than **someone** who doesn't do so.
free choice (FC)		✓	...they invite **anyone** on, including musicians sometimes.

Table 1: Usage classes of IPs, an indication of those subsumed by *some*- and *any*-, and examples from our corpora.

et al., 2017; Sakaguchi et al., 2017; Marvin and Linzen, 2018; Goldberg, 2019) – to identify the subtle infelicities that stem from the semantic confusion introduced by *some*- and *any*- IPs. We show that while state-of-the-art models obtain encouraging initial results on this task, they leave room for future improvement (possibly informed by our linguistic findings) in mastering the semantic nuances of the system of English IPs.

The contribution of this work is thus three-fold: First, to our knowledge, we develop the first large-scale empirical investigation of second-language acquisition of indefinite pronouns, constituting a case study of taking a computational approach in linguistic analysis to yield novel insights into challenges in L2 acquisition. Second, we suggest and evaluate an automatic approach to detect infelicities stemming from these challenges in a large collection of L2 productions. Finally, in both cases, we extend our experiments to utterances of highly proficient L2 speakers – a population that has heretofore received little attention in the context of automatic error/infelicity detection.[2]

2 Linguistic Insights into English IPs

Previous work has suggested that the English system of IPs is crosslinguistically atypical, with precise analogues to *some*- and *any*- unusual across languages (Haspelmath, 1997; Beekhuizen et al., 2017). Building on a suggestion from Beekhuizen et al. (2017), we analyze the factors that could lead to difficulty in learning these IPs, and develop detailed hypotheses concerning the challenges that L2 speakers are predicted to face.

Our analysis is based on patterns of *colexification* (Franois, 2008): that is, how usages expressing different semantics are grouped (or not) in various combinations under a single word. As the basis for our analysis, we first need to specify the allowable semantic and syntactic usages of IPs. These *usage classes* are adapted from Haspelmath (1997), who outlines a universal set of IP semantic functions across all languages.[3] Our usage classes are shown in Table 1, with an indication of the classes that *some*- and *any*- can express.

Table 1 illustrates a striking fact about colexification of the usage classes in English: *some*- and *any*- each cover a very broad range of classes, with a high degree of overlap. This level of overlap in languages appears to be very rare: in the 40 languages studied by Haspelmath (1997), we find that only some 10% of languages have IPs that overlap over such a broad area of the semantic space.[4]

Within any of these classes, some semantic/syntactic contexts call for just one of *some*- or *any*-, while others allow both, but with differing meanings (and frequencies/preferences). For example, these similar contexts allow both, but the preferred pronoun differs:

1. *...people care a lot* ***if something is a repost****...*
2. *...before you know* ***if anything is wrong****...*

We thus predict a difficulty for English L2 speakers in having to choose between two (not interchangeable) terms that can be used in highly similar semantic/syntactic environments.

In addition to looking at difficulties posed by the colexification of IPs *within English*, we can consider *crosslinguistic* patterns of colexification for further insight. Semantic typologists have proposed (and empirically supported, across many domains) that the more two underlying concepts are colexified across languages, the more similar those two concepts are (e.g., Anderson, 1982). In

[2] All code and data are available at https://github.com/ellarabi/indefinite-pronouns

[3] Haspelmath's functions are determined by syntactic, semantic, and pragmatic factors. Our usage classes emphasize the syntactic context, for ease of automatic identification and consistent annotation.

[4] Computed using the original Haspelmath's mapping into functions, therefore, not strictly comparable to the slightly different notation of usage classes in this work.

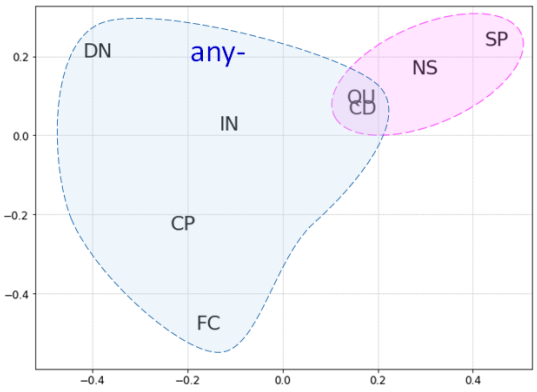

Figure 1: Layout of usage classes in crosslinguistic semantic space; light blue illustrates the scope of English *any-*, pink illustrates the natural grouping of QU/CD with SP/NS.

this way, crosslinguistic patterns of colexification can be used to deduce pairwise similarity among concepts, yielding a universal semantic similarity space for a domain (e.g., Berlin and Kay, 1969; Levinson et al., 2003).

Here, we derive such a similarity space over the IP usage classes of Table 1, using the colexification data across 40 languages, from Haspelmath (1997).[5] We form a distance matrix (found in supplemental materials, A.1) by recording, for every pair of usage classes, the number of languages that have a term subsuming both those classes (indicating their relative similarity). We then use Multidimensional Scaling (MDS) to project the space onto two dimensions, as exemplified in Figure 1.[6]

Figure 1 demonstrates, first, that SP, FC, and DN form three natural "extremes" of the semantic space. In English, these correspond to the canonical uses of the IPs *some-*, *any-*, and *no-*, respectively; thus *some-* is anchored at SP and *any-* at FC (cf. Table 1). Moreover, we find that the usage classes of QU and CD are very close to SP and NS, indicating that QU and CD are most frequently colexified with SP/NS, in particular, much more so than with FC. For English, this means that it is much more natural for *some-* to express QU/CD than for *any-* to do so.

To summarize, our linguistic analysis reveals two potential challenges of English *some-* and *any-*: their confusability across many classes, and the particular difficulty of *any-* in the QU/CD classes. We further find empirically that *some-* IPs are more frequent than *any-* in native English text, suggesting that *some-* will be easier for L2 speakers, and that they may overgeneralize it when faced with uncertainty of which pronoun to use. Collectively, these findings motivate:

Hypothesis 1: The unusually large and overlapping extents of *some-* and *any-* are expected to pose difficulty for L2 speakers; *any-* is predicted to be especially difficult due to its lower frequency.

Hypothesis 2: Due to greater naturalness of grouping QU and CD with other classes subsumed by *some-*, we predict that QU and CD usages of *any-* will be particularly difficult for L2 speakers.

In exploring each of these hypotheses, we look for evidence in two forms: overuse of *some-* compared to native speakers, and more errors involving *any-*. We focus on the frequent semantic categories of *people* and *things*, specifically the set of IPs *someone*, *anyone*, *something*, and *anything*.[7]

3 Materials and Methods

3.1 Datasets

We expect that mastery of IPs will depend on a speaker's command of English, and therefore consider language productions both of learners (largely beginner-to-intermediate), and of L2 speakers on Reddit (shown to be highly proficient, almost on par with Reddit natives; Rabinovich et al. 2018). Our learner dataset comprises several sub-corpora: EFCAMDAT (Geertzen et al., 2013), TOEFL11 (Blanchard et al., 2013), and the freely available part of the FCE corpus (Yannakoudakis et al., 2011). The advanced L2 dataset includes online posts by advanced non-native English speakers from the L2-Reddit corpus (released by Rabinovich et al., 2018, and comprising utterances by native as well as highly-proficient non-native speakers, published on the Reddit platform). We extended the L2-Reddit corpus (originally collected in 2017) with data published through September 2018; the final dataset includes over 320M native and L2 English sentences. Table 2 presents details of the two corpora.

Dataset	Sentences	Tokens	L1s
learners	5.6M	72M	>13
advanced L2s (Reddit)	177M	2.4B	51
native (Reddit)	146M	2.1B	–

Table 2: Statistics on datasets.

[5] For this, we map our classes to Haspelmath's functions.

[6] The relative distances slightly differ, but remain highly similar across many such projections we produce.

[7] We excluded *somebody/anybody* as they are about 1/10 the frequency of their *-one* counterparts in our data.

3.2 Classification of IP Usages

Evaluating our hypotheses in Section 2 depends on assessing which usage class an utterance with a *some-/any-* pronoun belongs to, so we can compare patterns of usage and infelicities across classes. In English, the IP usage classes are often associated with particular lexical or syntactic cues in the clause with the IP – e.g., a negative adverb for DN (*I don't want anything from this collection.*), or a question mark for QU (*Would you like to buy something online?*). This enabled us to develop a rule-based classifier (see supplemental materials (A.3) for details), using a parser (Kitaev and Klein, 2018) and a set of heuristic rules.

We evaluated the classifier on sentences manually annotated by three in-house native English speakers with a background in linguistics. A sample of 750 sentences produced by Reddit native English speakers was selected for annotation, and the annotators assigned a label to each sentence from within the set of {DN, QU, CD, CP, MIXED}, where the MIXED class comprises the SP, NS, FC, and IN classes (cf. Table 1). The MIXED grouping contains classes that are (1) difficult to distinguish using simple lexical and syntactic cues (essentially, an "other" class), and (2) predicted by our linguistic analysis to be relatively similar in their error patterns. Average annotator agreement on our task was $\kappa = 0.932$; detailed annotation guidelines can be found in supplemental materials (A.2).

Table 3 shows that our rule-based classification is a reliable way to categorize a sentence with an IP (five-way classification baseline is 0.2). Because we use a subset of sentences associated with each usage class throughout our experiments, we focus on classification precision, while maintaining recall. We use this classifier to automatically label L2 sentences by usage class.

Class	DN	QU	CD	CP	MIXED
P	0.835	0.882	0.853	0.833	0.849
R	0.723	0.789	0.853	0.962	0.874
F1	0.775	0.833	0.853	0.893	0.861

Table 3: Evaluation of classification of IP usage classes.

3.3 Annotation of (In)felicitous Usages

We used the FigureEight crowdsourcing platform for collecting annotations to be used as ground truth of L2 infelicities. We extracted a randomly sampled set of 3,711 sentences from our learner corpus representing a balanced distribution over the five usage classes,[8] and a similar set of 10,000 sentences from our advanced L2 (Reddit) corpus, each containing a usage of *someone*, *something*, *anyone*, or *anything*.[9] Each sentence was annotated by five native English speakers in a choice-based annotation scheme. The occurrence of the IP in the sentence was replaced with a blank line, and each annotator marked their preference for the *some-* or *any-* pronoun in that context (or "other"), reflecting the most natural choice between the two. The gold annotation for each sentence was determined by its majority choice, and the confidence score was computed based on the number of selections (out of five annotators) of each of the two pronouns. Annotation guidelines and a sample of 500 manually annotated sentences can be found in the supplemental materials (A.4).

Table 4 presents example sentences produced by learners and L2 Reddit authors where the majority annotation unanimously differed from the original pronoun (as indicated). The utterances are provided verbatim, maintaining grammatical errors typical to productions in our corpora.

Sentences with a confidence level ≤ 0.6 are considered close to equally felicitous with either pronoun, while the confidence of 1 represents a unanimous preference for one of the alternatives. Because we used a forced-choice task, if both pronouns were acceptable (e.g., *Did you see something/anything you like?*), we expect that the confidence score will indicate the level of naturalness or typicality of the pronoun in that context. For this reason, we only consider an example infelicitous when it differs from annotator choice with a confidence ≥ 0.8, which indicates a stronger preference for one pronoun over the other.

The final annotation results include 50% (1556) and 77% (2857) of sentences with a confidence of 1.0 and of ≥ 0.8, respectively, for learners. Our advanced L2 data has 56% (5639) of sentences with a confidence of 1.0 and 81% (8079) of ≥ 0.8.

A question arises as to how meaningful it is to label an IP usage as infelicitous – i.e., the preferred IP in annotation differed from the original – if both *some-* and *any-* are in fact acceptable. To explore this, we also got crowdsourced annotations on 500

[8] Aiming at 1K per class, limited by 587 and 124 sentences in the QU and CP classes in our learner data, respectively.

[9] We excluded sentences with idiomatic expressions containing IPs from this work; see supplemental materials (A.5).

L2 utterance	Annotation
Moreover, he also takes a risk of not knowing **someone** from this country.	anyone
About 20 years ago, we didn't know **someone** who cares about them, who defend animal's right, but today, I know many people who cares about, cause animals need to be protected.	anyone
It is justified to say that they have to change **anything** to cope with the now situation.	something
I never said **something** about political science, probably it was not very good worded but my point is just that it shows how the extremes of two sides can come closer together again.	anything
I think it's a sampling bias rather than **anyone** massaging the numbers to see what they want to see.	someone
If there is a day where no one works then this is useless because you can't do **something** on that day with family besides walking in forests because everything would be closed.	anything

Table 4: Example sentences annotated by human annotators for infelicitous pronoun choice (original pronoun is boldfaced). The top part refers to learners' utterances, the bottom part refers to advanced L2s'.

native utterances from Reddit, and compared the percentages of usages annotated as infelicitous to those of 500 randomly sampled sentences by advanced L2s. We found that 3% of native utterances were annotated as infelicitous at a confidence level of ≥ 0.8, indicating a high agreement among native writers and our annotators, while for advanced L2s, the percentage was around twice that high – 6.7%. Despite acceptable variation in *some-*/*any*-usage in a given context, even advanced L2 speakers differ from natives in their relative preferences.

4 Analysis of IP Infelicities in L2

4.1 Distribution of IPs by Usage Types

First, considering **Hypothesis 1** from Section 2, we expect the confusability of *some-* and *any-* to be reflected in overgeneralization of *some-* due to its higher frequency. The subtle distinction between these pronoun types is assumed to be better mastered by advanced L2 speakers, so we expect the divergence from the native distribution to be amplified in learners' productions.

Figure 2 presents relative frequencies of *some-* and *any-* pronouns in a random sample of 5M native, advanced L2, and learner productions, both in the entire sample (left) and distributed by usage class (right). In line with our predictions, we find in Figure 2 (left) that overall, L2 speakers use *some-* pronouns more than *any-* pronouns compared to native speakers. We can further see in Figure 2 (right), and discussed in detail below, that this pattern occurs in almost all the IP usage classes, especially pronounced for learners.

Elaborating on **Hypothesis 1**, we further suggest that in addition to *general* overuse of *some-* vs. *any-* (which may partly be due to avoidance of *any-*), L2 speakers are also expected *in their infelicities* to more often use *some-* where native speakers would use *any-*, than vice versa. This prediction is also supported by our annotated data: In cases where the preferred pronoun is *some-*, learners infelicitously use *any-* 8.4% of the time, but in cases where the preferred pronoun is *any-*, learners infelicitously use *some-* almost 23% of the time. That is, learners have almost three times as many infelicities of using *some-* instead of *any-* than the reverse. Our advanced L2s speakers also show more infelicities using *some-* instead of *any-* than vice versa, but the difference is less pronounced (5.8% and 10.1% respectively), as we expect given their greater proficiency.

4.2 Distribution of Infelicitous Usages

Next we turn to **Hypothesis 2** from Section 2, which further predicts that the precise extent of deviation from native-like usage patterns will not be distributed uniformly across the different usage classes, but rather there will be a higher degree of deviation in classes that are atypically grouped under *any-* – that is, QU and CD – than in those that introduce less of a semantic challenge (DN, CP, and those in the MIXED class). L2 speakers are expected to exhibit both more overuse of *some-* and more infelicities in the QU and CD classes.

Our predictions regarding the non-uniform overuse of *some-* are largely borne out in Figure 2: the classes expected to be most difficult for L2 speakers – QU and CD – show a significant difference not only for learners, but even for advanced L2 speakers compared to natives, while DN and CP show only a difference for learners.

A few observations from Figure 2 do not follow our hypothesis. First, the difference in learner usage of *some-* vs. *any-* for DN goes in the direction opposite to the prediction: i.e., learners use *any-* more than *some-* pronouns in direct negation. We attribute this to the sheer frequency of *any-* in direct negation, such that learners are overgen-

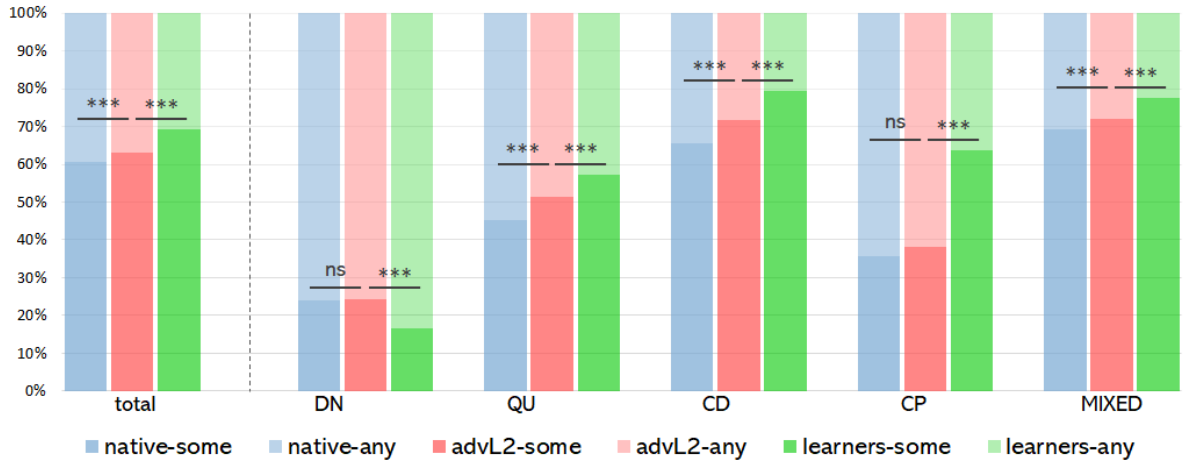

Figure 2: Distribution of *some-* and *any-* pronouns by usage class (native, advL2, learner, left-to-right in each); see Table 1 for definitions of classes. 'total' refers to *some-* and *any-* counts extracted from the sample of 5M sentences for each population. '***' indicates significant difference at the level of $p < .001$; 'ns' indicates non-significant difference.

eralizing *any-* here. Second, the MIXED grouping also shows a difference for the advanced L2 speakers, although these usages are not predicted to be especially difficult by our linguistic analysis. This class contains a very large and diverse set of usages, making it difficult to predict what is driving this effect, and we leave this for future work. Finally, the largest gap in overuse of *some-* vs. *any-* is observed in the CP class for learners, thereby not complying with our prediction of the highest difficulty being introduced by the QU and CD classes. Note, however, that this result is based on a relatively small amount of data in the CP class for learners (only 124 sentences; see Table 5).

To consider the pattern of infelicities across the usage classes, Table 5 shows the results from our crowdsourced annotation of IP usages of learners (top) and advanced L2s (bottom), separated by the classes. As expected, learners exhibit a very high percentage of infelicities in the QU class (24%); the CD class is not nearly as bad (12%), but is still higher than the other three (8–9%). Although advanced L2s have much fewer infelicities than learners, they also have more in the QU and CD classes (7% and over 9% respectively) than in the others (5–6%). Thus, as with Hypothesis 1, **Hypothesis 2** is largely borne out by the data, and we find additional evidence that the IP system of English is particularly challenging for beginning to intermediate learners.

5 Automatic Detection of Infelicities

Our motivation for the above analysis is to use these insights to drive development of tools for L2 learners. Here we consider the first step, that of detection of infelicities with a language model (LM).

Usage class	DN	QU	CD	CP	MIXED
# annotated	1000	587	1000	124	1000
# infelicitous	81	141	124	11	87
% infelicitous	8.1	24.0	12.4	8.9	8.7
# annotated	2000	2000	2000	2000	2000
# infelicitous	106	141	182	102	113
% infelicitous	5.3	7.1	9.1	5.1	5.7

Table 5: Distribution of annotated infelicities by usage class. Top panel: learners; bottom: advanced L2s.

Neural network based approaches are currently among the most successful LMs. While being easily applied to a wide range of tasks, they provide significant improvements over classic backoff n-gram models. A common use of a pre-trained LM – typically trained on an extremely large corpus – is to predict the likelihood of an 'unseen' sample of text: The higher the score (or the lower the perplexity) a text is assigned, the more probable it is, given the model. In particular, a fluent, well-formed text is likely to be scored higher by an LM than a text containing linguistic anomalies.

Encouraged by results on the task of grammatical error detection (Yuan and Briscoe, 2016; Ji et al., 2017), we adhere to a similar approach, casting the detection of infelicities as a binary classification scenario: An LM is applied on a sentence with an original pronoun (e.g., *something*) and on the same sentence where the pronoun is substituted with its alternative (e.g., *anything*); then the one predicted as more probable (scored highest) is chosen as a model decision.

5.1 Models

Aiming to test the effect of various factors, such as training data size and register, on the predictive power of LMs in our task, we used both pretrained models and models trained locally on in-domain, albeit much smaller, data.

Gulordava et al.: A successful variant of RNNs, the long short-term memory model (LSTM, Hochreiter and Schmidhuber, 1997), used for syntactic error detection in Gulordava et al. (2018). We trained the model using a similar set of parameters to Gulordava et al. (2018),[10] on 10M sentences by native English speakers of Reddit (see Section 3), using a 20K sentence validation set and a 50K sentence test set. This model allows us to test the benefits of using *in-domain* data (for advanced L2s), despite its significantly lower volume, compared to other models.

Google 1B: A very large publicly available LM released by Jozefowicz et al. (2016). This fine-tuned language model, trained on a billion-word corpus (Chelba et al., 2013), requires a massive infrastructure for training. It achieves impressive perplexity scores on common benchmarks, and has been shown effective on a range of NLP tasks.

BERT: A recent bidirectional encoder representations from transformers (BERT) LM released by Google (Devlin et al., 2018). Proven highly effective in several language modeling tasks, it achieves state-of-the-art results in syntax-sensitive scenarios (Goldberg, 2019), pushing the limits of what is feasible with current language modeling tools.

We report the models' precision, recall and F1 scores for infelicitous and correct classes separately. We also report the overall accuracy of each, computed as the ratio of correctly classified cases out of all sentences. Following the intuition laid out in Section 3.3, we conducted two sets of experiments: (1) considering cases where annotators' confidence score was 0.8 or higher, and (2) considering cases with confidence of 1. Sentences with a lower confidence score (i.e., where both *some-* and *any-* were roughly equally preferred) were excluded from these experiments.

[10] Specifically, we used two hidden layers of 200 units per layer, dropout rate of 0.2, batch size of 20, and initial learning rate of 20, and trained for 40 epochs (until the validation set perplexity converged).

5.2 Results and discussion

Tables 6 and 7 present the results for learners and advanced L2 speakers, each split by the degree of annotation confidence. Baseline accuracy is computed as the ratio of felicitous usages (the majority class) out of all instances. The Gulordava et al. LM yields results inferior to the baseline, despite training on in-domain (but much smaller) data. BERT performs best overall, and both it and Google 1B exceed the baseline for learners, but BERT performs only at baseline for advanced L2s, confirming the extreme difficulty of this task. Results obtained for the correct class are far superior to those for the infelicitous class, suggestive of the inherent difficulty of the latter cases, compared to (occasionally clear-cut) correct usage patterns.

Systematically higher scores obtained for learner utterances (Table 6), compared to advanced L2s (Table 7), imply that the mild infelicities of the latter pose a higher challenge to automatic tools. That is, not only do advanced L2s show fewer errors, but their errors are likely more subtle and more difficult to detect. The high-confidence setup ($= 1.0$) yields results superior to those produced by the lower-confidence setup (≥ 0.8), further supporting that clear-cut infelicities are more easily captured by an LM.

Returning to our linguistic predictions, the preference of *some-* over *any-* predicted by **Hypothesis 1** and shown for non-native speakers (Section 4.1) does not hold for our best-performing LM. We found a roughly equal rate (up to two percent points) of infelicities in model preferences in cases with *some-* vs. *any-* gold annotations, showing that the model (unlike non-natives) does not have greater difficulty with *any-* overall.

We also consider the non-uniform difficulty of IPs across various usage cases, predicted by **Hypothesis 2** and shown for non-natives (Section 4.2). To address this question, we test BERT for infelicitous choices compared to annotators' decisions: That is, for each sentence, we compare the pronoun preferred by the model to the gold annotation. Table 8 presents statistics across usage classes, for learners and advanced L2s (taken from Table 5), as well as for BERT. The top panel refers to learner data; the bottom panel, to advanced L2 data. While (expectedly) outperforming the two non-native populations, the model exhibits similar distributional patterns, with more infelicities in the CD and QU classes. The model also has

Learners		Infelicitous class			Correct class			
	model	P	R	F1	P	R	F1	acc

	BERT (pre-trained)	**0.503**	**0.790**	**0.614**	**0.990**	**0.964**	**0.977**	**0.956**

Table 7: Automatic detection of infelicities in advanced L2 data (sentences where annotation disagrees with author usage of IP), with confidence level ≥ 0.8 (top), and with confidence level $= 1$ (bottom). Baseline accuracy is 0.918 for the former and 0.956 for the latter. Best result in a column (for each part) is boldfaced.

a higher number of infelicities in the CP class for learners; again, we note the small sample of data in this class, entailing a need for further investigation of this particular pattern. The model results here pose intriguing questions for future work regarding the nature of challenges faced by automatic neural methods, and their potential analogues to those of humans.

	DN	QU	CD	CP	MIXED
learners	8.1	24.0	12.4	8.9	8.7

6 Related Work

Computational approaches to grammatical error correction (GEC) in learners' productions has been a prolific field of research in recent years. A standard approach to dealing with grammar and spelling errors makes use of a machine-learning classification paradigm; a comprehensive survey of these methods can be found in Ng et al. (2014). Recent advances in the field of GEC were achieved by using neural models (Yuan and Briscoe, 2016; Ji et al., 2017; Sakaguchi et al., 2017; Lo et al., 2018). Most studies used a *supervised* setup for selecting a correct choice (e.g., a preposition) out of a set of multiple alternatives, rendering our experimental setup not directly comparable.

Another line of work has assessed the capability of neural LMs to capture errors stemming from violation of syntax-sensitive dependencies (Linzen et al., 2016; Gulordava et al., 2018; Marvin and Linzen, 2018). The recent BERT model (Devlin et al., 2018) has been shown to be highly effective for detection of syntactic anomalies stemming from subject-verb disagreement (Goldberg, 2019).

Most research on L2 error correction focuses on function words, such as prepositions and determiners. Very little work has been done on detecting and correcting incorrect usage of content words. Most has been focused on the felicity of word combinations, such as identifying disfluencies stemming from L1 paraphrases (e.g., *eat medicine* or *look movies*, Brooke and Hirst, 2011; Dahlmeier and Ng, 2011), or using models of compositionality to detect semantically deviant pairs (*residential steak*, Vecchi et al., 2011) or infelicitous collocations (?*big importance* vs. *great importance*, Kochmar and Briscoe, 2013). A shared task on automatic evaluation of scientific writing (Daudaravicius et al., 2016) addressed automatic detection of a variety of grammatical errors (e.g., misuse of an article or punctuation) and lexical infelicities (e.g., phrasing choices stem-

ming from style requirements of the genre) in scientific papers, edited by a professional company.

While most closely related to the field of semantic error detection, our work deals with subtle linguistic choices that shape the ultimate attainment of L2 in non-native speakers. Compared to grammatical and semantic anomalies explored in previous work, the choice of indefinite pronoun is often guided by implicit contextual clues that are not necessarily reflected in superficial collocational patterns, thereby posing a higher challenge for automatic techniques.

7 Conclusion

We develop and evaluate linguistic hypotheses on the difficulties for second language learners of the atypical system of English indefinite pronouns. We find that the tangled relation between *some-* and *any-* pronouns pose challenges that are evident in the productions of both learners and advanced L2 speakers. This work thus demonstrates the promise of extending computational approaches for error-detection in L2 productions to more subtle semantic usages. Moreover, our results reveal the challenges that these subtleties can pose for even advanced non-native speakers.

Much research in second language acquisition establishes *native language transfer* as one of the major factors that shape productions of non-native speakers. While the work here addresses *universal* (i.e., native-language independent) challenges posed to L2 speakers, a plausible assumption is that mastery of English IPs is also affected by the proximity of the analogous system in a speaker's L1. We leave this direction for future research.

We also evaluate here the ability of language models to detect the errors arising in the use of English indefinite pronouns in L2 productions. Not surprisingly, we find that the more clearcut errors exhibited by learners are easier to automatically identify than the potentially more subtle errors that arise with advanced L2 speakers. The best performing language model shows a varying match to human patterns of difficulty, raising issues for further research regarding the factors that influence difficulty for both humans and language models.

The practical impact of this work will be in facilitating the development of educational applications for L2 English speakers at various levels of proficiency. At present, most error correction and detection tools focus on explicit spelling or grammar errors. Enriching these tools with the ability to capture subtle semantic infelicities in the usage of IPs would advance the current state of the art in educational applications for language learners.

Abstract

Image captioning models are usually evaluated on their ability to describe a held-out set of images, not on their ability to generalize to unseen concepts. We study the problem of compositional generalization, which measures how well a model composes unseen combinations of concepts when describing images. State-of-the-art image captioning models show poor generalization performance on this task. We propose a multi-task model to address the poor performance, that combines caption generation and image–sentence ranking, and uses a decoding mechanism that re-ranks the captions according their similarity to the image. This model is substantially better at generalizing to unseen combinations of concepts compared to state-of-the-art captioning models.

1 Introduction

When describing scenes, humans are able to almost arbitrarily combine concepts, producing novel combinations that they have not previously observed (Matthei, 1982; Piantadosi and Aslin, 2016). Imagine encountering a purple-colored dog in your town, for instance. Given that you understand the concepts PURPLE and DOG, you are able to compose them together to describe the dog in front of you, despite never having seen one before.

Image captioning models attempt to automatically describe scenes in natural language (Bernardi et al., 2016). Most recent approaches generate captions using a recurrent neural network, where the image is represented by features extracted from a Convolutional Neural Network (CNN). Although state-of-the-art models show good performance on challenge datasets, as measured by text-similarity metrics, their performance as measured by human judges is low when compared to human-written captions (Vinyals et al., 2017, Section 5.3.2).

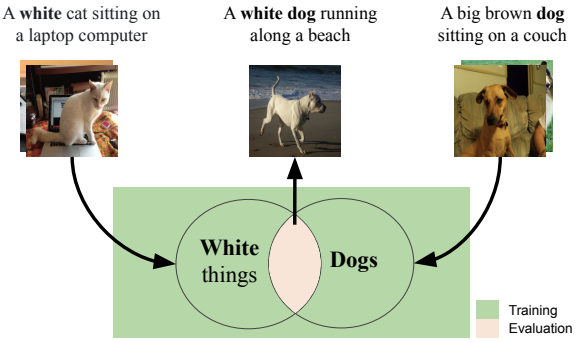

Figure 1: We evaluate whether image captioning models are able to compositionally generalize to unseen combinations of adjectives, nouns, and verbs by forcing *paradigmatic gaps* in the training data.

It is widely believed that systematic compositionality is a key property of human language that is essential for making generalizations from limited data (Montague, 1974; Partee, 1984; Lake et al., 2017). In this work, we investigate to what extent image captioning models are capable of compositional language understanding. We explore whether these models can compositionally generalize to unseen adjective–noun and noun–verb composition pairs, in which the constituents of the pair are observed during training but the combination is not, thus introducing a *paradigmatic gap* in the training data, as illustrated in Figure 1. We define new training and evaluation splits of the COCO dataset (Chen et al., 2015) by holding out the data associated with the compositional pairs from the training set. These splits are used to evaluate how well models generalize to describing images that depict the held out pairings.

We find that state-of-the-art captioning models, such as Show, Attend and Tell (Xu et al., 2015), and Bottom-Up and Top-Down Attention (Ander-

son et al., 2018), have poor compositional generalization performance. We also observe that the inability to generalize of these models is primarily due to the language generation component, which relies too heavily on the distributional characteristics of the dataset and assigns low probabilities to unseen combinations of concepts in the evaluation data. This supports the findings from concurrent work (Holtzman et al., 2019) which studies the challenges in decoding from language models trained with a maximum likelihood objective.

To address the generalization problem, we propose a multi-task model that jointly learns image captioning and image–sentence ranking. For caption generation, our model benefits from an additional step, where the set of captions generated by the model can be re-ranked using the jointly-trained image–sentence ranking component. We find that the ranking component is less affected by the likelihood of n-gram sequences in the training data, and that it is able to assign a higher ranking to more informative captions which contain unseen combinations of concepts. These findings are reflected by improved compositional generalization.

2 Related Work

2.1 Caption Generation and Retrieval

Image Caption Generation models are usually end-to-end differentiable encoder-decoder models trained with a maximum likelihood objective. Given an image encoding that is extracted from a convolutional neural network (CNN), an RNN-based decoder generates a sequence of words that form the corresponding caption (Vinyals et al., 2015, *inter-alia*). This approach has been improved by applying top-down (Xu et al., 2015) and bottom-up attention mechanisms (Anderson et al., 2018). These models show increasingly good performance on benchmark datasets, e.g. COCO, and in some cases reportedly surpass human-level performance as measured by n-gram based evaluation metrics (Bernardi et al., 2016). However, recent work has revealed several caveats. Firstly, when using human judgments for evaluation, the automatically generated captions are still considered worse in most cases (Fang et al., 2015; Vinyals et al., 2017). Furthermore, when evaluating out-of-domain images or images with unseen concepts, it has been shown that the generated captions are often of poor quality (Mao et al., 2015; Vinyals et al., 2017). Attempts have been made to address the latter issue by leveraging unpaired text data or pre-trained language models (Hendricks et al., 2016; Agrawal et al., 2018).

Image–Sentence Ranking is closely related to image captioning. Here, the problem of language generation is circumvented and models are instead trained to rank a set of captions given an image, and vice-versa (Hodosh et al., 2013). A common approach is to learn a visual–semantic embedding for the captions and images, and to rank the images or captions based on similarity in the joint embedding space. State-of-the-art models extract image features from CNNs and use gated RNNs to represent captions, both of which are projected into a joint space using a linear transformation (Frome et al., 2013; Karpathy and Fei-Fei, 2015; Vendrov et al., 2016; Faghri et al., 2018).

2.2 Compositional Models of Language

Investigations of compositionality in vector space models date back to early debates in the cognitive science (Fodor and Pylyshyn, 1988; Fodor and Lepore, 2002) and connectionist literature (McClelland et al., 1986; Smolensky, 1988) regarding the ability of connectionist systems to compose simple constituents into complex structures. In the NLP literature, numerous approaches that (loosely) follow the linguistic principle of compositionality[2] have been proposed (Mitchell and Lapata, 2008; Baroni and Zamparelli, 2010; Grefenstette and Sadrzadeh, 2011). More recently, it has become standard to employ representations which are learned using neural network architectures. The extent to which these models behave compositionally is an open topic of research (Lake and Baroni, 2017; Dasgupta et al., 2018; Ettinger et al., 2018; McCoy et al., 2018) that closely relates to the focus of the present paper.

Compositional generalization in image captioning has received limited attention in the literature. In Atzmon et al. (2016), the captions in the COCO dataset are replaced by subject-relation-object triplets, circumventing the problem of language generation, and replacing it with structured

[1] https://github.com/mitjanikolaus/compositional-image-captioning

[2] *The meanings for complex expressions are derived from the meanings of their parts via specific composition functions.* (Partee, 1984)

triplet prediction. Other work explores generalization to unseen combinations of visual concepts as a classification task (Misra et al., 2017; Kato et al., 2018). Lu et al. (2018) is more closely related to our work; they evaluate captioning models on describing images with unseen noun-noun pairs.

In this paper, we study compositional generalization in image captioning with combinations of multiple classes of nouns, adjectives, and verbs.[3] We find that state-of-the-art models fail to generalize to unseen combinations, and present a multi-task model that improves generalization by combining image captioning (Anderson et al., 2018) and image–sentence ranking (Faghri et al., 2018). In contrast to other models that use a re-ranking step[4], our model is trained jointly on both tasks and does not use any additional features or external resources. The ranking model is only used to optimize the global semantics of the generated captions with respect to the image.

3 Compositional Image Captioning

3.1 Problem Definition

In this section we define the compositional captioning task, which is designed to evaluate how well a model generalizes to captioning images that *should* be described using previously unseen combinations of concepts, when the individual concepts have been observed in the training data.

We assume a dataset of captioned images $\mathcal{D}$, in which N images are described by K captions: $\mathcal{D} := \{\langle i^1, s_1^1, ..., s_K^1\rangle, ..., \langle i^N, s_1^N, ..., s_K^N\rangle\}$. We also assume the existence of a concept pair $\{c_i, c_j\}$ that represents the concepts of interest in the evaluation. In order to evaluate the compositional generalization of a model for that concept pair, we first define a training set by identifying and removing instances where the captions of an image contain the pair of concepts, creating a *paradigmatic gap* in the original training set: $\mathcal{D}_{\text{train}} := \{\langle i^n, s_k^n\rangle\}$ s.t. $\forall_{n=1}^{N} \nexists\ k : c_i \in s_k^n \wedge c_j \in s_k^n$. Note that the concepts c_i and c_j can still be independently observed in the captions of an image of this set, but *not* together in the same caption. We also define validation and evaluation sets D_{val} and D_{eval} that *only* contain instances where at least one of the captions of an image contains the pair of concepts: $\mathcal{D}_{\text{val/eval}} := \{\langle i^n, s_k^n\rangle\}$ s.t. $\forall_{n=1}^{N} \exists\ k : c_i \in s_k^n \wedge c_j \in s_k^n$. A model is trained on the $\mathcal{D}_{\text{train}}$ training set until it converges, as measured on the $\mathcal{D}_{\text{val}}$ validation set. The compositional generalization of the model is measured by the proportion of evaluation set captions which successfully combined a held out pair of concepts $\{c_i, c_j\}$ in D_{eval}.

3.2 Selection of Concept Pairs

We select pairs of concepts that are likely to be represented in an image recognition model. In particular, we identify adjectives, nouns, and verbs in the English COCO captions dataset (Chen et al., 2015) that are suitable for testing compositional generalization. We define concepts as sets of synonyms for each word, to account for the variation in how the concept can be expressed in a caption. For each noun, we use the synonyms defined in Lu et al. (2018). For the verbs and adjectives, we use manually defined synonyms (see Appendix D). From these concepts, we select adjective–noun and noun–verb pairs for the evaluation. To identify concept pair candidates, we use StanfordNLP (Qi et al., 2018) to label and lemmatize the nouns, adjectives, and verbs in the captions, and to check if the adjective or verb is connected to the respective noun in the dependency parse.

Nouns: We consider the 80 COCO object categories (Lin et al., 2014) and additionally divide the "person" category into "man", "woman" and "child". It has been shown that models can detect and classify these categories with high confidence (He et al., 2016). We further group the nouns under consideration into animate and inanimate objects. We use the following nouns in the evaluation: `woman`, `man`, `dog`, `cat`, `horse`, `bird`, `child`, `bus`, `plane`, `truck`, `table`.

Adjectives: We analyze the distribution of the adjectives in the dataset (see Figure 4 in Appendix A). The captions most frequently contain descriptions of the color, size, age, texture or quantity of objects in the images. We consider the color and size adjectives in this evaluation. It has been shown that CNNs can accurately classify the color of objects (Anderson et al., 2016); and we assume that CNNs can encode the size of objects because they can predict bounding boxes, even for small

[3] This is different from the "robust image captioning" task (Lu et al., 2018) because we are testing for the composition of nouns with adjectives or verbs, and not the co-occurrence of different nouns in an image.

[4] Fang et al. (2015) use a discriminative model that has access to sentence-level features and a multimodal similarity model in order to capture global semantics. Wang et al. (2017) uses a conditional variational auto-encoder to generate a set of diverse captions and a consensus-based method for re-ranking the candidates.

black cat	big bird	red bus
small plane	eat man	lie woman
white truck	small cat	brown dog
big plane	ride woman	fly bird
white horse	big cat	blue bus
small table	hold child	stand bird
black bird	small dog	white boat
stand child	big truck	eat horse

Table 1: The 24 concept pairs used to construct the training $\mathcal{D}_{\text{train}}$ and eval $\mathcal{D}_{\text{eval}}$ datasets.

objects (Bai et al., 2018). In the evaluation, we use the following adjectives: `big`, `small`, `black`, `red`, `brown`, `white`, `blue`.

Verbs: Sadeghi and Farhadi (2011) show that it is possible to automatically describe the interaction of objects or the activities of objects in images. We select verbs that describe simple and well-defined actions and group them into transitive and intransitive verbs. We use the following verbs in the pairs: `eat`, `lie`, `ride`, `fly`, `hold`, `stand`.

Pairs and Datasets: We define a total of 24 concept pairs for the evaluation, as shown in Table 1. The training and evaluation data is extracted from the COCO dataset, which contains K=5 reference captions for N=123,287 images. In the compositional captioning evaluation, we define the training datasets D_{train} and validation datasets D_{val} as subsets of the original COCO training data, and the evaluation datasets D_{eval} as subsets of the COCO validation set, both given the concept pairs.

To ensure that there is enough evaluation data, we only use concept pairs for which there are more than 100 instances in the validation set. Occurrence statistics for the considered concept pairs can be found in Appendix B.

3.3 Evaluation Metric

The performance of a model is measured on the $\mathcal{D}_{\text{eval}}$ datasets. For each concept pair evaluation set consisting of M images, we dependency parse the set of $M \times K$ generated captions $\{\langle s_1^1, ..., s_K^1\rangle, ..., \langle s_1^M, ..., s_K^M\rangle\}$ to determine whether the captions contain the expected concept pair, and whether the adjective or verb is a dependent of the noun.[5] We denote the set of captions for which these conditions hold true as $\mathcal{C}$.

[5]This means that a model gains no credit for predicting the concept pairs without them attaching to their expected target.

There is low inter-annotator agreement in the human reference captions on the usage of the concepts in the target pairs.[6] Therefore, one should *not* expect a model to generate a *single* caption with the concepts in a pair. However, a model can generate a larger set of K captions using beam search or diverse decoding strategies. Given K captions, the recall of the concept pairs in an evaluation dataset is:

$$\text{Recall@K} = \frac{|\{\langle s_k^m\rangle \mid \exists k : s_k^m \in \mathcal{C}\}|}{M} \quad (1)$$

Recall@K is an appropriate metric because the reference captions were produced by annotators who did not need to produce any specific word when describing an image. In addition, the set of captions $\mathcal{C}$ is determined with respect to the same synonym sets of the concepts that were used to construct the datasets, and so credit is given for semantically equivalent outputs. More exhaustive approaches to determine semantic equivalence for this metric are left for future work.

4 State-of-the-Art Performance

4.1 Experimental Protocol

Models: We evaluate two image captioning models on the compositional generalization task: Show, Attend and Tell (SAT; Xu et al., 2015) and Bottom-up and Top-down Attention (BUTD; Anderson et al., 2018). For SAT, we use ResNet-152 (He et al., 2016) as an improved image encoder.

Training and Evaluation: The models are trained on the $\mathcal{D}_{\text{train}}$ datasets, in which groups of concept pairs are held out—see Appendix C for more information. Hyperparameters are set as described in the respective papers. When a model has converged on the $\mathcal{D}_{\text{val}}$ validation split (as measured in BLEU score), we generate K captions for each image in $\mathcal{D}_{\text{eval}}$ using beam search. Then, we calculate the Recall@K metric (Eqn. 1, K=5) for each concept pair in the evaluation split, as well as the average over all recall scores to report the compositional generalization performance of a model.

We also evaluate the compositional generalization of a BUTD model trained on the full COCO

[6]We calculate the inter-annotator agreement for the target pairs between the 5 reference captions for every image in the COCO dataset: on average, only 1.57 / 5 captions contain the respective adjective–noun or noun–verb concept pair, if it is present in any. We ascribe this lack of agreement to the open nature of the annotation task: there were no restrictions given for what should be included in an image caption.

training dataset (FULL). In this setting, the model is trained on compositions of the type we seek to evaluate in this task, and thus does not need to generalize to new compositions.

Pretrained Language Representations: The word embeddings of image captioning models are usually learned from scratch, without pretraining[7]. Pretrained word embeddings (e.g. GloVe (Pennington et al., 2014)) or language models (e.g. Devlin et al. (2019)) contain distributional information obtained from large-scale textual resources, which may improve generalization performance. However, we do use them for this task because the resulting model may not have the expected paradigmatic gaps.

4.2 Results

Image Captioning: The models mostly fail to generate captions that contain the held out pairs. The average Recall@5 for SAT and BUTD are 3.0 and 6.5, respectively. A qualitative analysis of the generated captions shows that the models usually describe the depicted objects correctly, but, in the case of held out adjective–noun pairs, the models either avoid using adjectives, or use adjectives that describe a different property of the object in question, e.g. *white and green airplane* instead of *small plane* in Figure 3. In the case of held out noun–verb pairs, the models either replace the target verb with a less descriptive phrase, e.g. *a man sitting with a plate of food* instead of *a man is eating* in Figure 3, or completely omit the verb, reducing the caption to a simple noun phrase.

In the FULL setting, average Recall@5 reaches 33.3. We assume that this score is a conservative estimate due to the low average inter-annotator agreement (see Footnote 6). The model is less likely to describe an image using the target pair if the pair is only present in one of the reference captions, as the feature is likely not salient (e.g. the car in the image has multiple colors, and the target color is only covering one part of the car). In fact, if we calculate the average recall for images where at least 2 / 3 / 4 / 5 of the reference captions contain the target concept pair, Recall@5 increases to 46.5 / 58.3 / 64.9 / 75.2. This shows that the BUTD model is more likely to generate a caption with the expected concept pair when more human annotators agree that it is a salient pair of concepts in an image.

[7]Exceptions: You et al. (2016); Anderson et al. (2017)

Image–Sentence Ranking: In a related experiment, we evaluate the generalization performance of the VSE++ image–sentence ranking model on the compositional captioning task (Faghri et al., 2018). We use an adapted version of the evaluation metric because the ranking model does not generate tokens.[8] The average Recall@5 with the adapted metric for the ranking model is 46.3. The respective FULL performance for this model is 47.0, indicating that the model performs well whether it has seen examples of the evaluation concept pair at training time or not. In other words, the model achieves better compositional generalization than the captioning models.

5 Joint Model

In the previous section, we found that state-of-the-art captioning models fail to generalize to unseen combinations of concepts, however, an image-sentence ranking model does generalize. We propose a multi-task model that is trained for image captioning and image–sentence ranking with shared parameters between the different tasks. The captioning component can use the ranking component to re-rank complete candidate captions in the beam. This ensures that the generated captions are as informative and accurate as possible, given the constraints of satisfying both tasks.

Following Anderson et al. (2018), the model is a two-layer LSTM (Hochreiter and Schmidhuber, 1997), where the first layer encodes the sequence of words, and the second layer integrates visual features from the bottom-up and top-down attention mechanism, and generates the output sequence. The parameters of the ranking component θ_2 are mostly a subset of the parameters of the generation component θ_1. We name the model **B**ottom-**U**p and **T**op-down attention with **R**anking (BUTR). Figure 2 shows a high-level overview of the model architecture.

5.1 Image–Sentence Ranking

To perform the image–sentence ranking task, we project the images and captions into a joint visual-semantic embedding space $\mathbb{R}^J$. We introduce a

[8]For each image in the evaluation set, we construct a test set that consists of the 5 correct captions and the captions of 1,000 randomly selected images from the COCO validation set. We ensure that all captions in the test set contain exactly one of the constituent concept pairs, but not both (except for the 5 correct captions). We construct a ranking of the captions in this test set with respect to the image, and use the top-K ranked captions to calculate the concept pair recall (Eqn. 1).

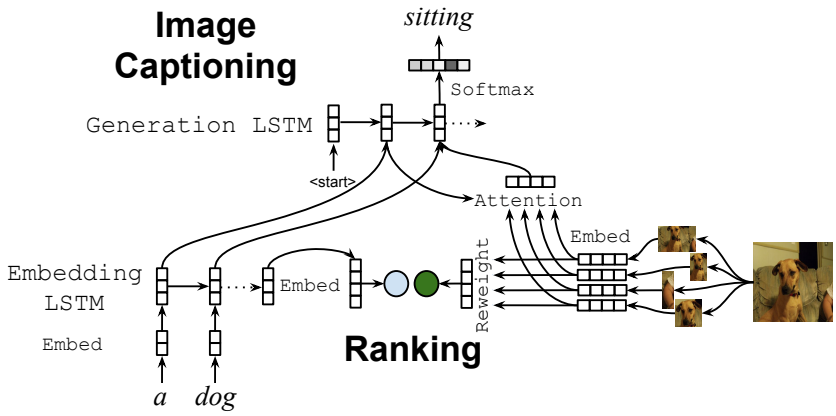

Figure 2: An overview of BUTR, which jointly learns image–sentence ranking and image captioning.

language encoding LSTM with a hidden layer dimension of L.

$$\boldsymbol{h}_t^l = \text{LSTM}(\boldsymbol{W}_1 \boldsymbol{o}_t, \boldsymbol{h}_{t-1}^l) \tag{2}$$

where $\boldsymbol{o}_t \in \mathbb{R}^V$ is a one-hot encoding of the input word at timestep t, $\boldsymbol{W}_1 \in \mathbb{R}^{E \times V}$ is a word embedding matrix for a vocabulary of size V and $\boldsymbol{h}_{t-1}^l$ the state of the LSTM at the previous timestep. At training time, the input words are the words of the target caption at each timestep.

The final hidden state of the language encoding LSTM $\boldsymbol{h}_{t=T}^l$ is projected into the joint embedding space as $\boldsymbol{s}^* \in \mathbb{R}^J$ using $\boldsymbol{W}_2 \in \mathbb{R}^{J \times L}$:

$$\boldsymbol{s}^* = \boldsymbol{W}_2 \boldsymbol{h}_{t=T}^l \tag{3}$$

The images are represented using the bottom-up features proposed by Anderson et al. (2018). For each image, we extract a set of R mean-pooled convolutional features $v_r \in \mathbb{R}^I$, one for each proposed image region r. We introduce $\boldsymbol{W}_3 \in \mathbb{R}^{J \times I}$, which projects the image features of a single region into the joint embedding space:

$$\boldsymbol{v}_r^e = \boldsymbol{W}_3 \boldsymbol{v}_r \tag{4}$$

To form a single representation $\boldsymbol{v}^*$ of the image from the set of embedded image region features $\boldsymbol{v}_r^e$, we apply a weighting mechanism. We generate a normalized weighting of region features $\beta \in \mathbb{R}^R$ using $\boldsymbol{W}_4 \in \mathbb{R}^{1 \times J}$. β_r denotes the weight for a specific region r. Then we sum the weighted region features to generate $\boldsymbol{v}^* \in \mathbb{R}^J$:

$$\beta_r' = \boldsymbol{W}_4 \boldsymbol{v}_r^e \tag{5}$$

$$\boldsymbol{\beta} = \text{softmax}(\boldsymbol{\beta}') \tag{6}$$

$$\boldsymbol{v}^* = \sum_{r=1}^{R} \beta_r \boldsymbol{v}_r^e \tag{7}$$

We define the similarity between an image and a caption as the cosine similarity $cos(\boldsymbol{v}^*, \boldsymbol{s}^*)$.

5.2 Caption Generation

For caption generation, we introduce a separate language generation LSTM that is stacked on top of the language encoding LSTM. At each timestep t, we first calculate a weighted representation of the input image features. We calculate a normalized attention weight $\alpha_t \in \mathbb{R}^R$ (one $\alpha_{r,t}$ for each region) using the language encoding and the image region features. Then, we create a single weighted image feature vector:

$$\alpha_{r,t}' = \boldsymbol{W}_5 \tanh(\boldsymbol{W}_6 \boldsymbol{v}_r^e + \boldsymbol{W}_7 h_t^l) \tag{8}$$

$$\boldsymbol{\alpha}_t = \text{softmax}(\boldsymbol{\alpha}_{r,t}') \tag{9}$$

$$\hat{\boldsymbol{v}}_t = \sum_{r=1}^{R} \boldsymbol{\alpha}_{r,t} \boldsymbol{v}_r^e \tag{10}$$

where $\boldsymbol{W}_5 \in \mathbb{R}^H$, $\boldsymbol{W}_6 \in \mathbb{R}^{H \times J}$ and $\boldsymbol{W}_7 \in \mathbb{R}^{H \times L}$. H indicates the hidden layer dimension of the attention module.

These weighted image features $\hat{\boldsymbol{v}}_t$, the output of the language encoding LSTM $\boldsymbol{h}_t^l$ (Eqn. 2) and the previous state of the language generation LSTM $\boldsymbol{h}_{t-1}^g$ are input to the language generation LSTM:

$$\boldsymbol{h}_t^g = \text{LSTM}([\hat{\boldsymbol{v}}_t, \boldsymbol{h}_t^l], \boldsymbol{h}_{t-1}^g) \tag{11}$$

The hidden layer dimension of the LSTM is G. The output probability distribution over the vocabulary is calculated using $\boldsymbol{W}_8 \in \mathbb{R}^{V \times G}$:

$$p(w_t | w_{<t}) = \text{softmax}(\boldsymbol{W}_8 \boldsymbol{h}_t^g) \tag{12}$$

5.3 Training

The model is jointly trained on two objectives. The caption generation component is trained with

a cross-entropy loss, given a target ground-truth sentence s consisting of the words $w_1, \ldots, w_T$:

$$\mathcal{L}_{\text{gen}}(\theta_1) = -\sum_{t=1}^{T} \log p(w_t | w_{<t}; i) \quad (13)$$

The image–caption ranking component is trained using a hinge loss with emphasis on hard negatives (Faghri et al., 2018):

$$\mathcal{L}_{\text{rank}}(\theta_2) = \max_{s'}[\alpha + \cos(i, s') - \cos(i, s)]_+ + \max_{i'}[\alpha + \cos(i', s) - \cos(i, s)]_+ \quad (14)$$

where $[x]_+ \equiv max(x, 0)$.

These two loss terms can take very different magnitudes during training, and thus can not be simply added. We use GradNorm (Chen et al., 2018) to learn loss weighting parameters w_{gen} and w_{rank} with an additional optimizer during training. These parameters dynamically rescale the gradients so that no task becomes too dominant. The overall training objective is formulated as the weighted sum of the single-task losses:

$$\mathcal{L}(\theta_1, \theta_2) = w_{\text{gen}}\mathcal{L}_{\text{gen}}(\theta_1) + w_{\text{rank}}\mathcal{L}_{\text{rank}}(\theta_2) \quad (15)$$

5.4 Inference

The model generates B captions for each image using beam search decoding. At each timestep, the tokens generated so far for each item on the beam are input back into the language encoder (Eqn. 3). The output of the language encoder is concatenated with the image representation (Eqn. 7) and the previous hidden state of the generation LSTM, and input to the generation LSTM (Eqn. 11) to predict the next token (Eqn. 12).

The jointly-trained image–sentence ranking component can be used to re-rank the generated captions comparing the image embedding with a language encoder embedding of the captions (Eqn. 4). We expect the ranking model will produce a better ranking of the B captions than only beam search by considering their relevance and informativity with respect to the image.

6 Results

We follow the experimental protocol defined in Section 4 to evaluate the joint model. See Appendix E for training details and hyperparameters.

Table 2 shows the compositional generalization performance, as well as the common image captioning metric scores for all models. BUTR uses the same image features and a decoder architecture as the BUTD model. Thus, when using the standard beam search decoding method, BUTR does not improve over BUTD. However, when using the improved decoding mechanism with re-ranking BUTR + RR, Recall@5 increases to 13.2. We also observe an improvement in METEOR and SPICE, and a drop in BLEU and CIDEr compared to the other models. We note that BLEU has the weakest correlations (Elliott and Keller, 2014), and SPICE and METEOR have the strongest correlations with human judgments (Kilickaya et al., 2017).

Model	R	M	S	C	B
SAT	3.0	23.2	16.6	80.4	27.5
BUTD	6.5	25.8	19.1	**98.1**	**32.6**
BUTR	6.5	25.7	19.0	97.0	32.0
BUTR + RR	**13.2**	**26.4**	**20.4**	92.7	28.8
FULL	33.3	27.4	20.9	105.3	36.6

Table 2: Average results for Recall@5 (**R**; Eqn. 1), METEOR (**M**; Denkowski and Lavie, 2014), SPICE (**S**; Anderson et al., 2016) , CIDEr (**C**; Vedantam et al., 2015), BLEU (**B**; Papineni et al., 2002). RR stands for re-ranking after decoding.

	Color		Size		Verb	
	A	I	A	I	T	I
SAT	3.7	10.5	0	0	1.6	2.2
BUTD	5.4	10.9	0.5	0	11.6	10.3
BUTR	6.4	16.2	0.3	0.2	7.0	8.6
+ RR	**13.8**	**26.0**	**1.4**	**0.8**	**20.3**	**16.9**
FULL	42.7	38.7	5.9	33.3	39.6	39.5

Table 3: Detailed Recall@5 scores for different categories of held out pairs. The scores are averaged over the set of scores for pairs from the respective category. RR stands for re-ranking after decoding. Color and size adjectives are split into **A**nimate or **I**nanimate objects; Verbs are split into **T**ransitive and **I**ntransitive verbs.

The Recall@5 scores for different categories of held out pairs is presented in in Table 3, and Figure 3 presents examples of images and the generated captions from different models. We observe that all models are generally best at describing colors, especially of inanimate objects; they nearly never correctly describe held out size modifiers; and for held out noun–verb pairs, performance is slightly better for transitive verbs.

Concepts	white horse	blue bus	small cat	small plane	man eat	bird stand
						
SAT	a black and white cow standing on top of a lush green field	a bus parked on the side of the street	a cat sitting on top of a wooden bench	a fighter jet on top of a lush green field	a man sitting at a table with a plate of food	a white bird sitting on top of a car
BUTD	a brown and white cow standing on a lush green field	a public transit bus on a city street	a cat sitting on top of a wooden bench	a white and green airplane on a field	a man sitting down with a plate of food	a white bird sitting on top of a car
BUTR+RR	a large **white horse** standing on top of a green field	a **blue** and yellow **bus** traveling down the street	a cat sitting on a bench near a wall	a white and green plane is parked on the grass	a **man** sitting down **eating** a plate of food	a large white **bird standing** on top of a car

Figure 3: Selected examples of the captions generated by SAT, BUTD, and BUTR for six different concept pairs. The **bold words** in a caption indicate compositional success.

7 Analysis and Discussion

Describing colors: The color–noun pairings studied in this work have the best generalization performance. We find that all models are better at generalizing to describing inanimate objects instead of animate objects, as shown in the detailed results in Table 3. One explanation for this could be that the colors of inanimate objects tend to have a higher variance in chromaticity when compared to the colors of animate objects (Rosenthal et al., 2018), making them easier to distinguish.

Describing sizes: The generalization performance for size modifiers is consistently low for all models. The CNN image encoders are generally able to predict the sizes of object bounding boxes in an image. However, this does not necessarily relate to the actual sizes of the objects, given that this depends on their distance from the camera. To support this claim, we perform a correlation analysis in Appendix F showing that the bounding box sizes of objects in the COCO dataset do not relate to the described sizes in the respective captions.

Nevertheless, size modification is challenging from a linguistic perspective because it requires reference to an object's comparison class (Cresswell, 1977; Bierwisch, 1989). A large mouse is so with respect to the class of mice, not with respect to the broader class of animals. To successfully learn size modification, a model needs to represent such comparison classes.

We hypothesize that recall is reasonable in the FULL setting because it exploits biases in the dataset, e.g. that trucks are often described as BIG. In that case, the model is not actually learning the meaning of BIG, but simple co-occurrence statistics for adjectives with nouns in the dataset.

Describing actions: In these experiments, the models were better at generalizing to transitive verbs than intransitive verbs. This may be because images depicting transitive events (e.g. eating) often contain additional arguments (e.g. cake); thus they offer richer contextual cues than images with intransitive events. The analysis in Appendix G provides some support for this hypothesis.

Diversity in Generated Captions: A crucial difference between human-written and model-generated captions is that the latter are less diverse (Devlin et al., 2015; Dai et al., 2017). Given that BUTR+RR improves compositional generalization, we explore whether the diversity of the captions is also improved. Van Miltenburg et al. (2018) proposes a suite of metrics to measure the diversity of the captions generated by a model. We apply these metrics to the captions generated by BUTR+RR and BUTD and compare the scores to the best models evaluated in Van Miltenburg et al. (2018).

The results are presented in Table 4. BUTR+RR shows the best performance as measured by most of the diversity metrics. BUTR+RR produces the highest percentage of novel captions (%Novel), which is important for compositional generalization. It generates sentences with a high average sentence length (ASL) – performing similarly to Liu et al. (2017) – but with a larger standard deviation, suggesting a greater variety in the captions. The total number of word types (Types) and cover-

Model	ASL	Types	TTR_1	TTR_2	%Novel	Cov	Loc_5
Liu et al. (2017)	**10.3** $\pm$ 1.32	598	0.17	0.38	50.1	0.05	0.70
Vinyals et al. (2017)	10.1 $\pm$ 1.28	953	0.21	0.43	90.5	0.07	0.69
Shetty et al. (2017)	9.4 $\pm$ 1.31	**2611**	0.24	0.54	80.5	**0.20**	0.71
BUTD	9.0 $\pm$ 1.01	1162	0.22	0.49	56.4	0.09	0.78
BUTR+RR	10.2 $\pm$ **1.76**	1882	**0.26**	**0.59**	**93.6**	0.14	**0.80**
Validation data	11.3 $\pm$ 2.61	9200	0.32	0.72	95.3	-	-

Table 4: Scores for diversity metrics as defined by Van Miltenburg et al. (2018) for different models.

age (Cov) are higher for Shetty et al. (2017), which is trained with a generative adversarial objective in order to generate more diverse captions. However, these types are more equally distributed in the captions generated by BUTR+RR, as shown by the higher mean segmented type-token ratio (TTR_1) and bigram type-token ratio (TTR_2).

The increased diversity of the captions may explain the lower BLEU score of BUTR+RR compared to BUTD. Recall that BLEU measures weighted n-gram precision, hence it awards less credit for captions that are lexically or syntactically different than the references. Thus, BLEU score may decrease if a model generates diverse captions. We note that METEOR, which incorporates non-lexical matching components in its scoring function, is higher for BUTR+RR than BUTD.

Decoding strategies: The failure of the captioning models to generalize can be partially ascribed to the effects of maximum likelihood decoding. Holtzman et al. (2019) find that maximum likelihood decoding leads to unnaturally flat and high per-token probability text. We find that even with grounding from the images, the captioning models do not assign a high probability to the sequences containing compositions that were not observed during training. BUTR is jointly trained with a ranking component, which is used to re-rank the generated captions, thereby ensuring that at the sentence-level, the captions are relevant for the image. It can thus be viewed as an improved decoding strategy such as those proposed in Vijayakumar et al. (2018); Fan et al. (2018); Radford et al. (2019); Holtzman et al. (2019).

8 Conclusion

Image captioning models are usually evaluated without explicitly considering their ability to generalize to unseen concepts. In this paper, we argued that models should be capable of *compositional generalization*, i.e. the ability to produce captions that include combinations of unseen concepts. We evaluated the ability of models to generalize to unseen adjective–noun and noun–verb pairs and found that two state-of-the-art models did not generalize in this evaluation, but that an image–sentence ranking model did. Given these findings, we presented a multi-task model that combines captioning and image–sentence ranking, and uses the ranking component to re-rank the captions generated by the captioning component. This model substantially improved generalization performance *without* sacrificing performance on established text-similarity metrics, while generating more diverse captions. We hope that this work will encourage researchers to design models that better reflect human-like language production.

Future work includes extending the evaluation to other concept pairs and other concept classes, analysing the circumstances in which the re-ranking step improves compositional generalization, exploring the utility of jointly trained discriminative re-rankers into other NLP tasks, developing models that generalize to size modifier adjectives, and devising approaches to improve the handling of semantically equivalent outputs for the proposed evaluation metric.

Abstract

We introduce a new embedding model to represent movie characters and their interactions in a dialogue by encoding in the same representation the language used by these characters as well as information about the other participants in the dialogue. We evaluate the performance of these new character embeddings on two tasks: (1) character relatedness, using a dataset we introduce consisting of a dense character interaction matrix for 4,761 unique character pairs over 22 hours of dialogue from eighteen movies; and (2) character relation classification, for fine- and coarse-grained relations, as well as sentiment relations. Our experiments show that our model significantly outperforms the traditional Word2Vec continuous bag-of-words and skip-gram models, demonstrating the effectiveness of the character embeddings we introduce. We further show how these embeddings can be used in conjunction with a visual question answering system to improve over previous results.

1 Introduction

Understanding characters (or more broadly people) plays a critical role in the human-level interpretation of dialogues – be those in stories, movies, or day-to-day conversations. The verbal interaction between characters provides important information (Iyyer et al., 2016; Elson et al., 2010). In these contexts, the names of characters trigger reasoning at a much deeper level than other regular words, due to the character background, behaviors, social network, and so forth. Currently, the most commonly used word embedding models such as Word2Vec (Mikolov et al., 2013a,b) and Glove (Pennington et al., 2014) represent characters using the embeddings corresponding to the tokens used to name them. Using these models in a dialogue setting to represent the characters poses three main issues. First, name mentions in dialogues are sparse (Azab et al., 2018), which makes it difficult for these models to learn a good quality representation for these names (Barteld, 2017). Second, in dialogues or narratives, names often do not refer to the same person, and yet these embeddings have a single vector representation for each word in the vocabulary. For example, "Danny" in the dialogue of the "American History X" movie is different from "Danny" in the "Ocean's Eleven" movie. Finally, the learned embeddings of these names reflect the co-occurrences of these name mentions and other words uttered by these characters, but do not model how related these characters are. Thus, the resulting embeddings cannot be effectively used to further reason about the characters and their relations.

Henry:	I did not know you could fly a plane.
Indiana:	Fly yes. Land no. Dad, you have to use the machine gun. Get it ready. Eleven o'clock!
Henry:	What happens at eleven o'clock?
Indiana:	Twelve, eleven, ten. Eleven o'clock, fire! Dad, are we hit?
Henry:	More or less. Son, I am sorry. They got us.
Indiana:	Hang on, dad. We are going in.

Table 1: A snippet of conversation between two characters from the "Indiana Jones and the Last Crusade" movie with each dialogue turn annotated with its corresponding speaker name. We aim to generate embedding representations for "Indiana" and "Henry" in a way that captures their relation.

The representation of characters in dialogues has been an important task for social network extraction (Elson et al., 2010), character relation modeling (Chaturvedi et al., 2016), and persona-based conversation models (Li et al., 2016). However, most of the previous work relies upon the ex-

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 99–109
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

traction of linguistic features like explicit forms of address (Makazhanov et al., 2014), the length of the utterance, or the frequency of exchanges between the characters (Elson et al., 2010).

In this work, we address the task of representing characters in dialogues, specifically focusing on movies and plays. Given a set of dialogue turns, annotated with the corresponding speaker names, our goal is to generate a vector representation for each of these characters that captures the relation with other characters. We propose a new approach to embed characters in dialogues based not only on what a character is saying, but also to whom. This model allows the information from the words in a dialogue turn to propagate to the representation of the previous and following speakers.

Despite its simplicity, our model yields strong empirical performance. By evaluating our model on two different tasks – namely character relatedness and character relation classification (fine-grained, coarse-grained, and sentiment) – we find that the model exceeds by a large margin several strong baselines, which indicates that our model effectively captures the various characteristics of characters. Additionally, in the process of evaluating the model, we build a new dataset consisting of 4,761 character relation pairs obtained from eighteen movies, manually annotated with relatedness scores and relations of various granularities. We are making the dataset publicly available.

2 Related Work

Learning distributional representation of words plays an increasingly important role in representing text in many tasks (Bengio et al., 2013; Chen and Manning, 2014). The existence of huge datasets allowed learning high quality word embeddings in an unsupervised way by training a neural network on fake objectives (Mikolov et al., 2013a,b; Turney and Pantel, 2010). A major strength of these learned word embeddings is that they are able to capture useful semantic information that can be easily used in other tasks of interest such as semantic similarity and relatedness between pair of words (Mikolov et al., 2013a; Pennington et al., 2014; Wilson and Mihalcea, 2017) and dependency parsing (Chen and Manning, 2014; Dyer et al., 2015). However, these models treat names and entities no more than the tokens used to mention them. As a result, these models are unable to well represent names in narrative understanding task because the word "John" in a given story can be very different from the word "John" in another narrative. In this work, we only focus on representing character names and not the whole embedding space (Ji et al., 2017).

Recently, several approaches have been proposed to build dynamic representations for entities (Henaff et al., 2016; Ji et al., 2017; Kobayashi et al., 2016, 2017). One common approach is to rely on neural language models to encode the local context of an entity and use the resulting context vectors as the embedding for subsequent occurrences of that entity (Kobayashi et al., 2016, 2017). Another approach is to learn a generative model that generates the representation of an entity mention (Ji et al., 2017). Henaff et al. (2016) proposed an explicit entity tracking model by relying on an external memory to store information about entities as they appear in a given sentence. While these rich representations improve the performance on several tasks such as coreference and reading comprehension, they rely on explicit mentions of entities in text as available in toy datasets such as bAbi (Weston et al., 2015). Thus, it is difficult to apply these representations in a dialogue setting due to the sparseness of name mentions in dialogue, as well as the lack of explicit conversation connections between characters (as available in movies) (Azab et al., 2018). Most of the existing story understanding work feeds the model with the vector representations of names based on a global model such as Word2Vec or Glove, which hinders the ability of these models to understand dialogue (Tapaswi et al., 2016; Na et al., 2017; Lei et al., 2018). Recently, Li et al. (2016) relied on TV series scripts in order to learn speaker persona representations and used these representations to improve the performance of neural conversation models. Unlike (Ji et al., 2017; Li et al., 2016), we focus on representing character names in dialogue settings and learning different embeddings for characters from different story dialogues in a way that reflects the relatedness of story characters; more specifically, we propose the use of speaker prediction as an auxiliary supervision to improve the character representation.

Identifying and analyzing character relations in literary texts is a well studied problem (Agarwal et al., 2013; Makazhanov et al., 2014; Elson et al., 2010; Iyyer et al., 2016). Most of these models depend on analyzing the co-occurrence of the char-

acters and stylistic features used while characters address each other. These models are really important to summarize, understand, and generate stories (Elson et al., 2010). In this work, we use the task of character relation classification as an extrinsic evaluation task to evaluate the impact of character embeddings on this task.

3 Character Embeddings

Characters play an important role in any dialogue, including movies or plays. Yet, work to date has rarely considered specialized character representations. We hypothesize that a representation that leverages both the language uttered by the characters as well as information on the other characters in the dialogue could result in richer encodings. The intuition behind our hypothesis is explained by the example in table 1. Here, the word "Dad" should be associated not only with "Indiana" but also propagate its information to "Henry", conditioned by "Indiana". Our proposed model is well conveying this intuition to encode characters.

3.1 Setup

Our architecture builds on a pretrained embedding model generated by standard Word2Vec models (Mikolov et al., 2013a,b) or pre-trained contextualized word representations from neural language models (ELMo) (Peters et al., 2018). We start by collecting sets of (current speaker, previous speakers, next speakers, context words) as training examples. We split the four elements in the sets into target and context depending on our objectives. Figure 1 describes the input-output (target-context) pairs of our system. Additionally, our model works as an unsupervised post-training of existing embeddings, rather than starting the training from scratch. This is due to the fact that getting a good representation for characters is a separate task from getting a general representation of tokens. A good pre-trained embedding space is an essential component to map characters so that they will be distributed in a semantically meaningful embedding space. While a good pre-trained embedding is important, our models focus on "moving" the character embeddings without affecting any other word representations.

3.2 Architecture

We propose two post-training schemes, which we refer to as Character Embedding (SG) and Character Embedding (CBOW). The differences stand in the objective of post-training, given sets of (current speaker, previous speakers, next speakers, context words) as training examples. Formally, given the sequence of speakers at each turn $S = s_1, s_2, s_3, , , s_{T-1}, s_T$, we define context words C for turn t as the set of words found by a sliding context window in the utterance. We propose our post-training objectives as following:

$$L = \frac{1}{N} \sum_{s_i \in S} \sum_{w_i \in C(s_i)} \sum_{-sw \leq j \leq sw} \log(p(w_i|s_{i+j}))) \quad (1)$$

$$L = \frac{1}{N} \sum_{s_i \in S} \sum_{w_i \in C(s_i)} (\log(p(s_i|w_i) + \sum_{-sw \leq j \leq sw, j \neq 0} \log(p(s_i|s_{i+j}))) \quad (2)$$

Our Character Embedding (SG) model maximizes the objective on Equation 1, while Character Embedding (CBOW) maximizes the objective on Equation 2, where N indicates the number of training examples and sw indicates the size of the speaker window (speaker window of size one means we consider speakers of one preceding turn and one succeeding turn). Our formulation defines probabilities $p(s_i|w_i)$, $p(s_i|s_{i+j})$ and $p(w_i|s_{i+j})$ using the softmax equation. We also define two transformations of our network – lookup table (LUT) initialized by embedding of pre-trained embedding model and Linear Projection Layer W.

To examine the generality of our post-training schemes, we also apply them to another pre-trained word embedding model. Given a dialogue turn, we encode it using ELMo's pre-trained Bi-LSTM model (Peters et al., 2018) to generate a sequence of contextualized vectors for words. We add a linear projection layer on top that takes the generated embedding, in addition to the previous and following speakers, and train it to predict the speaker of the current turn. We refer to this model as Character Embedding (ELMo).

3.3 Training

We represent our contexts and targets as a one hot vector of length equal to the vocabulary size. The purpose of our model is to update the embedding

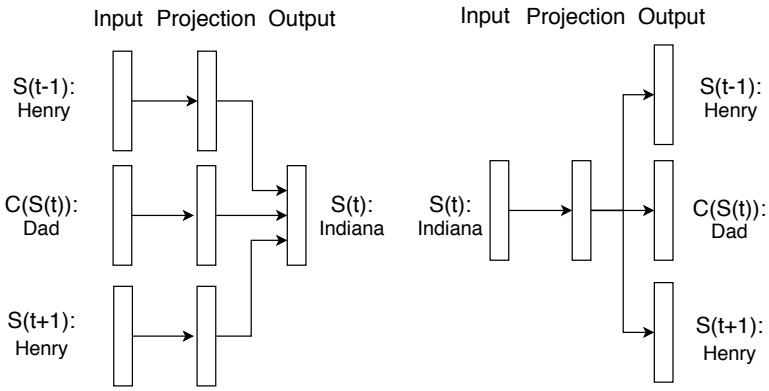

Figure 1: The conceptual figure describing input /output pairs of our character embedding model. The diagram describes when both the speaker window and the context window are size one. **Left**: Character Embedding(CBOW), **Right**: Character Embedding(SG).

of characters in LUT by propagating the gradient from our objectives. We use cross-entropy to calculate the loss, and we use gradient descent to update the parameters. The description of our Character Embedding (SG) model with a speaker window size of one is showed in Algorithm 1.

4 Evaluation Tasks and Datasets

We evaluate the quality of our speaker embedding model across two different tasks. Our goal is to evaluate how well each embedding model captures simple and complex character representations and interactions.

4.1 Character Relatedness

Measures of semantic relatedness between words indicate the degree to which words are associated with any kind of semantic relationship such as synonymy, antonymy, and so on. Semantic relatedness is commonly used as an absolute intrinsic evaluation task to assess and compare the quality of different word embeddings (Schnabel et al., 2015; Yih and Qazvinian, 2012; Upadhyay et al., 2016) and phrase embeddings (Wilson and Mihalcea, 2017).

Similarly, we define character relatedness as the degree to which a pair of characters in a given story are related to each other based on the story plot and their level of interaction throughout the dialogue. Given a pair of characters, we would like the relatedness score between their embedding representations to have a high correlation with their corresponding human-based relatedness score. Thus, the distance of the embeddings between closely related characters should be smaller than the distance between less related ones.

To measure the relatedness between characters in movies, we construct a new annotated dataset based on a publicly available dataset (Azab et al., 2018). That dataset includes 28K turns spoken by 396 different speakers in eighteen movies covering different genres, with the subtitles of each movie labeled with the character name of their corresponding speakers. On average, each character uttered 452 words.

For each movie in that dataset, two human annotators watched the movies and annotated a dense relatedness matrix of characters on a 1-5 scale. Table 2 shows the meaning of each score. These scores reflect the level of interaction or how closely related the characters are over the course of the movie. For example, given two characters X and Y, a high score for X and Y is assigned if e.g., X is the father of Y, regardless of the amount of interaction between the two characters. We also give a high score for the cases where X and Y are closely interacted, even if they are unrelated in terms of kinship. Due to the sparseness of the number of closely related characters, we asked the annotators to select the higher score when hesitating between two scores.

For three movies, the Pearson correlation between the two annotators is 0.8394, which reflects a very good agreement. We then average the scores assigned by the annotators and use the result as the human relatedness ground-truth score for each pair of characters.

In this dataset, we have 4,761 unique character pairs annotated with a relatedness score. Figure 2 shows the statistics over the relatedness scores. As shown in the table, only a small number of character pairs are closely related, while the majority

of the characters have either interacted very few times or did not interact at all. However, it is important to include these unrelated pairs while evaluating the quality of the character embeddings, as unrelated pairs might be closer than related ones especially for minor characters that do not speak much during the dialogue.

4.2 Character Relationships

Understanding the relationships between characters is a primary task in extracting and analyzing social relation networks from literary novels (Elson et al., 2010; Agarwal et al., 2013). It is also important for improving computational story summarization and generation methods (Elsner, 2012; Gorinski and Lapata, 2015).

Character relationship is a more complex task than character relatedness. In this task, given a pair of character embeddings, we would like to classify the type of their relationship on multiple dimensions. Specifically, we consider: fine-grained relations, such as sister/father/friend/enemy; coarse-grained relations, such as familial/social/professional; and relation sentiment, i.e., positive, negative or neural. The goal of this task is to evaluate the quality of our character embeddings and how well it captures such complex information in an unsupervised fashion. It also serves as an extrinsic evaluation for the impact of our character representations on downstream tasks.

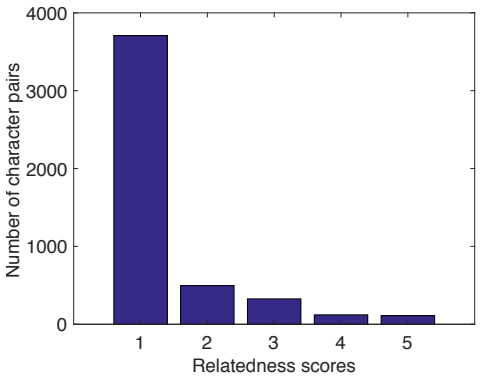

Figure 2: Statistics of the character relatedness dataset on movies of speaker naming dataset.

We use a subset of character relationships in a literary dataset (Massey et al., 2015). This dataset includes annotations for eighteen fine-grained relationship classes, four coarse-grained relationship classes, and three relation sentiment classes.[1] We use the 31 Shakespeare plays in this dataset, and obtain their corresponding text from project Gutenberg. We use the Shakespeare plays because they have the dialogue turns annotated with speakers names, which is necessary for training our character embedding models. The plays include a total of 605 character pair relationship annotations.

5 Experiments

5.1 Baselines

For each task, we compare our character embedding models against five baselines:

[1]Annotations on temporal change in the sentiment between each pair of characters is also included, but since our models do not have the ability to track such temporal information, we do not use these annotations.

Interaction Frequency. We count the number of exchanged dialogue turns between every pair of characters and normalize it by the total number of turns spoken by a given pair of characters.

TF-IDF. We treat all the utterances of a character as a document and calculate a tf-idf weight for each word. We then represent a character by its tf-idf vector of the words that they uttered.

Word2Vec (CBOW) model. We use the traditional Word2Vec architecture to train a word embedding space based on the continuous bag-of-words approach (Mikolov et al., 2013a). Given a sequence of words D, the context words that exist in a defined window size are considered as input to the network and the objective is to predict the target word by maximizing the average long probability:

$$L = \frac{1}{|D|} \sum_{w_i \in D} \log P(w_i | C(w_i)) \quad (3)$$

Word2Vec (SG) model. We use the skip-gram architecture of Word2Vec with negative sampling (Mikolov et al., 2013b). In this architecture, the objective is to learn a representation of the target word that would be good at predicting the words within a defined window by maximizing the average log probability:

$$L = \frac{1}{|D|} \sum_{w_i \in D} \sum_{w_0 \in C(w_i)} \log P(w_0 | w_i) \quad (4)$$

Character BOW. We represent each character as the mean-pooling of a 300-dimension pre-trained Word2Vec representation of all the words that this character has uttered through the entire dialogue.

Doc2Vec. We train a Doc2Vec model (Le and Mikolov, 2014) as tagged documents using the character names as the document tags. We then represent each character as the Doc2Vec representation of all the words that this character has uttered through the entire dialogue.

ELMo (Mean-Pooling). We use pre-trained contextualized word representations from neural language models (ELMo) (Peters et al., 2018) to generate character names representations based on the sentences that include their names.[2] To generate these representations, we feed the pre-trained ELMo model with a Glove representation for the words and ELMo augments their representation with the hidden states of its two layers bi-directional LSTM to represent the words with respect to their context. For each character name, we average their contextualized representations through the entire dialogue.

[2]We also tried training ELMo from scratch on our data but the pre-trained model produces better results.

5.2 Experimental Setting

To have these models trained on in-domain data, we use GenSim (Řehůřek and Sojka, 2010) to train the different architectures of Word2Vec on the almost 600K sentences / 4M words of subtitles and Shakespeare plays. For the target movies and plays, the speaker names are included in the training data so that we can have a vector representation for each character name. The names in our corpus have been manually normalized so that 'Joe' and 'Joseph' in a movie get the same representation, while 'Joseph' in a different movie gets a different representation. To achieve the first part of the name normalization, we utilize the name-clustering algorithm provided by Bamman (2014) to extract and cluster name tokens from the text and annotate the true representation of names for each cluster. We achieve the second part of the name normalization by adding the text title to the name tokens (e.g., 'Michael' becomes 'Michael$_{Othello}$').

For GenSim (Řehůřek and Sojka, 2010), we set the learning rate to 0.1, the window size to 4 and the samples to 50 for negative sampling. We run 30 epochs to train our baselines. For post-training by our models, we use a gradient decent to update our parameters. For general experiments, we set the learning rate to 0.1 and the learning rate decays by the factor of 0.9 per 10 epochs. We run maximum 40 epochs for our post-training. For Character Embedding (CBOW), we use a context window of size two. We use a speaker window of size one for both the Character Embedding (CBOW) and the Character Embedding (SG).

5.3 Results

Character Relatedness. For each model, given a pair of characters we compute the cosine similarity score between the embeddings of these two characters, defined as:

$$similarity(\boldsymbol{C}1, \boldsymbol{C}2) = \frac{\boldsymbol{C}1 \cdot \boldsymbol{C}2}{||\boldsymbol{C}1|| \cdot ||\boldsymbol{C}2||} \quad (5)$$

and compute the similarity score between two characters in the embedding space similar to (Col-

Character Embedding(SG)	**0.4933**
Character Embedding(ELMo)	**0.3475**

Table 4: Comparison between the average Pearson correlation coefficient scores of the different models against average human relatedness scores.

Table 4 shows the Pearson correlation coefficients of the resulting similarity scores of each model against the average human annotation scores. These results suggest that having the context window over the utterance and adding the previous and next speakers to the input layer greatly improves the ability of the character embeddings to capture the relatedness between the different characters in a given story dialogue.

Table 3 shows an example of characters that are most related to "Alice Lomax" from the movie "The Devil's Advocate" as calculated based on each model sorted in descending order according to their cosine similarity scores. It is worth noting that Kevin Lomax is Alice's son, John Milton is Kevin's father and Mary Ann Lomax is Kevin's wife. On the other hand the characters suggested by both Word2Vec CBOW and SG models did not interact with Alice through the whole movie.

To further analyze the quality of the produced character embeddings, we evaluate the embeddings across different characters according to the their frequency of appearance in the movies. Figure 3 shows a comparison between the performance of the different models over minor and major characters based on the number of dialogue turns that each character uttered. These results show that our character embedding model consistently outperforms the traditional Word2Vec baseline models and reflect the robustness of our model in generating better character embeddings.

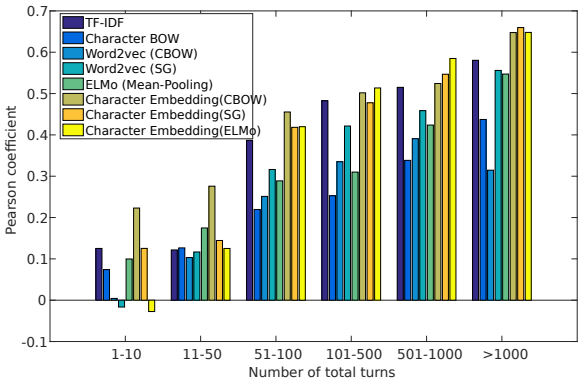

Figure 3: Comparison of the average Pearson correlation coefficient over characters who had different number of turns.

Character Relationship. We have three classification tasks for character relationships: 1) fine-grained relationship classification; 2) coarse-grained relationship classification; 3) relation sentiment classification. For each of these tasks, we train a logistic regression classifier using the Scikit-learn library (Pedregosa et al., 2011). These classifiers take a pair of character embeddings as a concatenation of their vectors and predict their

Table 6: Example of classification task on Shakespeare's play, using different baselines and our character representation methods. The classification output consists of the relations of character 2 from character 1's perspective. A bold face indicates a correct relation classification.

relationship. We use a leave-one-play-out cross-validation in which character pairs from each play are used as a test set and character pairs from the other plays are used to train the models. Table 5 shows the classification average precision, recall and weighted F-score obtained by training the logistic regression classifiers using the character embeddings produced by the different models. Training classifiers using our character embedding models consistently outperforms the classifiers trained using the other models, which reflects the quality of the semantic information captured by our character embeddings when compared to other models. Table 6 shows examples of the three character relation classification tasks as classified by our character embedding models and the baselines.

Question Answering. As a final evaluation, we test the impact of our character embedding on dialogue understanding. TVQA (Lei et al., 2018) is a challenging dataset that includes 152.5K multiple choice question answers about 21.8K video clips from 6 TV shows such as the *Big Bang Theory*, *House*, and so on. These questions were created in a way that requires understanding of both the dialogue and the visual content of a given video. Each video clip includes the video frames and subtitles with speaker names aligned automatically with their corresponding show scripts (around 69% of the subtitle segments include speakers names). We follow the same dataset splits for training, validation, and test.

	Accuracy	
	Q+S	Q+S+V
MS (Glove) (Lei et al., 2018)	0.6515	0.6770
MS (Glove w/o names)	0.6177	0.6467
MS (CharEmbedding(CBOW))	**0.6590**	**0.6852**
MS (CharEmbedding(SG))	**0.6554**	**0.6884**

Table 7: Comparison on the TVQA validation dataset using the MS method with Glove and Glove fine-tuned using our proposed character embedding method.

To evaluate our embedding, we use the baseline implementation proposed with the TVQA dataset, namely Multi-Stream (MS). This model relies on bidirectional attention between context (represented by subtitles and/or visual content) and question answer pairs as queries to predict the correct answer (Lei et al., 2018). Visual features are included as textual labels of detected visual concepts in the frames of the video clip. To measure the effect of the person names on the model, we apply a named entity recognizer and replace the names with a fixed randomly generated embedding. Table 7 shows the results from the MS method using Glove, Glove with removing names from subtitles, and using a fine-tuned Glove using our character embedding model. The use of our character embeddings bring improvements over the pre-trained Glove embeddings, which demonstrates the usefulness of these character representations.

6 Conclusion

In this paper, we presented a novel unsupervised embedding model to represent characters and their interaction in a dialogue. Our embedding model produces character representations that reflect the language used by the characters as well as information about their relations with other characters. To evaluate the performance of our character embeddings, we experimented with two tasks on two datasets: (1) character relatedness, using a dataset we introduced consisting of a dense character interaction matrix for 4,761 unique character pairs over 22 hours of dialogue extracted from 18 movies; and (2) character relation classification, for fine- and coarse-grained relations, as well as relation sentiment. Our experiments show that our model significantly outperforms the traditional Word2Vec continuous bag-of-words and skip-gram models, thus demonstrating the effectiveness of the character embeddings we introduced. We further showed how the character embeddings can be used in conjunction with a visual question answering system to improve over previous results.

The dataset annotated with character relatedness scores introduced in the paper is publicly available from http://lit.eecs.umich.edu/downloads.html.

Cross-lingual word embeddings and the structure of the human bilingual lexicon

Abstract

Research on the bilingual lexicon has uncovered fascinating interactions between the lexicons of the native language and of the second language in bilingual speakers. In particular, it has been found that the lexicon of the underlying native language affects the organisation of the second language. In the spirit of interpreting current distributed representations, this paper investigates two models of cross-lingual word embeddings, comparing them to the shared-translation effect and the cross-lingual coactivation effects of false and true friends (cognates) found in humans. We find that the similarity structure of the cross-lingual word embeddings space yields the same effects as the human bilingual lexicon.

1 Introduction

Research on the bilingual lexicon has uncovered fascinating interactions between the L1 (native language) and L2 (second language) lexicons showing that both production and comprehension coactivate lexical items in both languages, indicating that bilinguals store lexical representations from their native and their second language in the same space (Kroll and Dijkstra, 2012; Williams, 2014).[1]

This paper presents the first bilingual investigation of models of cross-lingual word embeddings and asks whether the bilingual spaces they define have similar properties to the human bilingual lexicon. Among the many questions and results in the vast bilingualism literature, we concentrate on coactivation effects in items with shared translations. We also study interference or facilitatory effects in form-meaning mapping, the case of *false friends*, words that share form but differ in meaning across the two languages, and *true friends*, words that share both form and meaning. We find that the similarity structure of cross-lingual word embeddings matches well with known experimental findings of the human bilingual lexicon.

2 The structure of the bilingual lexicon

The core findings about the bilingual lexicon confirm that the two languages occupy an integrated space and they interact with each other (Wolter, 2001). For example, both in the monolingual and bilingual lexicon the best predictor of the time to recognise a word is the number of similarly spelled words, within and across languages (Johnson and Pugh, 1994; van Heuven et al., 1998).[2] This implies that, functionally, the bilingual lexicon is an integrated system. Specifically, it has been proposed that languages do not simply share graphemes or phonemes, but that the lexicon, monolingual, bilingual or multi-lingual, is a space of distributed word representations where word forms from different languages map onto a common abstract conceptual code (Van Hell and de Groot, 1998). This general structural and functional assumption explains many findings. We concentrate here on two sets of coactivation effects.

[1] Throughout this paper, and following the current literature on the topic, we use the term 'bilingual' loosely, to refer to any speaker of more than one language. Although there has been much research on all aspects of bilingualism, and at all stages of proficiency, the effects we model here have been found in experiments testing speakers who began to learn their second language after their first, usually in a school context, and who are at an advanced level of proficiency. The form German-English below will indicate, for example, a native speaker of German who learnt English as a second language (Williams, 2014).

[2] Monolingual work has provided a finer-grained picture of this result, modulated by number of word senses and the semantic closeness of sense extensions, but the main result remains valid (Rodd et al., 2002).

2.1 The shared translation effect

Polysemous words that have many translations, such as English *bank* translated as *banca* (financial institution) or *riva* (river bank) in Italian, coactivate the correspondences for all the word senses, with various effects. One-to-many translations have been shown to slow down acquisition and processing for Italian-English bilinguals (Degani and Tokowicz, 2010), and to slow down response times of German-English speakers in anomaly detection tasks (Elston-Güttler and Williams, 2008).[3]

We are mainly interested in the result of Degani et al. (2011), as it concerns similarity spaces in shared translations. Degani et al. (2011) asked Hebrew-English bilinguals to rate the semantic relatedness of English word pairs that shared a translation in Hebrew (e.g., *tool* and *dish* both translated into Hebrew *kli*). Compared to both English pairs with different Hebrew translations, and to ratings by monolingual English speakers, bilinguals judged shared-translation pairs as more related in meaning (the shared-translation effect).[4]

2.2 Form-meaning mappings in translation

Competition (and facilitation) effects have been found both in comprehension and production depending on convergence and divergence of form-meaning mappings in translation. Recall that *false friends* are cross-linguistically similar in form but not in meaning, such as the English-Italian *estate*, which in Italian means *summer*, and *true friends* are words that share both (orthographic or phonological) form and meaning, such as English-French *glucose* or *danger*, in translation.

False friends effect In a cross-modal picture decision task, Weber and Cutler (2004) find that Dutch-English speakers are slower in matching an English word *(desk)* with the corresponding picture if the target picture's word form matches the Dutch form of one of the alternative pictures *(deskel = lid)*. It should be noted, however, that while the decision time was slower, the decision accuracy was not. Bilingual speakers do know which is the right word-picture match and perform accurately. Also, for English-Dutch false friends like *rust* (*rest* in Dutch) lexical decision times are slower than expected, if the list in which they are embedded also contains words from the other language (Dijkstra et al., 1998; Smits et al., 2006).

True friends effects In recognition, Dutch-English bilinguals performing a lexical decision task in English were found to be faster than expected for words like *type*, a near true friend with a slight difference in pronunciation (Dijkstra et al., 1999; Smits et al., 2006; Dijkstra et al., 2010). Similar cognate facilitation effects also occur in production tasks, such as picture-naming. If an advanced Catalan-Spanish bilingual is asked to name pictures in Spanish, they are faster to do so for true friends such as *gato* (*gat* in Catalan 'cat') than for non-cognates. The effect, although smaller, can also be obtained when pictures are to be named in the L1 (Costa et al., 2000). Similar effects have also been obtained for Japanese-English bilinguals, despite the difference in the scripts (Hoshino and Kroll, 2008).

3 Predictions

In this work, we ask if the structure of cross-lingual word embeddings spaces have the properties that would be expected given human bilingual behaviour. Assuming the distributed, integrated model of the lexicon proposed in the bilingualism literature, the underlying linking hypothesis is that coactivation effects (whether expressed as similarity judgments or measured as reaction times) are the expression of greater or smaller proximity in a multi-dimentional space. On this basis, several hypotheses are proposed. The first hypothesis aims to establish whether cross-lingual word embeddings are sensitive to a bilingual situation and generate an integrated cross-lingual space. Secondly, we test if cross-lingual word embeddings show the shared-translation effect. Finally we test the cross-linguistic competition/priming of lexical forms from the L1 to the L2 language, comparing cross-lingual to monolingual spaces in true friends and false friends scenarios.

We will often talk about a word and its *translation*. By this term, we mean the pair of words that a bilingual dictionary would indicate as equivalent lexical entries, a translations pair.

[3] German-English speakers, compared to monolingual English speakers, are slower in recognising, for example, that the word *bubble* is infelicitous in contexts where the word *blister* is required, due to the fact that these two words are translated as the same word *Blase* in German.

[4] Notice that this effect is robust as it was also replicated for English-Hebrew bilinguals, who learned Hebrew as an L2. Moreover, Degani et al. (2011) used as stimuli semantically unrelated word pairs, extending previously established results for sense-related words, such as *home-house* (Jiang, 2002).

3.1 The integrated bilingual lexicon

We test the idea that the bilingual lexicon is an integrated system by looking at effects of such a system in one-to-one mappings and one-to-many mappings.

The simplest and most basic prediction that a model of the integrated bilingual lexicon needs to be able to confirm is that words in the bilingual lexicon are "closer" to each other than word mappings across two aligned mono-lingual lexicons.

HYPOTHESIS 1 Given an L1 word w_1 and its translation w_2 in L2, the similarity between the word embeddings pair in a cross-lingual space (w_1^{cr}, w_2^{cr}) is higher than their similarity between their aligned monolingual counterparts $(w_1^{m_1}, w_2^{m_2})$.

$$sim(w_1^{cr_1}, w_2^{cr_2}) > sim(w_1^{m_1}, w_2^{m_2}) \quad (1)$$

The second prediction is based on the finding of shared translations, where a shared translation in L1 affects L2 similarity judgments.

HYPOTHESIS 2 Given an L1 word w_1 and its translations w_{2a} and w_{2b} in L2, the similarity between the cross-lingual embeddings of the translation pair will be greater than the similarity between their monolingual counterparts.

$$sim(w_{2a}^{cr_2}, w_{2b}^{cr_2}) > sim(w_{2a}^{m_2}, w_{2b}^{m_2}) \quad (2)$$

3.2 Form-meaning competitions in the biligual lexicon

The following experiments investigate the competition faced by words with a high level of lexical similarity. Simplifying, words across two languages can be similar in form or meaning, or both or neither. For the following predictions, then, we define five different types of word pairs. Examples are shown in Figure 3.

FALSE FRIENDS: words that share the same form, but are semantically different.

REAL TRANSLATIONS of the false friends: the real L2 translations of the L1 word that also has a false friend.

TRUE FRIENDS: words sharing form and meaning.

NORMAL TRANSLATIONS: words semantically equivalent, but with a different form.

UNCORRELATED WORDS: words lexically and semantically uncorrelated.

False and true friends coactivation In bilingual speakers, false friends show an inhibitory effect of the L1 meaning in L2 tasks, but they do not affect the final accuracy of the task completion. Consequently, in our cross-lingual vectorial space, false friends should not have higher similarity score than their real translations, but they should be included in the top translations, i.e. the difference in similarity score between the real translation and the false friends should be smaller than the difference between the real translations and other words (appropriately matched to the false friends). This in turn can be demonstrated by two expected inequalities: false friends are not closer than real translations but false friends are significantly more similar than (matching) uncorrelated words.

Precisely, given an L1 word w_1, and its real L2 translation w_2 and the false friend w_{2ff} in cross-lingual space, we expect the similarity score between the pair (w_1, w_2) not to be lower than the similarity score between the pair (w_1, w_{2ff}).

HYPOTHESIS 3 Real translations have a better or equal similarity score than their corresponding false friends.

$$sim(w_1, w_2) >= sim(w_1, w_{2ff}) \quad (3)$$

Moreover, false friends (w_1, w_{2ff}) have a similarity score that is higher than uncorrelated words (w_1, w_{2nc}). This is because the false friends pair (w_1, w_{2ff}) shares similarity of form even if it is, in fact, semantically uncorrelated.

HYPOTHESIS 4 False friends have a better similarity score than pairs with no correlation.

$$sim(w_1, w_{2ff}) > sim(w_1, w_{2nc}) \quad (4)$$

Lexical similarity can also work in the opposite direction. L1 words that are similar to the L2 word both in form and meaning, *true friends*, have been shown, in bilinguals speakers, to facilitate tasks in L2. In cross-lingual word embeddings, we expect that true friends (w_{1tf}, w_{2tf}) have a higher similarity score than normal translation pairs (w_{1n}, w_{2n}), whose interaction is not enhanced by lexical or morphological resemblances.

HYPOTHESIS 5 True friends have a better similarity score than normal translation pairs.

$$sim(w_{1tf}, w_{2tf}) > sim(w_{1n}, w_{2n}) \quad (5)$$

HYP. 1 Cross-lingual word embeddings pairs are more similar than their aligned monolingual counterparts	$sim(w_1^{cr_1}, w_2^{cr_2}) > sim(w_1^{m_1}, w_2^{m_2})$
HYP. 2 For two L2 words sharing a translation in L1, cross-lingual word embeddings are more similar than monolingual word embeddings	$sim(w_{2a}^{cr_2}, w_{2b}^{cr_2}) > sim(w_{2a}^{m_2}, w_{2b}^{m_2})$
HYP. 3 Real translations are more similar than their corresponding false friends	$sim(w_1, w_2) >= sim(w_1, w_{2ff})$
HYP. 4 False friends are more similar than uncorrelated pairs	$sim(w_1, w_{2ff}) > sim(w_1, w_{2nc})$
HYP. 5 True friends are more similar than normal translation pairs	$sim(w_{1tf}, w_{2tf}) > sim(w_{1n}, w_{2n})$
HYP. 6 Normal translation pairs are more similar than real translations of false friends	$sim(w_{1n}, w_{2n}) > sim(w_1, w_2)$

Figure 1: The six experimental predictions.

Another hypotheses can also be formulated that follows logically from these preceding ones. Consider the pair (w_1, w_2) where w_2, as seen before, is the real translation of w_1 in a pair that also has a false translation. In this case, it is important to remember that w_1 has a false friend w_{2ff}, so we know that accessing w_2 is more effortful since, for a bilingual speaker, w_{2ff} will also be activated. Consequently, we can assume that a normal pair of words (w_{1n}, w_{2n}), a pair of translated words that have no false friend, are closer in space than (w_1, w_2) precisely because (w_{1n}, w_{2n}) is not inhibited by a false translation as in the case of (w_1, w_2).

HYPOTHESIS 6 Normal translation pairs have a higher similarity score than real translations of false friends.

$$sim(w_{1n}, w_{2n}) > sim(w_1, w_2) \quad (6)$$

The predictions are summarised in Figure 1. If confirmed, they give us a fairly detailed view of the structure of the lexicon conceived as a multi-dimensional, integrated multilingual space. In particular, they inform us on the respective importance of formal and meaning properties of words in this cross-lingual similarity space.

4 Experiments 1 and 2

We test our hypotheses using two different cross-lingual word embeddings models. (The numbering of the experiments corresponds to the numbering of the hypotheses.)

One model is VECMAP, a word-level cross-lingual word embedding method, developed by Artetxe et al. (2018), which offers different options, ranging from fully supervised to weakly supervised or unsupervised, the state-of-the-art for bilingual lexicon induction. This method, unlike other models, does not use an existing dictionary for initialization. The values of the word vectors in both the source and the target distribution are sorted, vectors that have similar permutations are identified as possible translations and are used to initialize a dictionary that is then further improved by self-iterative training.

translation pairs	shared translation pairs

block-ceppo	blocco bloccare
block-bloccare	blocco ostacoalre
block-ostacolare	ceppo bloccare
	ceppo ostacolare

Figure 2: Sample of translation pairs and sample of shared translation pairs used in experiments 1 and 2.

We also test M2VEC, a weakly-supervised, concept-based adversarial model (Wang et al., 2019). This method is based on the idea that languages use similar words to express similar concepts (Søgaard et al., 2015). The adversarial training uses concepts, drawn from Wikipedia, rather than words, to learn competitive cross-lingual word embeddings. The alignments are learnt by a generative adversarial networks (GAN) adapted to the cross-lingual mapping objective.

4.1 Data

Word-embeddings data For training VECMAP, we use the English-Italian portion of the data used in Artetxe et al. (2018), which is based on the dataset described in Dinu et al. (2015). The English-Italian dataset provided by Dinu et al. (2015) contains 300-dimensional CBOW monolingual word embeddings for a total of 200K words trained on the WacKy crawling corpora.[5] The English word embeddings use 2.8 billion tokens (ukWAC + Wikipedia + BNC) and the Italian word embeddings use 1.6 billion tokens (itWAC). An English-Italian gold standard bilingual dictionary built from Europarl [6] word alignments is also provided with a training set of 5000 entries ordered by English frequency. For M2VEC, 300-dimensional monolingual word embeddings are trained with FastText. The training corpus is taken from a Wikipedia dump.[7] The word embeddings are augmented to include concept-aligned articles extracted from the Linguatools Wikipedia comparable corpus.[8] VECMAP uses word-level embeddings and M2VEC character-level embeddings.

Word lists For testing, we build lists of English words that have multiple translations in Italian. The lists of polysemous words were validated with the support of the Cambridge Bilingual Dictionary[9] and by two bilingual speakers. Some example pairs are shown in Figure 2. Word lists are available as supplementary materials.

	p		0.021	0.003

Table 1: Results of experiments 1 and 2.

4.2 Results

The results are shown in Table 1. Recall the two hypotheses, hypothesis 1 and hypothesis 2 summarised in Figure 1.

The results confirm both hypotheses for both cross-lingual models and are statistically significant under a one-tailed pairwise t-test with $\alpha = 0.25$. Cross-lingual word embeddings have a higher mean similarity score than aligned monolingual word embeddings. Also, cross-lingual word embeddings, like humans, show a shared-translation effect. Both cross-lingual models show higher mean similarity scores for L2-words that share a common L1 source than the monolingual model.

5 Experiments 3, 4, 5 and 6

The next four experiments test whether the hypotheses concerning true and false friends in word embeddings are confirmed. The numbering of the experiments corresponds to the numbering of the hypotheses.

5.1 Data

Word embedding data In this set of experiments, we use the same data from the previous two experiments (the dataset described in Dinu

et al. (2015)) with the addition of the FastText pre-trained word embeddings for English and Italian (Bojanowski et al., 2017).[10] These publicly available vectors are obtained by a 5-word window, for 300 resulting dimensions, on CommonCrawl and Wikipedia data using the Skip-gram model. Every word is represented as an n-grams of characters, for n training between 3 and 6. Each n-gram is represented by a vector and the sum of these vectors forms the vector representing the given word. So we have three cross-lingual models: two versions of VECMAP, one trained on CBOW (word-level) and the other on FastText (character-level), and the concept-based adversarial model M2VEC, which also uses character-based FastText representations. The inclusion of FastText embeddings is important for these experiments, as the embeddings need to be sensitive to character-level sequences to detect similarity of form in false and true friends. VECMAP was used to obtain the cross-lingual word embeddings. Having two versions of VECMAP, one that use Skip-gram and one that uses CBOW is based on their different performance on rare words. The CBOW model predicts a word from its context and is better in accuracy for frequent words, but encounters problems with rare words, while the Skip-gram model predicts the context from a target word, and so has good representation of rare words or phrases (Mikolov et al., 2013a,c). In the figures they will be indicated, respectively, as Vecmap, FastText and Concepts.

Word lists The data required for the following experiments comprise five lists of word pairs, defined in section 3.2: false friends, real translations, true friends, normal translations and uncorrelated words. Examples are shown in Figure 3 and the complete lists are available in the appendix, with their similarity scores.

These word lists have been constructed from various online resources, adding also words that were found serendipitously by the authors in different texts.[11] The normal translations and uncorrelated word pairs were built by one of the authors.

[10] https://github.com/facebookresearch/fastText

[11] The false friends list was built starting from http://www.lifemilan.it/en/false-friends-a-must-learn-list/ and https://www.reference.tjtaylor.net/false-friends/. The true friends list was started from https://takelessons.com/blog/italian-grammar-cognates-z09.

	Judge 1					
Judge 2	FF	TF	RT	NT	UN	Total
FF	93	1	0	0	0	94
TF	3	127	0	0	0	130
RT	0	2	130	8	1	141
NT	1	3	7	133	0	144
UN	0	0	0	0	97	97
Total	97	133	137	141	98	606

Table 2: Inter-judge partition of the five lists of words, rounded to closest integer. TF = true friends; FF = false friends; RT = real translations; NT = normal translations; UN = uncorrelated.

Normal translations were selected by the bilingual dictionary excluding those that had true or false friends. The uncorrelated words were selected ensuring that they were entirely uncorrelated. They were validated with the help of the Cambridge Bilingual dictionary,[12] where each translation of each pair of words was checked to ensure correctness and complete disjunction in meaning. The online English-Italian dictionary was not comprehensive: not all the meanings were reported, unlike the English-Spanish or English-French dictionaries. Therefore, sometimes a false friend was not reported by the English-Italian dictionary, but was found with the help of the other bilingual dictionaries.

Once the lists were constructed, we run an inter-judge agreement validation. The words were shuffled and the two authors, who master both languages well, classified them in the five types discussed above. Cohen's Kappa was 94.6, showing very high agreement. Fractional numbers were distributed in the few cases of multiple classification by one or both judges. The main source of disagreement were those words that are, at the same time, false friends and true friends depending on the context. The inter-judge agreemeent table is shown in Table 2.

As can be seen in Figure 3, the real translations list (151 pairs of words) is larger than the false friends list (97 pairs of words) due to the different meanings that an L1 word can have in L2.

As for the uncorrelated list, the same L1 words from the false friends list have been used for a direct comparison between the false friends similarity and the uncorrelated words similarity. Since

[12] https://dictionary.cambridge.org/dictionary/english-italian/

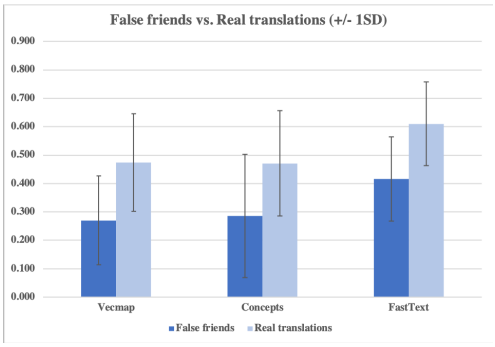

Figure 4: Experiment 3: false friends compared to real translations.

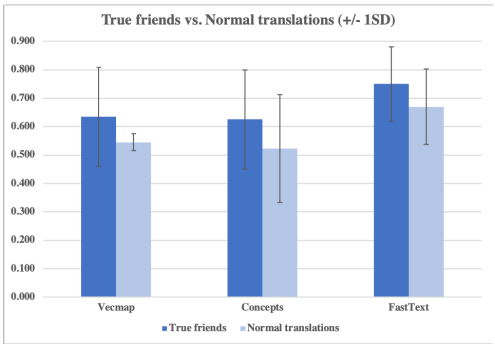

Figure 6: Experiment 5: true friends compared to normal translations.

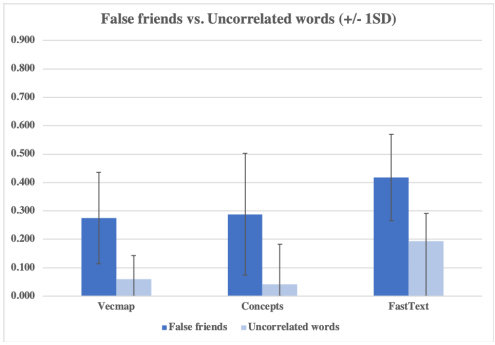

Figure 5: Experiment 4: false friends compared to pairs without correlation.

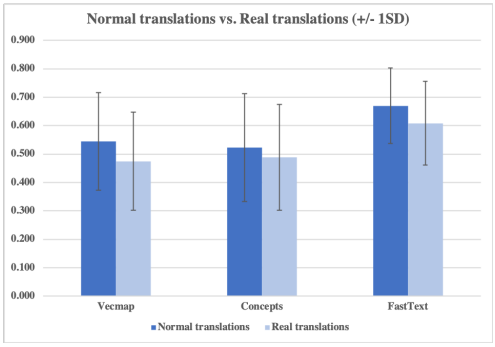

Figure 7: Experiment 6: Normal translations compared to real translations of false friends.

the real translations list contains the largest number of pairs, for the comparison between real translations and normal translations, the real translations have been sampled to have equal size.

5.2 Results

As shown in the Figures 4 to 7, overall the three methods are consistent as they show the same pattern of results. In terms of cosine similarity, the Vecmap+FastText word embeddings tend to have higher means than the other methods.

HYPOTHESIS 3 The first hypothesis concerning false friends —real translations have a better similarity score than their corresponding false friends— is confirmed. Figure 4 shows a cosine similarity that is 0.2 points higher for real translations pairs ($p < 0.0001$ in all three cases for a paired one-tailed t-test).

HYPOTHESIS 4 Based on the scores shown in Figure 5, the second hypothesis concerning false friends is also confirmed. False friends are significantly more similar in the cross-lingual space than uncorrelated words, as the similarity scores for false friends, in all three systems, are higher by more than 0.2 points ($p < 0.0001$ in all three cases).

HYPOTHESIS 5 The hypothesis that true friends have a better similarity score than normal translation pairs is also confirmed. Figure 6 shows that the mean true friends similarity is higher than the mean similarity of the normal translations ($p < 0.001$ in all three cases).

HYPOTHESIS 6 The hypothesis that normal pairs of words have a higher similarity score than real translations of false friends is confirmed, see Figure 7. The mean similarity score for real translations is lower than the mean score for normal translations. This difference is statistically significant for Vecmap and FastText ($p < 0.01$). For the concept-based system, on the other hand, we do not have enough evidence to reject the null hypothesis as $p > 0.025$ and T(296)<t-value. Thus, in this case, we must conclude that the normal translations are as similar as the real translations.

BONFERRONI CORRECTION As Hypotheses 3 and 4, hypotheses 3 and 6 and hypotheses 5 and 6 use the same data (respectively false friends, real translations and normal translations), we run

the Bonferroni correction not to incur in α inflation. All hypotheses are further confirmed, except for hypothesis 6 where the concept-based system again shows a non-significant result (Bonferroni correction higher than α (0.106>0.025)).

6 Discussion

Cross-lingual word embeddings show a lexical structure matching the bilingual lexicon for the three properties that we tested.

They are an integrated multi-lingual space and exhibit the shared-translation effect. This suggests that the initial monolingual embeddings, in our case the Italian ones, are affected by the cross-lingual mapping as word vectors are changed to accommodate cross-lingual interactions. Intuitively, this is similar to the behavior of bilinguals when they gradually learn a new language and semantic links are created by associating the new words to an existing one in their native language.

Cross-lingual word embeddings did not show interference effects of false friends. They are not as affected by the lexical or morphological level when there is a semantic correlation between words. However, false friends show more similarity than uncorrelated words, showing that, like for humans, they have a different status from orthographically and semantically uncorrelated words. True friends in cross-lingual space behave like the lexicon of bilinguals, when the semantic, lexical and morphological level are aligned.

The last hypothesis shows varying results, as only two systems accept the bilingual hypothesis: Vecmap and FastText have a higher similarity score for normal translations, confirming the assumption that real translations are inhibited by false friends. Notice that this result argues again that cross-lingual word embeddings are indirectly affected by false friends, as there is no other difference between real translations and normal translations. Interestingly, on the other hand, the concept-based system is not sensitive to the indirect effect of false friends in the cross-lingual space. This is not unexpected as the concept-based model is less affected by surface form. The difference between word-based models and the concept-based model could yield an hypothesis to be tested for the human lexicon with precise underlying formal models.

Because our predictions are confirmed, they also confirm that the similarity structure defined by current cross-lingual word embedding models is promising as a view of the structure of the lexicon conceived as a multi-dimensional, integrated multilingual space. In particular, our results inform us on the respective importance of formal and meaning properties of words in this cross-lingual similarity space. Notice that the pairwise results described so far define, by transitivity, a total order of similarity: true friends > normal translations > real translations > false friends > uncorrelated pairs. True friends match both in form and meaning, normal and real translations match only in meaning, and false friends match only in form. Thus, this order clearly indicates that while both form and meaning matter, similarity based on meaning is more important that similarity based on form.

7 Related work

The related work for the investigation reported here comprises work on the human bilingual lexicon, cross-lingual word embeddings models and computational models of the bilingual lexicon. As the relevant work on the first topic has already been discussed, we concentrate here on the latter two.

Vectors of words that are semantically or syntactically similar have been shown to be close to each other in the same space (Mikolov et al., 2013a,c; Pennington et al., 2014), making them widely useful in many natural language processing tasks such as machine translation and parsing (Bansal et al., 2014; Mi et al., 2016), both in a single language and across different languages.

Mikolov et al. (2013b) first observed that the geometric positions of similar words in different languages were related by a linear relation. Zou et al. (2013) showed that a cross-lingually shared word embedding space is more useful than a monolingual space in an end-to-end machine translation task. However, traditional methods for mapping two monolingual word embeddings require high quality aligned sentences or dictionaries (Faruqui and Dyer, 2014; Ammar et al., 2016).

Reducing the need for parallel data, then, has become the main issue for cross-lingual word embedding mapping. Methods that rely on sentence-alignments and also document-alignments have been proposed. Hermann and Blunsom (2014) present a method that, given enough data, train bilingual word embeddings from a sentence-

aligned corpus. Luong et al. (2015) propose a model, BiSkip, that takes as input a parallel corpus with both sentence and word-level alignment. Unlike other methods, BiSkip tries to learn not only target word representations from source words but also source word representations from target words. Vulic and Moens (2016) induces bilingual word embeddings from document-aligned comparable data that have been merged and shuffled producing a pseudo-bilingual document.

Some recent work aiming at reducing resources has shown competitive cross-lingual mappings across similar languages, using a pseudo-dictionary, such as identical character strings between two languages (Smith et al., 2017), or a simple list of numerals, thanks to a self-learning iterative framework (Artetxe et al., 2017). Furthermore, as indicated in section 4, Artetxe et al. (2018) extend their self-learning framework to unsupervised models, and build the state-of-the-art for bilingual lexicon induction. Another weakly-supervised model is proposed by Wang et al. (2019), a weakly-supervised concept-based adversarial method, used in our experiments, as also indicated in section 4.

Several computational models of human bilingualism exist, see Li (2013) for an overview. More relatedly to the current work that uses distributional approaches, aspects of the bilingual lexicon have been proposed for word associations (Matusevych et al., 2018). These associations are different in bilingual and monolingual speakers. For example, cognates, collocations and phonological responses are produced more frequently by non-native speakers. This work proposes a model of word association in bilinguals, implemented as a semantic network paired with a retrieval mechanism. Computational models of the influence of the native language on second language learning have also been investigated in Matusevych (2016), specifically for argument structure.

8 Conclusion

In the spirit of better understanding distributed representations and how well they match what we know about the structure and processing of language in humans (Linzen et al., 2016), this paper investigates two models of cross-lingual word embeddings comparing them to the shared translation effect and cross-lingual coactivation effects involving true and false friends found in humans. We find that predictions about cross-lingual word embeddings are mostly confirmed, making them promising functional models of at least some aspects of the bilingual lexicon, despite their structural simplicity.

9 Acknowledgments

We thank Haozhou Wang for giving us access to his model M2VEC and to the embeddings it produces, and to Suzanne Stevenson and Yevgen Matusevych for pointing us to relevant work.

Abstract

We propose algorithms to train production-quality n-gram language models using federated learning. Federated learning is a distributed computation platform that can be used to train global models for portable devices such as smart phones. Federated learning is especially relevant for applications handling privacy-sensitive data, such as virtual keyboards, because training is performed without the users' data ever leaving their devices. While the principles of federated learning are fairly generic, its methodology assumes that the underlying models are neural networks. However, virtual keyboards are typically powered by n-gram language models for latency reasons.

We propose to train a recurrent neural network language model using the decentralized `FederatedAveraging` algorithm and to approximate this federated model server-side with an n-gram model that can be deployed to devices for fast inference. Our technical contributions include ways of handling large vocabularies, algorithms to correct capitalization errors in user data, and efficient finite state transducer algorithms to convert word language models to word-piece language models and vice versa. The n-gram language models trained with federated learning are compared to n-grams trained with traditional server-based algorithms using A/B tests on tens of millions of users of a virtual keyboard. Results are presented for two languages, American English and Brazilian Portuguese. This work demonstrates that high-quality n-gram language models can be trained directly on client mobile devices without sensitive training data ever leaving the devices.

Figure 1: Glide trails are shown for two spatially-similar words: "Vampire" (in red) and "Value" (in orange). Viable decoding candidates are proposed based on context and language model scores.

1 Introduction

1.1 Virtual keyboard applications

Virtual keyboards for mobile devices provide a host of functionalities from decoding noisy spatial signals from tap and glide typing inputs to providing auto-corrections, word completions, and next-word predictions. These features must fit within tight RAM and CPU budgets, and operate under strict latency constraints. A key press should result in visible feedback within about 20 milliseconds (Ouyang et al., 2017; Alsharif et al., 2015). Weighted finite-state transducers have been used successfully to decode keyboard spatial signals using a combination of spatial and language models (Ouyang et al., 2017; Hellsten et al., 2017). Figure 1 shows the glide trails of two spatially-similar words. Because of the similarity of the two trails, the decoder must rely on the language model to discriminate between viable candidates. For memory and latency reasons, especially on low-end devices, the language models are typically based on n-grams and do not exceed ten megabytes. A language model (LM) is a probabilistic model on words. Given previous words $x_1, x_2, \ldots, x_{m-1}$, an LM assigns a probability to the new words, i.e. $p(x_m|x_{m-1}, \ldots, x_1)$. An n-gram LM is a Markovian distribution of order

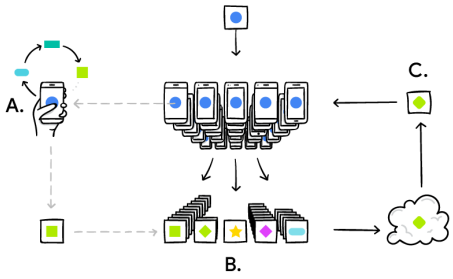

Figure 2: An illustration of the federated learning process from McMahan and Ramage (2017): (A) client devices compute SGD updates on locally-stored data, (B) a server aggregates the client updates to build a new global model, (C) the new model is sent back to clients, and the process is repeated.

$n-1$, defined by

$$p(x_m|x_{m-1},\ldots,x_1) = p(x_m|x_{m-1},\ldots,x_{m-n+1}),$$

where n is the order of the n-gram. For computation and memory efficiency, keyboard LMs typically have higher-order n-grams over a subset of the vocabulary, e.g. the most frequent 64K words, and the rest of the vocabulary only has unigrams. We consider n-gram LMs that do not exceed 1.5M n-grams and include fewer than 200K unigrams.

N-gram models are traditionally trained by applying a smoothing method to n-gram counts from a training corpus (Chen and Goodman, 1999). The highest quality n-gram models are trained over data that are well-matched to the desired output (Moore and Lewis, 2010). For virtual keyboards, training over users' typed text would lead to the best results. Of course, such data are very personal and need to be handled with care.

1.2 Federated learning

We propose to leverage *Federated Learning* (FL) (Konečnỳ et al., 2016; Konečný et al., 2016), a technique where machine learning models are trained in a decentralized manner on end-users' devices, so that raw data never leaves these devices. Only targeted and ephemeral parameter updates are aggregated on a centralized server. Figure 2 provides an illustration of the process. Federated learning for keyboard input was previously explored in Hard et al. (2018), in which a federated recurrent neural network (RNN) was trained for next-word prediction. However, latency constraints prevent the direct use of an RNN for decoding. To overcome this problem, we propose to derive an n-gram LM from a federated RNN LM model and use that n-gram LM for decoding. Specifically, the approximation algorithm is based on `SampleApprox`, which was recently proposed in Suresh et al. (2019a,b). The proposed approach has several advantages:

Improved model quality: Since the RNN LM is trained directly on domain-matched user data, its predictions are more likely to match actual user behavior. In addition, as shown in Suresh et al. (2019a), an n-gram LM approximated from such an RNN LM is of higher quality than an n-gram LM trained on user data directly.

Minimum information transmission: In FL, only the minimal information necessary for model training (the model parameter deltas) is transmitted to centralized servers. The model updates contain much less information than the complete training data.

Additional privacy-preserving techniques: FL can be further combined with privacy-preserving techniques such as secure multi-party computation (Bonawitz et al., 2017) and differential privacy (McMahan et al., 2018; Agarwal et al., 2018; Abadi et al., 2016). By the post-processing theorem, if we train a single differentially private recurrent model and use it to approximate n-gram models, all the distilled models will also be differentially private with the same parameters (Dwork et al., 2014).

For the above reasons, we have not proposed to learn n-gram models directly using `FederatedAveraging` of n-gram counts for all orders.

2 Outline

The paper is organized along the lines of challenges associated with converting RNN LMs to n-gram LMs for virtual keyboards: the feasibility of training neural models with a large vocabulary, inconsistent capitalization in the training data, and data sparsity in morphologically rich languages. We elaborate on each of these challenges below.

Large vocabulary: Keyboard n-gram models are typically based on a carefully hand-curated vocabulary to eliminate misspellings, erroneous capitalizations, and other artifacts. The vocabulary size often numbers in the hundreds of thousands. However, training a neural model directly over the vocabulary is memory intensive as the embedding and softmax layers require space $|\mathcal{V}| \times N_e$, where

$|\mathcal{V}|$ is the vocabulary size and N_e is the embedding dimension. We propose a way to handle large vocabularies for federated models in Section 3.

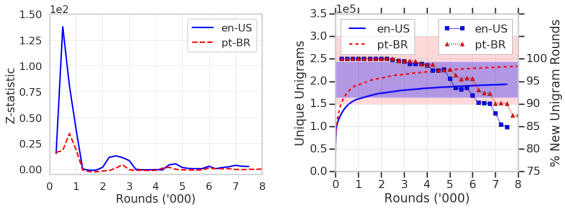
Incorrect capitalization: In virtual keyboards, users often type with incorrect casing (e.g. "She lives in new york" instead of "She lives in New York"). It would be desirable to decode with the correct capitalization even though the user-typed data may be incorrect. Before the discussion of capitalization, the `SampleApprox` algorithm is reviewed in Section 4. We then modify `SampleApprox` to infer capitalization in Section 5.

Language morphology: Many words are composed of root words and various morpheme components, e.g. "crazy", "crazily", and "craziness". These linguistic features are prominent in morphologically rich languages such as Russian. The presence of a large number of morphological variants increases the vocabulary size and data sparsity ultimately making it more difficult to train neural models. Algorithms to convert between word and word-piece models are discussed in Section 6.

Finally, we compare the performance of word and word-piece models and present the results of A/B experiments on real users of a virtual keyboard in Section 7.

3 Unigram distributions

Among the 200K words in the vocabulary, our virtual keyboard models only use the top 64K words in the higher-order n-grams. We train the neural models only on these most frequent words and train a separate unigram model over the entire vocabulary. We interpolate the two resulting models to obtain the final model for decoding.



3.1 Collection

Unigrams are collected via a modified version of the `FederatedAveraging` algorithm. No models are sent to client devices. Instead of returning gradients to the server, counting statistics are compiled on each device and returned. In our experiments, we aggregate over groups of approximately 500 devices per training round. We count a unigram distribution U from a whitelist vocabulary by $U = \sum_i w_i C_i$, where i is the index over devices, C_i are the raw unigram counts collected from a single device i, and w_i is a weight applied to device i.

To prevent users with large amounts of data from dominating the unigram distribution, we apply a form of L1-clipping:

$$w_i = \frac{\lambda}{\max(\lambda, \sum C_i)}, \tag{1}$$

where λ is a threshold that caps each device's contribution. When $\lambda = 1$, L1-clipping is equivalent to equal weighting. The limit $\lambda \to \infty$ is equivalent to collecting the true counts, since $w_i \to 1$.

(a) (b)

Figure 3: Unigram distribution convergence. Note that by 3000 rounds, the unigram distribution is stable, but the model is still learning new tail unigrams.

3.2 Convergence

Convergence of the unigram distribution is measured using the unbiased chi-squared statistic (for simplicity, referred to as the Z-statistic) defined in Bhattacharya and Valiant (2015), the number of unique unigrams seen, and a moving average of the number of rounds needed to observe new unigrams.

Figure 3(a) shows the overall distributional convergence based on the Z-statistic. At round k, unigram counts after $k/2$ and k rounds are compared. Figure 3(b) plots the number of whitelist vocabulary words seen and a moving average of the number of rounds containing new unigrams. New unigrams are determined by comparing a round k with all rounds through $k-1$ and noting if any new words are seen. The shaded bands range from the LM's unigram capacity to the size of the whitelist vocabulary.

3.3 Experiments

Since the whitelist vocabulary is uncased, capitalization normalization is applied based on an approach similar to Section 5. We then replace the unigram part of an n-gram model with this distribution to produce the final LM.

In A/B experiments, unigram models with different L1-clipping thresholds are compared against a baseline unigram model gathered from

Model	acc@1 [%]	OOV rate [%]
baseline	8.14	18.08
$\lambda = 1$	$+0.19 \pm 0.21$	-1.33 ± 0.75
$\lambda = 1K$	$+0.11 \pm 0.24$	-1.06 ± 0.66
$\lambda = 5K$	-0.08 ± 0.26	-0.78 ± 0.93

Table 1: Relative change with L1-clipped unigrams on live traffic of en_US users on the virtual keyboard. Quoted 95% confidence intervals are derived using the jackknife method with user buckets.

centralized log data. Results are presented in Table 1. Accuracy is unchanged and OOV rate is improved at $\lambda = 1$ and $\lambda = 1K$.

Before we discuss methods to address inconsistent capitalization and data sparsity in morphologically rich languages, we review `SampleApprox`.

4 Review of `SampleApprox`

`SampleApprox`, proposed in Suresh et al. (2019a,b), can be used to approximate a RNN as a weighted finite automaton such as an n-gram model. A *weighted finite automaton* (WFA) $A = (\Sigma, Q, E, i, F)$ over $\mathbb{R}_+$ (probabilities) is given by a finite alphabet Σ (vocabulary words), a finite set of states Q (n-gram contexts), an initial state $i \in Q$ (sentence start state), a set of final states $F \in Q$ (sentence end states), and a set of labeled transitions E and associated weights that represent the conditional probability of labels (from Σ) given the state (list of n-grams and their probabilities). WFA models allow a special *backoff* label φ for succinct representation as follows. Let $L[q]$ be the set of labels on transitions from state q. For $x \in L[q]$, let $w_q[x]$, be the weight of the transition of x at state q and $d_q[x]$ be the destination state. For a label x and a state q,

$$\begin{aligned} p(x|q) &= w_q[x] && \text{if } x \in L[q], \\ &= w_q[\varphi] \cdot p(x|d_q[\varphi]) && \text{otherwise.} \end{aligned}$$

In other words, φ is followed if $x \notin L[q]$. The definition above is consistent with that of backoff n-gram models (Chen and Goodman, 1999). Let $B(q)$ denote the set of states from which q can be reached by a path of backoff labels and let $q[x]$ be the first state at which label x can be read by following a backoff path from q.

Given an unweighted finite automaton A and a neural model, `SampleApprox` finds the probability model on A that minimizes the Kullback-Leibler (KL) divergence between the neural model and the WFA. The algorithm has two steps: a counting step and a KL minimization step. For the counting step, let $\bar{x}(1), \bar{x}(2), \ldots, \bar{x}(k)$ be k independent samples from the neural model. For a sequence $\bar{x}$, let x_i denote the i^{th} label and $\bar{x}^i = x_1, x_2, \ldots, x_i$ denote the first i labels. For every $q \in Q$ and $x \in \Sigma$, the algorithm computes $C(x, q)$ given by

$$\sum_{q' \in B(q)} \sum_{j=1}^{m} \sum_{i \geq 0} 1_{q(\bar{x}^i(j))=q', q=q'[x]} \cdot p_{\text{nn}}(x|\bar{x}^i(j)).$$

We illustrate this counting with an example. Suppose we are interested in the count of the bi-gram New York. Given a bi-gram LM, `SampleApprox` generates m sentences and computes

$$C(\text{York}, \text{New}) = \sum_{j, i: x_i(j)=\text{New}} p_{\text{nn}}(\text{York}|\bar{x}^i(j)).$$

In other words, it finds all sentences that have the word New, observes how frequently York appears subsequently, and computes the conditional probability. After counting, it uses a difference of convex (DC) programming based algorithm to find the KL minimum solution. If ℓ is the average number of words per sentence, the computational complexity of counting is $\tilde{\mathcal{O}}(k \cdot \ell \cdot |\Sigma|)$ [1] and the computational complexity of the KL minimization is $\tilde{\mathcal{O}}(|E| + |Q|)$ per iteration of DC programming.

5 Capitalization

As mentioned in Section 2, users often type with incorrect capitalization. One way of handling incorrect capitalization is to store an on-device capitalization normalizer (Beaufays and Strope, 2013) to correctly capitalize sentences before using them to train the neural model. However, capitalization normalizers have large memory footprints and are not suitable for on-device applications. To overcome this, the neural model is first trained on uncased user data. `SampleApprox` is then modified to approximate cased n-gram models from uncased neural models.

As before, let $\bar{x}(1), \bar{x}(2), \ldots, \bar{x}(k)$ be k independent (uncased) samples from the neural model. We capitalize them correctly at the server using Beaufays and Strope (2013). Let

[1] $a_n = \tilde{\mathcal{O}}(b_n)$, means $a_n \leq b_n \cdot \text{poly}\log(n), \forall n \geq n_0$.

$\bar{y}(1), \bar{y}(2), \ldots \bar{y}(k)$ represent the corresponding k correctly capitalized samples. Let p_{cap} be another probability model on non-user data that approximates the ratio of uncased to cased probabilities given a context. Given a label y, let $u(y)$ be the uncased symbol. For example, if y is York, then $u(y)$ is york. With the above definitions, we modify the counting step of `SampleApprox` as follows:

$$\sum_{q' \in B(q)} \sum_{j=1}^{m} \sum_{i \geq 0} 1_{q(\bar{y}^i(j))=q', q=q'[y]} \cdot \tilde{p}(y|\bar{y}^i(j)),$$

where $\tilde{p}(y|\bar{y}^i(j))$ is given by

$$p_{\text{nn}}(u(y)|u(\bar{y}^i(j))) \cdot \frac{p_{\text{cap}}(y|\bar{y}^i(j))}{\sum_{y':u(y')=u(y)} p_{\text{cap}}(y'|\bar{y}^i(j))}.$$

We refer to this modified algorithm as `CapSampleApprox`. We note that word-piece to word approximation incurs an additional computation cost of $\tilde{\mathcal{O}}((|E|+|Q|+|\Delta|)\ell)$, where Δ is the number of words, E and Q are the set of arcs and set of states in the word n-gram model, and ℓ is the maximum number of word-pieces per word.

6 Morphologically rich languages

To train neural models on morphologically rich languages, subword segments such as byte-pair encodings or word-pieces (Shibata et al., 1999; Schuster and Nakajima, 2012; Kudo, 2018) are typically used. This approach assigns conditional probabilities to subword segments, conditioned on prior subword segments. It has proved successful in the context of speech recognition (Chiu et al., 2018) and machine translation (Wu et al., 2016). Following these successes, we propose to train RNN LMs with word-pieces for morphologically rich languages.

We apply the word-piece approach of Kudo (2018), which computes a word-piece unigram LM using a word-piece inventory $\mathcal{V}_{\mathcal{P}}$. Each word-piece $x_i \in \mathcal{V}_{\mathcal{P}}$ is associated with a unigram probability $p(x_i)$. For a given word y and its possible segmentation candidates, the word is encoded with the segmentation that assigns the highest probability.

Throughout this paper we apply 4K, 16K, and 30K as the word-piece inventory sizes. These values lie within a range that provides good trade-off between the LSTM embedding size and the richness of the language morphology. We apply 100% character coverage to include all the symbols that appeared in the unigram distribution (Section 3), including the common English letters, accented letters e.g. é, ô, and digits. Accented letters are important for languages like Portuguese. For fast decoding, the n-gram models still need to be at the word-level, since word-piece n-gram models increase the depth of the beam-search during decoding. We convert the word n-gram topology to an equivalent word-piece WFA topology and use `SampleApprox` to approximate the neural word-piece model on the word-piece WFA topology. We then convert the resulting word-piece WFA LM to the equivalent n-gram LM. The remainder of this section outlines efficient algorithms for converting between word and word-piece WFA models.

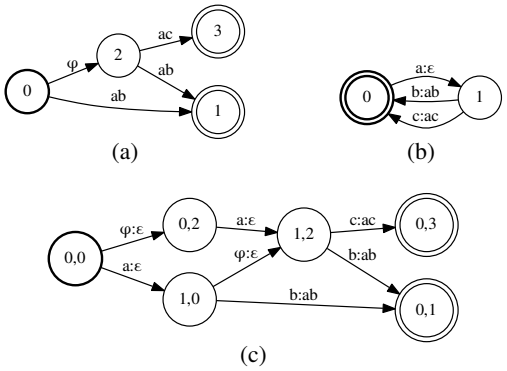


Figure 4: The (a) WFA A and WFSTs (b) T and (c) B for the word vocabulary $\{ab, ac\}$ and word-piece vocabulary $\{a, b, c\}$. Initial states are represented by bold circles and final states by double circles.

A natural way to represent the transduction from word-piece sequences to word sequences is with a finite-state transducer. Given the properties of our word-piece representation, that transducer can be made sequential (i.e., input deterministic).

A *sequential weighted finite-state transducer* (WFST) is a deterministic WFA where each transition has an output label in addition to its (input) label and weight. We will denote by $o_q[x]$ the output label of the transition at state q with input label x, $o_q[x] \in \Delta \cup \{\epsilon\}$, where Δ denotes the output alphabet of the transducer and ϵ the empty string/sequence.

Let M be the minimal sequential (unweighted) finite-state transducer (FST) lexicon from word-piece sequences in Σ^* to word sequences in Δ^*, where Σ denotes our word-piece inventory, Δ denotes our vocabulary, and $*$ is Kleene closure. A word-piece topology B equivalent to the word

[a] T denotes an unweighted topology and A denotes the weighted n-gram model. Superscript u represents uncased models.

topology A can be obtained by composing the word-piece-to-word transducer M with A:

$$B = M \circ A.$$

Since A has backoff transitions, the generic composition algorithm of (Allauzen et al., 2011) is used with a custom composition filter that ensures the result, B, is deterministic with a well-formed backoff structure, and hence is suitable for the counting step of `SampleApprox`. We give an explicit description of the construction of B, from which readers familiar with Allauzen et al. (2011) can infer the form of the custom composition filter.

The states in B are pairs (q_1, q_2), with $q_1 \in Q_M$ and q_2 in Q_A, initial state $i_B = (i_M, i_A)$, and final state $f_B = (f_M, f_A)$. Given a state $(q_1, q_2) \in Q_B$, the outgoing transitions and their destination states are defined as follows. If $x \in L[q_1]$, then an x-labeled transition is created if one of two conditions holds:

1. if $o_{q_1}[x] \in L[q_2]$, then

$$d_{(q_1,q_2)}[x] = (d_{q_1}[x], d_{q_2}[o_{q_1}[x]]) \text{ and}$$
$$o_{(q_1,q_2)}[x] = o_{q_1}[x];$$

2. if $o_{q_1}[x] = \epsilon$ and $R[d_{q_1}[x]] \cap L[q_2] \neq \emptyset$, then

$$d_{(q_1,q_2)}[x] = (d_{q_1}[x], d_{q_2}[o_{q_1}[x]]) \text{ and}$$
$$o_{(q_1,q_2)}[x] = \epsilon$$

where $R[q]$ denotes the set of output non-ϵ labels that can be emitted after following an output-ϵ path from q. Finally if $\varphi \in L[q_1]$, a backoff transition is created:

$$d_{(q_1,q_2)}[\varphi] = (q_1, d_{q_2}[\varphi]) \text{ and } o_{q_1,q_2}[\varphi] = \epsilon.$$

The counting step of `SampleApprox` is applied to B, and transfers the computed counts from B to A by relying on the following key property of M. For every word y in Δ, there exists a unique state $q_y \in Q_M$ and unique word-piece x_y in Σ such that $o_{q_y}[x_y] = y$. This allows us to transfer the counts from B to A as follows:

$$w_q[y] = w_{(q_y,q)}[x_y]$$

The KL minimization step of `SampleApprox` to A is applied subsequently.

As an alternative, the unweighted word automaton A could be used to perform the counting step directly. Each sample $\bar{x}(j)$ could be mapped to a corresponding word sequence $\bar{y}(j)$, mapping out-of-vocabulary word-piece sequences to an unknown token. However, the counting steps would have become much more computationally expensive, since $p_{\text{nn}}(y|\bar{y}^i(j))$ would have to be evaluated for all i, j and for all words y in the vocabulary, where p_{nn} is now a word-piece RNN.

7 Experiments

7.1 Neural language model

LSTM models (Hochreiter and Schmidhuber, 1997) have been successfully used in a variety of sequence processing tasks. LSTM models usually have a large number of parameters and are not suitable for on-device learning. In this work, we use various techniques to reduce the memory footprint and to improve model performance.

We use a variant of LSTM with a Coupled Input and Forget Gate (CIFG) (Greff et al., 2017) for the federated neural language model. CIFG couples

Model	N_l	N_h	N_e	S_e	S_{total}
W_{30K}	1	670	96	2.91M	3.40M
$P_{4K\text{-}S}$	1	670	96	0.38M	0.85M
$P_{4K\text{-}L}$	2	1080	140	0.56M	2.70M
$P_{4K\text{-}G}$	2	1080	280	1.12M	2.71M
$P_{16K\text{-}S}$	1	670	96	1.54M	2.00M
$P_{16K\text{-}L}$	1	670	160	2.56M	3.33M
P_{30K}	1	670	96	2.91M	3.40M

Table 2: Parameters for neural language models. W and P refer to word and word-piece models, respectively. N_l, N_h, N_e, S_e and S_{total} refer to the number of LSTM layers, the number of hidden states in LSTM, the embedding dimension size, the number of parameters in the embedding layer and in total, respectively. The suffixes "S" and "L" indicate small and large models. "G" represents GLSTM. The suffixes 4K, 16K and 30K represent the vocabulary sizes.

the forget and input decisions together, which reduces the number of LSTM parameters by 25%. We also use group-LSTM (GLSTM) (Kuchaiev and Ginsburg, 2017) to reduce the number of trainable variables of an LSTM matrix by the number of feature groups, k. We set $k = 5$ in experiments. Table 2 lists the parameter settings of the word (W) and word-piece (P) models used in this study. Due to the memory limitations of on-device training, all models use fewer than $3.5M$ parameters. For each vocabulary size, we first start with a base architecture consisting of one LSTM layer, a 96-dimensional embedding, and 670 hidden state units. We then attempt to increase the representational power of the LSTM cell by increasing the number of hidden units and using multi-layer LSTM cells (Sutskever et al., 2014). Residual LSTM (Kim et al., 2017) and layer normalization (Lei Ba et al., 2016) are used throughout experiments, as these techniques were observed to improve convergence. To avoid the restriction that $N_h = N_e$ in the output, we apply a projection step at the output gate of the LSTM (Sak et al., 2014). This step reduces the dimension of the LSTM hidden state from N_h to N_e. We also share the embedding matrix between the input embedding and output softmax layer, which reduces the memory requirement by $|\mathcal{V}| \times N_e$. We note that other recurrent neural models such as *gated recurrent units* (Chung et al., 2014) can also be used instead of CIFG LSTMs.

The federated RNN LMs are trained on two language settings of the virtual keyboard: American English (en_US) and Brazilian Portuguese (pt_BR). Following McMahan et al. (2017), 500 reporting clients are used to compute the gradient updates for each round. A server-side learning rate of 1.0, a client-side learning rate of 0.5, and Nesterov momentum of 0.9 are used. Both the word and word-piece models are trained over the same time range and with the same hyperparameters. Prior to federated training of the RNN LM, the word-piece inventory is constructed from the unigram distribution collected via the federated approach introduced in Section 3.

A common evaluation metric for both word and word-piece models is desirable during federated training. Such a metric can be used to monitor the training status and select models to be used for the `CapSampleApprox` algorithm. Neither cross-entropy nor accuracy serves this need due to the mismatch in vocabularies used. Word-level accuracy is hard to compute for the word-piece model, since it requires hundreds of inference calls to traverse all combinations of a word from the word-piece vocabulary. In this study, we apply sentence log likelihood (SLL) in the evaluation. Given a sentence $\bar{x}^m = \{x_1, x_2, \ldots, x_m\}$ composed of m units (either words or word-pieces), SLL is evaluated as $\sum_{i=1}^{m} \log(p_{nn}(x_i|\bar{x}^{i-1}))$. One issue that arises is the handling of out-of-vocabulary (OOV) words. The OOV probability of the word model is about 8%. The comparable probability of an OOV word (according to $\mathcal{V}$) for word-piece models is the product of the corresponding word-piece conditional probabilities, which is much smaller than 8%. To mitigate this issue, we define SLL excluding OOV as:

$$\text{SLL}^e = \sum_{i:x_i \neq \text{OOV}}^{m} \log(p_{nn}(x_i|\bar{x}^{i-1})),$$

where the OOV in the equation includes word-pieces that are components of OOV words. In the following, SLL^e is used as model selection metric.

7.2 Approximated n-gram model

Algorithm 1 illustrates the workflow we use to generate different n-gram models for evaluation. Recall that `CapSampleApprox` takes a RNN LM, an n-gram topology, and a reweighting FST for capitalization normalization. The n-gram topology is empty under self-inference mode. Suresh et al. (2019a) showed that inferring topology from the RNN LM does not perform as well as

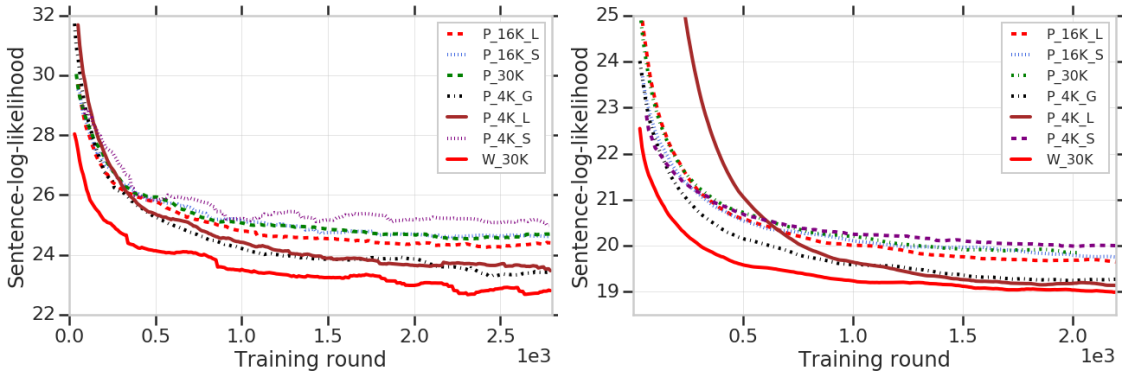

Figure 5: Sentence log likelihood excluding OOV token for en_US (left) and pt_BR (right).

Model	top-1
Baseline	10.03%
A_{P_e}	$10.49 \pm 0.03\%$
A_{P_i}	$10.46 \pm 0.03\%$
A_{P_m}	$10.48 \pm 0.04\%$
A_{P_r}	$10.53 \pm 0.03\%$

Table 4: Result of top-1 prediction accuracy on the live traffic of the virtual keyboard for en_US derived using word-piece models.

using the true n-gram topology obtained from the training corpus. Hence, we supplement the neural-inferred topology with the topology obtained by a large external large corpus denoted by A_W. We use `CapSampleApprox` on four topologies and compare the resulting models: an n-gram model obtained from an external corpus's topology A_e, an n-gram model obtained from a neural inferred topology A_i, an n-gram model obtained by interpolating (merging) the two models above A_m, and an n-gram model obtained by approximating on the interpolated topology A_r. We repeat this experiment for both word and word-piece RNN LMs and use subscripts W and P, respectively. We evaluate all eight produced n-gram models directly on the traffic of a production virtual keyboard, where prediction accuracy is evaluated over user-typed words.

7.3 Results

Figure 5 shows the SLL^e metric for all the experiments listed in Table 2. In general, larger models generate better results than smaller baseline models. For the baseline architectures with same RNN size, having a larger vocabulary leads to some gains. For the larger architectures that have similar total numbers of parameters, 4K word-piece models are shown to be superior to 16K and 30K. For 4K word-piece models, GLSTM is in general on-par with its $P_{4K\text{-}L}$ counterpart. The word model is better than all the word-piece models in both languages in SLL^e. We were surprised by this result, and hypothesize that it is due to the SLL^e metric discounting word-piece models' ability to model the semantics of OOV words. The solid lines are the best models we pick for A/B experiment evaluation for the virtual keyboard ($P_{4K\text{-}L}$ and W_{30K}).

Table 3 shows the A/B evaluation result on both en_US and pt_BR populations. The baseline model is an n-gram model trained directly from centralized logs. All of the federated trained models perform better than the baseline model. We repeated the A/B evaluation with word-piece models on en_US and the results are in Table 4. The performance of word-piece models is similar to that of word models. Among the federated models for en_US, A_{P_r} has the best result. This meets our expectation that the supplemental corpus helps improve the performance of the topology inferred from the RNN LM.

8 Conclusion

We have proposed methods to train production-quality n-gram language models using federated learning, which allows training models without user-typed text ever leaving devices. The proposed methods are shown to perform better than traditional server-based algorithms in A/B experiments on real users of a virtual keyboard.

Acknowledgments

The authors would like to thank colleagues in Google Research for providing the federated learning framework and for many helpful discussions.

Abstract

Conceptual spaces are geometric representations of meaning that were proposed by Gärdenfors (2000). They share many similarities with the vector space embeddings that are commonly used in natural language processing. However, rather than representing entities in a single vector space, conceptual spaces are usually decomposed into several facets, each of which is then modelled as a relatively low-dimensional vector space. Unfortunately, the problem of learning such conceptual spaces has thus far only received limited attention. To address this gap, we analyze how, and to what extent, a given vector space embedding can be decomposed into meaningful facets in an unsupervised fashion. While this problem is highly challenging, we show that useful facets can be discovered by relying on word embeddings to group semantically related features.

1 Introduction

Conceptual spaces (Gärdenfors, 2000) are vector space models that are aimed at representing the entities of a given kind (e.g. movies), together with their associated properties (e.g. scary) and concepts (e.g. thrillers). As such, they are similar in spirit to the vector space models that have been proposed in information retrieval (Deerwester et al., 1990) and natural language processing (Turney and Pantel, 2010; Mikolov et al., 2013), but there are also notable differences. First, in the context of conceptual spaces, an explicit distinction is made between the entities from the domain of discourse, which are represented as vectors, and the corresponding properties and concepts, which are represented as regions (e.g. polytopes) or soft regions (e.g. characterized by a Gaussian). Second, conceptual spaces are organised into a set of facets[1], each of which captures a different aspect of meaning. For instance, in a conceptual space of movies, we may have facets such as genre, language, geographic location, etc.

Each facet is associated with its own vector space, which intuitively captures similarity w.r.t. the corresponding facet. For instance, in a conceptual space of movies, the vector space for the budget facet would only capture whether two movies had a similar budget. Most of these facet spaces tend to be low-dimensional (e.g. modelling budget only needs a single dimension). This clearly differentiates them from traditional semantic spaces, which often have hundreds of dimensions. From an application point-of-view, the separation of vector space models into facets is appealing for several reasons. One key advantage is that it allows us to model similarity in a more flexible, and cognitively more plausible way. A related advantage is that the low-dimensional nature of the facet-specific spaces should make it easier to learn from few examples. Finally, the separation into facets can also make conceptual spaces more interpretable. However, the study of conceptual spaces has mostly focused on modelling cognitive and linguistic phenomena, such as metaphor (Gärdenfors, 1996) and vagueness (Douven et al., 2013), with only few works addressing the challenge of learning such representations from data.

Decomposing conceptual spaces into facets is similar to the problem of disentangled representation learning (DRL), which has recently received considerable interest. However, empirical studies suggest that purely unsupervised DRL methods are unlikely to be successful without a strong inductive bias. In fact, Locatello et al. (2018) found that what mostly matters was how such methods are initialized, rather than what particular optimization objective is used. Moreover, much of

[1] These facets are often referred to as *domains* in the context of conceptual spaces. However, we will use the term facets to avoid confusion with domains of discourse.

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 131–139
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

the work in DRL has focused on image processing rather than textual data (which is what we use in this paper). Finally, existing work in DRL is focused on learning factors which are uncorrelated. In our setting, however, the different facets are often highly correlated (e.g. natural disaster movies typically have a high budget).

In this paper, we explore a strategy for decomposing a given vector space embedding into separate facet spaces by first determining which interpretable features are modelled by the vector space and then clustering the word vectors corresponding to these features. Despite being intuitive, given that word embeddings are known to group together functionally similar words, we found this strategy to perform poorly in its basic form. First, simply looking for clusters in word embeddings often leads to thematic clusters, e.g. grouping *horror* together with words such as *scary* and *zombie* rather than other genres such as *western* and *drama*. To address this, we explicitly prevent two words from ending up in the same cluster if the features they are modelling are too similar. Second, in most domains, there are one or two central facets which tend to be highly correlated with most of the other facets (e.g. genre in the movie domain). To ensure that the resulting facet spaces are sufficiently different (rather than capturing minor variations of the most central facets), we found it useful to use an iterative approach, where previously found facets are "removed" from the vector space embedding before proceeding to find further facets. With these two modifications, we find that useful facets can indeed be found, which consistently lead to better classification performance compared to the original vector space embedding.

2 Related Work

Conceptual Spaces. A conceptual space (Gärdenfors, 2000) is a vector representation of the entities from some domain, where the dimensions tend to capture salient features. It is usually assumed that the dimensions of a conceptual space can be grouped into semantic domains, or facets. From a cognitive point of view, this grouping is important because it affects how similarity scores are computed. Intuitively, this is because the dimensions from the same facet tend to interact with each other whereas the dimensions from different facets can be considered in isolation. The problem of learning conceptual spaces from data has only received limited attention to date. One exception is the work of Derrac and Schockaert (2015), which we build on in this paper. In their work, textual descriptions of the considered entities are used to find dimensions that model salient semantic features in a given semantic space. For instance, in a semantic space of movies they found dimensions corresponding to features such as *scary*, *horror* and *zombie*. Note that because these features tend to be correlated, the corresponding dimensions are typically not orthogonal in the input semantic space. For this reason, they refer to these dimensions as *interpretable directions*. More recently, (Ager et al., 2018) proposed a post-processing method to fine-tune these interpretable directions. The main challenge which we address in this paper is to group the features that are found by the method from Derrac and Schockaert (2015) into semantically meaningful facets. A supervised variant of this problem was considered by Banaee et al. (2018). Their approach relies on feature selection methods to find subsets of features that are predictive of particular class labels, based on a set of labelled training examples. In contrast, our focus in this paper is on unsupervised methods, as suitable training data is often not available.

Disentangled Representation Learning (DRL). In the last few years, a large number of generative neural network models have been proposed, with variational autoencoders (VAEs) (Kingma and Welling, 2014) and generative adversarial networks (GANs) (Goodfellow et al., 2014) being the best-known examples. The main underlying idea behind these models is that high-dimensional data (e.g. images) can often be described in terms of a much lower-dimensional latent vector space. Each object can thus be compactly described by its latent code, i.e. the corresponding vector in this latent space. The problem of DRL is to learn such a latent vector representation which is such that (groups of) the dimensions of the latent codes correspond to meaningful interpretable factors. A variety of unsupervised and semi-supervised approaches for learning such disentangled representations have been proposed, such as InfoGAN (Chen et al., 2016), which is based on a modification of the loss function for GANs, and β-VAE (Higgins et al., 2017), which instead uses VAEs as the base model. Conceptually, these approaches modify the loss function of a given generative

model by insisting that the dimensions of the latent vector space are in some sense independent. In principle, the latent vector spaces learned by DRL methods can be viewed as conceptual spaces. It is unclear, however, whether purely statistical measures of independence can be sufficient for learning semantically meaningful factors. While interesting results have been obtained for particular applications, after a thorough empirical analysis Locatello et al. (2018) concluded that such results were highly sensitive to the random initialization of the neural network models and the value of hyper-parameters. Their results suggest that, in absence of a suitable supervision signal, high-quality factors can only be learned in the presence of a strong inductive bias. Going beyond unsupervised approaches, (Jain et al., 2018) propose a supervised approach for DRL for text. As supervision signal, they use triplets of the form $(s, d, o)_a$ which encode that relative to aspect a, it holds that s and d are more similar than d and o. Then they use a Convolutional Neural Network (CNN) based model to obtain low-dimensional document embeddings for each considered aspect.

3 Decomposing Conceptual Spaces

Let E be a set of entities of some particular type (e.g. movies) for which a vector space embedding is given. In the following, we will write $\mathbf{e} \in \mathbb{R}^n$ for the embedding of entity e. The first step of our approach consists in applying the method from Derrac and Schockaert (2015), which provides us with a set of words F, each corresponding to a feature that can be modelled as a direction in the vector space. For $f \in F$ we write $\mathbf{d_f}$ for the vector characterizing this direction. Formally, this means that $\mathbf{e_1} \cdot \mathbf{d_f} < \mathbf{e_2} \cdot \mathbf{d_f}$ iff e_2 has the feature f to a higher extent than e_1 (e.g. if f denotes the feature *scary*, then this would mean that movie e_2 is scarier than movie e_1). We briefly recall the method from Derrac and Schockaert (2015) in Section 3.1. Our hypothesis is that we can group these features into meaningful facets and that we can represent these facets as subspaces of the given vector space embedding. Section 3.2 discusses our approach for finding these subspaces.

3.1 Identifying Feature Directions

The method proposed in Derrac and Schockaert (2015) aims to finds a set of features F which can be modelled as directions in the given vector space. The input to their method consists of a text description D_e of each entity e, but they assume no other prior knowledge. In particular, each word w which occurs sufficiently frequently in the document collection $\mathcal{D} = \{D_e \,|\, e \in E\}$ is considered as a candidate feature. To determine whether w should be added as a feature, they train a linear SVM classifier to separate the vector representations of the entities e for which w is mentioned in D_e from the vector representations of the other entities. If this SVM classifier is sufficiently accurate[2], they assume that the word w captures a salient feature. The corresponding feature direction is then characterized by the normal vector $\mathbf{d_f}$ of the hyperplane that was learned by the SVM classifier. We will use the notation pos_w to refer to the set of entities from E which are classified as positive. In our experiments, we used logistic regression classifiers instead of SVMs, which we found to perform similarly but were faster to train.

3.2 Finding Facets

Our aim is to group the features from F into meaningful facets. For instance, in the movies domain, we might expect to see facets corresponding to e.g. genre, language and release date. It does not seem possible (nor desirable) to formally define what constitutes a good facet, a typical problem in unsupervised learning. Intuitively, however, a facet should group features which are of the same kind (e.g. genres) and should in some sense be exhaustive (i.e. all genres, rather than a set of features that refer to one or a few particular genres).

Using subspace clustering. The aim of subspace clustering is to decompose a high-dimensional space into the union of lower-dimensional spaces. This problem has found numerous applications, especially in computer vision. One may wonder whether we can learn useful facets by applying subspace clustering to feature directions $\mathbf{d_f}$. Unfortunately, in our initial experiments, this approach did not prove successful. This is illustrated for the movies domain in Table 1, where we used the state-of-the-art SSC-OMP subspace clustering method (You et al., 2016). For this comparison, we first manually grouped the features from F to obtain a gold standard. The first column of the table shows two of the resulting facets: one corresponding to genres and one corresponding to different

[2]Because of class imbalance, they used Cohen's Kappa instead of classification accuracy.

media types (which indirectly captures the time period during which a movie was released). The right-most column shows the closest facets that were found with SSC-OMP. As can be seen, these facets are largely non-sensical. For instance, in the first case, words such as *blu* and *disc* are clustered together with semantically unrelated words such as *fighting*, *england* and *accurate*. In the second example, genres such as *horror* and *thriller* are grouped together with unrelated words such as *cheesy*, *widescreen* and *award*. This negative result seems in accordance to the findings from Locatello et al. (2018) that unsupervised disentangled representation learning seems impossible without a strong inductive bias. We also tried several other subspace clustering methods, for a wide range of different configurations, without obtaining better results. Similarly, we experimented with neural approaches for learning disentangled representations directly from the bag-of-words representations of the entities, but again unsuccessfully.

Using word embeddings. These negative results strongly suggest that some kind of external knowledge is needed to find meaningful facets. To this end, we focus on the use of word embeddings, which seems natural given the fact that words of the same kind (e.g. different names of genres) tend to be used in similar contexts, and can thus be expected to have similar word vectors. In particular, our basic approach for identifying facets consists in clustering the word vectors, from some standard pre-trained word embedding model, corresponding to the features in F. One important drawback of this basic strategy, however, is that it often leads to thematic clusters. For instance, while we would want *horror* to be clustered together with other names of genres, when simply clustering word vectors without any further guidance, *horror* may be clustered together with thematically similar words such as *scary* and *zombie*. To avoid such clusters, we rely on the insight that if a and b are thematically similar words (e.g. *horror* and *zombie*) then the corresponding feature directions $\mathbf{d_a}$ and $\mathbf{d_b}$ will also be similar. However, for paradigmatically similar words, such as *horror* and *comedy*, this should not be the case. In other words, two words should intuitively end up in the same clusters if they have similar word vectors but dissimilar feature directions.

While there are many ways to implement this intuition, we found that using the cosine similarity between $\mathbf{d_a}$ and $\mathbf{d_b}$ was not always reliable. Instead we rely on the following measure of overlap between the sets pos_a and pos_b:

$$o(a,b) = \min\left(\frac{|pos_a \cap pos_b|}{|pos_a|}, \frac{|pos_a \cap pos_b|}{|pos_b|}\right)$$

The dissimilarity between features a and b from F is then defined as follows:

$$d(a,b) = \begin{cases} 1 - \cos(\mathbf{w}_a, \mathbf{w}_b) & \text{if } o(a,b) \leq \lambda \\ 1 & \text{otherwise} \end{cases}$$

where the overlap threshold λ is a hyperparameter and $\mathbf{w}_f$ denotes the word vector for feature f.

The aim of the clustering step is to find a number of disjoint subsets of F, each of which intuitively corresponds to a facet. We will denote these facets by $X_1, ..., X_k$. To avoid finding redundant facets, we identify them in an incremental fashion. In particular, from the clusters obtained by the clustering algorithm, we only select the single most important one, i.e. the one which is most

likely to describe a salient facet. For this purpose, we rank clusters according to the following score:

$$score(X_i) = |\bigcup_{f \in X_i} pos_f| \quad (1)$$

This score reflects the intuition that we prefer clusters with features that are general and diverse, i.e. such that most of the entities would have at least one of the features from the cluster. As will be explained below, after the subspace corresponding to this facet has been determined, we iteratively apply the same method on a reduced vector space to find the next most important facet, until the desired number of facets k has been found.

3.3 Modelling Facets as Subspaces

We model each facet X_i as a linear subspace of the given vector space embedding. To find this subspace, we learn new feature directions $\mathbf{c_f}$ for each $f \in X_i$, which still capture these features but lie in a low-dimensional subspace. In particular, we minimize the following objective:

$$\sum_{e \in E} \sum_{f \in X_i} \log \sigma(\mathbf{c_f e} + b_f) \quad (2)$$

where

$$\mathbf{c_f} = \lambda_1^f \mathbf{a_1^i} + \lambda_2^f \mathbf{a_2^i} + ... + \lambda_r^f \mathbf{a_r^i} \quad (3)$$

with r the desired number of dimensions of the subspace. Note that (2) essentially expresses that for each $f \in X_i$, we want to train a logistic regression classifier with coefficient vector $\mathbf{c_f}$. However, as expressed in (3), rather than learning these coefficient vectors independently, they are constrained such that they can be written as a linear combination of the vectors $\mathbf{a_1^i}, ..., \mathbf{a_r^i}$. The resulting feature directions thus span a subspace of (at most) r dimensions. Let $\mathbf{M}_i \in \mathbb{R}^{r \times n}$ be an orthonormal basis for this subspace. Then $\mathbf{e}^i = \mathbf{M}_i \mathbf{e}$ is the r-dimensional facet-specific embedding of entity e.

There may be some features from F which are not contained in X_i but can nonetheless be modelled well in the resulting subspace (i.e. if they are semantically related to the features in X_i). To identify these features, we apply the method from (Derrac and Schockaert, 2015) to the facet-specific embeddings. We write Y_i to denote the features that were thus identified, beyond the ones from X_i.

Next we determine a null space of the basis $\mathbf{M}_i$, i.e. an $(n-r) \times n$ dimensional matrix $\mathbf{R}_i$ satisfying

$$\mathbf{M}_i \mathbf{R}_i^T = \mathbf{0}$$

Dataset	Entities	Attribute	Classes

Building	3721	Country	2
		Administrative Location(AL)	2

Table 2: Overview of considered datasets.

This matrix $\mathbf{R}_i$ is a basis for the orthogonal complement of the subspace spanned by $\mathbf{M}_i$. Intuitively, it defines what remains of the vector space embedding after we remove (i.e. project away) the subspace modelling the facet X_i.

To find the remaining facets, we repeat the same procedure, but with two changes. First, the $n - r$ dimensional remainder space is used instead of the original embedding space, i.e. we use $\mathbf{R}_i \mathbf{e}$ as the vector representation of e. Second, the features in $X_i \cup Y_i$ are no longer considered by the clustering algorithm. This process is repeated until the desired number of facets has been found, each time considering an increasingly lower-dimensional remainder space and clustering only those features that are not already modelled in a previously identified facet. Intuitively, by learning the facets in this incremental way, we should be able to avoid finding multiple variants of the same facets.

The middle column of Table 1 shows two of the facets that were found with this approach. Intuitively, these facets are clearly more meaningful than those that were found with SSC-OMP.

4 Experimental Analysis

Methods. We have experimented with two clustering algorithms: agglomerative hierarchical average link clustering and HDBSCAN (Campello et al., 2013). However, in the case of HDBSCAN we noticed that when using overlap-based dissimilarity, we typically ended up without any clusters[3]. For HDBSCAN we therefore used cosine similarity instead. We refer to our method with agglomerative clustering as *IncAgg* and to the variant with HDBSCAN as *IncHDB*. In addition, we considered a variant of the method with agglomerative clustering which relies on cosine similarity instead of the overlap-based dissimilarity (*CosIncAgg*).

[3]Note that HDBSCAN does not cluster all the data points, as it removes data points which are considered as noise.

Table 3: Classification tasks performance (in terms of F1 score) when using the MDS space and four variation of the facet-based representations.

Finally, we also report results for variants of our methods in which we did not obtain the facets incrementally (*NonIncAgg* and *NonIncHDB*). In these cases, we simply extract r clusters from the initial set of features F and determine the corresponding facets directly. In all cases, we use 50-dimensional pre-trained GloVe word vectors (Pennington et al., 2014) for clustering the features.

To generate the initial vector space embedding, we follow the approach proposed in (Derrac and Schockaert, 2015) based on multi-dimensional scaling. In all cases, we used 100-dimensional vector spaces and learned 10 facets, each being modelled as a 10-dimensional subspace. To select the set of features F, we initially consider the 500 highest scoring words according to the Kappa metric. However, if we end up without any clusters (in the case of HDBSCAN), we expand the set of features to the 1000 top words. The overlap threshold λ is selected based on held-out tuning data, considering values from $\{0.3, 0.5, 0.7\}$. To flatten the agglomerative clustering, we tune the number of clusters from $\{50, 100, 200\}$[4].

[4]The source code is available online at https://github.com/rana-alshaikh/Disentangled-Facets.

Evaluation tasks. Intrinsic evaluation of the learned facets is difficult, among others because what we might consider to be a natural facet is highly subjective. Therefore, in our quantitative evaluation, we will focus on the impact of the learned facets in a number of classification tasks. This is also motivated by the view that some types of classifiers need semantically meaningful features to perform well. For example, Ager et al. (2018) used low-depth decision trees to evaluate a method for learning feature directions in vector space embeddings. Specifically, if $F = \{f_1, ..., f_m\}$ is the set of features that were identified, then they represent each entity e using the feature vector $(\mathbf{d_{f_1}} \cdot \mathbf{e}, ..., \mathbf{d_{f_m}} \cdot \mathbf{e})$, with $\mathbf{d_f}$ the direction modelling feature f as before. Given that a depth-1 decision tree can only use one of these features, the performance of such a decision tree essentially tells us to what extent the classes that are considered in the supervised classification task have been discovered as features. In our experiments, we will report the result of depth-1 and depth-3 decision trees. As the baseline method, referred to as *MDS*, we will use the top-2000 features that we obtained with the method from Derrac and Schockaert (2015). To evaluate the facets,

Bottom: showing the 10-dimensional representations for the facet $X_i = \{$ campuses, students, offices, centers, facilities, area, hotels, homes, bridges, hospitals, cities, shops, stations$\}$

we instead apply this method to find the top-200 features for each of the facet subspaces.

The performance of the decision trees will allow us to evaluate whether we are able to learn higher-quality feature directions thanks to the decomposition of the vector space into facet subspaces. To evaluate the quality of the facets independently of the quality of the feature directions, we also consider classifiers which use as input the facet-specific vector representations $\mathbf{e}^i$ of the entities. Specifically, we train a support vector machine (SVM) for each of the facets, leading to the predictions $p_1, ...p_k$. These predictions are then aggregated to a final prediction using a logistic regression meta-classifier. As baseline, we simply train a single SVM classifier in the full vector space. As our final classifier, we estimate a Gaussian model from the positive training examples. In particular, we estimate a univariate Gaussian for each dimension and multiply the corresponding probabilities. We chose this method because it is sensitive to how well the dimensions of the space are aligned with semantically meaningful properties, and because such Gaussians are commonly used for representing categories in conceptual spaces (Bouraoui and Schockaert, 2018). For the baseline, we use the dimensions of the full vector space. For the facet-based representations, we use the dimensions of the facet subspaces.

Dataset. We have carried out experiments with vector space embeddings for four different domains. First, we used the *movies* and *place type* domains from (Derrac and Schockaert, 2015), where the embeddings are learned respectively from movie reviews and from Flickr tag co-occurrence distributions. We also considered two additional domains, for which we used Wikipedia articles: *buildings* and *organisations*. In particular, we retrieved all Wikipedia pages whose semantic type on WikiData corresponds to building or organisation. Wikipedia pages containing fewer than 200 words were removed. The bag-of-words (BoW) representation of the remaining Wikipedia concepts were obtained using a standard preprocessing strategy (e.g. removing HTML tags and references), including stopword removal with NLTK (Bird and Loper, 2004). Furthermore, we POS tagged the documents and only retained the nouns and adjectives. Finally, frequent words that occurred in more than 60% of the Wikipedia articles about buildings (resp. organisations) were removed, as well as words that occurred fewer than 10 times. This approach was taken to stay broadly in line with the strategy that was used in (Derrac and Schockaert, 2015). As classification tasks, we used two attributes from WikiData in both domains (being the only attributes for which

BUILDINGS	
Initial cluster X_i:	**Top additional features Y_i:**
architecture, art, history, literature, architectural, society, culture, ancient, scholars, vernacular, classical, historical, contemporary, cultural, medieval	structure, floors, county, architect, graduate, palace, revival, property, hall, united, floor, farm, design, art, space, style, states, downtown, interior, mansion, arena, architectural, architecture, chemistry, entrance.

Table 5: Examples of the facets from the Buildings dataset (using *IncAgg* method).

a sufficient number of entities per attribute value was found). The full datasets will be released upon acceptance. The properties of the considered domains and associated classification problems are summarized in Table 2. For each classification problem, we randomly split the labelled examples into 2/3 for training and 1/3 for testing. For tuning we use 5-fold cross-validation over the training set. In the movies domain, where more labelled data is available, we have used fixed splits of 60% for training, 20% for tuning and 20% testing.

Results. The results are summarized in Table 3. Our main method *IncAgg* outperforms the *MDS* baseline for almost all classification tasks and types of classifiers. For the HDBSCAN based variant, the results are more mixed, which seems related to the fact that the overlap based dissimilarity could not be used in that case. Indeed, the cosine based variant of *IncAgg*, i.e. *CosIncAgg*, also performs consistently worse than *IncAgg*. Looking at the performance of *NonIncAgg* and *NonIncHDB* reveals that learning facets in an iterative fashion is critical, given that these two variants perform worse than the baseline in many cases.

Looking more closely at the results of our main method *IncAgg*, it is interesting to note that large improvements are obtained for depth-1 decision trees, which shows that our facet subspaces make it easier to identify features that correspond to the categories from the corresponding classification problems. However, large improvements can also be seen for SVMs, which shows that the actual decomposition of the space is also helpful.

Qualitative Analysis. Figure 1 illustrates how our subspaces capture similarity in a facet-specific way, showing the two first principal components of the embedding of *Birmingham School of Art* in the full space and in the subspace of a facet that intuitively captures building type. While the neighbours in the full space are a mixture of different building types (hotels, commercial buildings, museum, and educational buildings), in the facet subspace all nearest neighbors are universities.

Table 4 illustrates the impact of using overlap-based dissimilarity, where the clusters obtained with cosine similarity are clearly more thematic, while the ones obtained with the overlap-based metric intuitively capture a facet (i.e. geographic location and the natural–cultural opposition). Finally, Table 5 shows some of the facets obtained in the buildings domains. The first example shows a facet which intuitively captures the historical–contemporary opposition, while the second example shows a facet that captures the rural–city opposition.

5 Conclusions

We considered the problem of decomposing a vector space embedding into facets, which are characterized by a set of semantically related features and a corresponding subspace of the embedding. In particular, we focused on unsupervised methods, considering both approaches that rely on the vector space itself (i.e. using subspace clustering) and approaches that additionally take into account the information about word meaning that is captured by pre-trained word vectors. Overall, we found this problem to be highly challenging, in accordance with the findings from Locatello et al. (2018) regarding unsupervised disentangled representation learning. However, we were still able to obtain useful facets based on two crucial modifications to a standard clustering based strategy. First, we measure the similarity between features based on two factors: the similarity between their word vectors and the dissimilarity between their meaning in the vector space embedding (measured in terms of overlap). Second, we found it essential to learn facets in an iterative fashion, to avoid too much redundancy between the different facets.

Abstract

We conduct a manual error analysis of the CoNLL–SIGMORPHON 2017 Shared Task on Morphological Reinflection. In this task, systems are given a word in citation form (e.g., *hug*) and asked to produce the corresponding inflected form (e.g., the simple past *hugged*). This design lets us analyze errors much like we might analyze children's production errors. We propose an error taxonomy and use it to annotate errors made by the top two systems across twelve languages. Many of the observed errors are related to inflectional patterns sensitive to inherent linguistic properties such as animacy or affect; many others are failures to predict truly unpredictable inflectional behaviors. We also find nearly one quarter of the residual "errors" reflect errors in the gold data.

1 Introduction

A huge amount of work in natural language processing treats words as indivisible units, but the vast majority of the world's languages have rich word-internal structure. For instance, 80% of the languages analyzed in the *World Atlas of Linguistic Structure* (Dryer and Haspelmath 2013) inflect verbs for tense and 65% inflect nouns for case. Generating and processing complex words is thus crucial for multilingual speech and language technologies.

Recent work on large-scale, multilingual computational modeling of morphology (e.g., Durrett and DeNero 2013, Cotterell et al. 2016) targets supervised **inflection generation**. Such tasks require variable-length outputs, so they are less constrained than earlier segmentation-based tasks (e.g., Kurimo et al. 2010), but appear to be tractable with existing neural network–based models. For example, in the CoNLL–SIGMORPHON 2017 Shared Task (sub-task 1 and the "high-data condition"), the focus of this study, the best-ranked system generates novel inflectional forms with 90% accuracy or better for 46 out of the 52 target languages, It achieves perfect accuracy for four languages (Cotterell et al. 2017).

In light of these apparent success, we examine the failure modes of existing models for morphological generation. We first propose and motivate an error taxonomy for this task, inspired by similar proposals for other natural language generation and processing technologies such as grammatical error correction (e.g., Rozovskaya and Roth 2016) and machine translation (e.g., Popović and Ney 2011, Fishel et al. 2012, Irvine et al. 2013). We then use this taxonomy to perform a manual error analysis of the CoNLL–SIGMORPHON 2017 Shared Task. Such analyses can help to identify strengths and weaknesses of existing systems, suggest future improvements, and guide development of strong ensemble models, but are often neglected or treated as an afterthought. This annotation also allows us to measure the quality of the gold data.

Generating morphologically complex forms is a skill typically-developing children effortlessly acquire, so this task, and systems' error patterns, may have implications for the theory of language acquisition. While the shared task training paradigm is quite unlike human language learning, inference and evaluation resemble the classic *wug*-test (Berko 1958), in which speakers are presented with a word—either real or nonce—in citation form and prompted to provide a particular inflectional form of that word. Therefore, one can analyze inflection generation errors much like how one might analyze errors made by a child acquiring their first language. And, one can ask whether humans' and artificial learners' errors are in any way alike.

To answer these questions, we examine errors made by the two top-performing systems in the CoNLL–SIGMORPHON 2017 Shared Task for twelve languages.

2 Materials and methods

Here, we describe the shared task, data sources, and the targeted systems.

2.1 The task

The CoNLL–SIGMORPHON 2017 Shared Task (Cotterell et al. 2017) consists of two supervised morphological generation sub-tasks across 52 languages. In sub-task 1, the training data consists of triples of lemma, inflectional bundle, and inflected form, as in Table 1. At inference time, the system is given lemmata and inflectional bundles and asked to produce the appropriate inflected forms. In sub-task 2, training data consists of complete inflectional paradigms, and at inference time, the system is asked to produce full paradigms for unseen lemmata. We focus on the results from sub-task 1, primarily because only two of the twelve teams chose to compete in sub-task 2. However, the proposed error taxonomy could easily be applied to sub-task 2, or to later morphological generation challenges such as sub-task 2 of the CoNLL–SIGMORPHON 2018 shared task (Cotterell et al. 2018) or sub-task 1 of the SIGMORPHON 2019 shared task (McCarthy et al. 2019).

2.1.1 Data

The data in both sub-tasks is primarily sampled from UniMorph (Kirov et al. 2016, 2018), a free morphological database. In turn, UniMorph data for our twelve languages is automatically extracted from Wiktionary, a collaborative multilingual online dictionary. UniMorph pairs the cells of Wiktionary morphological paradigms, which bear prose labels like "genitive plural", to feature bundles in a language-independent morphological schema (Sylak-Glassman et al. 2015; also see Sylak-Glassman 2016). The data consist of the aforementioned triples of lemma, inflectional bundle, and inflected form. For sub-task 1, these triples were sampled from UniMorph paradigms according to frequencies of inflected forms as estimated from Wikipedia. Because of this sampling procedure, the data is sparse in the sense that there are rarely more than a few inflected forms per lemma. As such, this roughly mimics the statistical properties of the primary linguistic data encountered by child language learners (e.g., Chan 2008:71–100). Systems were evaluated under three training data conditions: low (100 triples), medium (1,000 triples) and high (10,000 triples). We focus on the high-data condition because nearly all systems performed poorly in the low- and medium-data conditions.

2.2 Systems

In sub-task 1, systems were ranked using the macro-averaged "per form" (i.e., full-token match) accuracy across all 52 target languages.[1] We analyze errors made by the two top-ranked systems, briefly described below.

UE-LMU-I **(Bergmanis et al. 2017)** This system uses a recurrent neural network (RNN) with a bidirectional gated recurrent unit (GRU) encoder, a unidirectional GRU decoder, and a standard attention mechanism. It enhances a closely-related competitor system (Kann and Schütze 2017) by augmenting the provided training data with identical input-output pairs so as to create a bias toward copying the input stem. It is ranked as the best-performing system on sub-task 1 (macro-average accuracy 95.32%).

CLUZH-7 **(Makarov et al. 2017)** This system also uses a neural encoder-decoder but replaces the "soft" attention mechanism with hard monotonic attention (Aharoni and Goldberg 2017) and special edit operations. It is ranked second-best overall on sub-task 2 (macro-average accuracy 95.12%) and also achieves the highest per form accuracy on eight languages including Hungarian and Spanish.

3 Error taxonomy

One major distinction in the proposed taxonomy of inflection generation errors is between those errors which can be given a linguistic characterization—i.e., in terms of misapplication of inflectional patterns independently attested in the target language—from those which cannot. As such we are inspired by a long and contentious debate in computational morphology research. Rumelhart and McClelland (1986) propose an early neural network model trained to generate the phonological form of English simple past tense verbs given the present tense. They claim that under in certain conditions, their model produces errors that are similar to those made by children acquiring English, such as **catched* for *caught*.[2]

[1] The other metric used in sub-task 1, average Levenshtein distance between word and target averaged over languages, ranks systems nearly identically (Cotterell et al. 2017:11).

[2] Such errors are known as **overregularizations** in the language acquisition literature (e.g., Marcus et al. 1992).

Language	Lemma	Inflection	Inflected form
English	hug	V;PST	hugged
	spark	V;V.PTCP;PRS	sparking
German	aufbauen	V;IND;PRS;2;SG	baust auf
	Ärtzin	N;DAT;PL	Ärtzinnen
Spanish	descomponer	V;NEG;IMP;2;PL	no descompagáis
	liberar	V;IND;FUT;2;SG	liberarás

Table 1: Sample training data for sub-task of the CoNLL–SIGMORPHON 2017 Shared Task. Each training example maps a **lemma** (a citation form) and **inflection** (a bundle of UniMorph morphosyntactic features) to an **inflected form**. At inference time, the inflected form is predicted given a lemma and inflection.

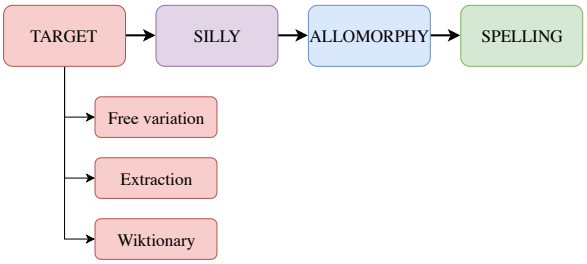

Figure 1: Overview of our annotation scheme, including subcategories. Annotators are instructed to proceed through the taxonomy from left to right.

Pinker and Prince (1988) and Sproat (1992:216f.) dispute this characterization, pointing out bizarre errors like **membled* for *mailed*. More recently, Kirov and Cotterell (2018) claim that modern neural network architectures—such as those used in the CoNLL–SIGMORPHON 2017 Shared Task—generalize reasonably well while largely eliminating these bizarre errors. However, Corkery et al. (2019) argue that the Kirov and Cotterell model predictions align poorly with human productions, and suggest that the reported results may be uncharacteristic due to fortuitous random seeding.

We desired a somewhat richer set of errors than this prior work. The final taxonomy—incorporating feedback from a ten-language pilot study—consists of four major error categories, with several additional sub-categories. The categories are applied sequentially, as in Figure 1. We now describe these categories.

Target errors This category consists of cases where the gold data is incorrect or incomplete.[3] We discern three sub-categories of target errors. **Free variation errors** occur when more than one acceptable inflected form exists, but only one is present in the UniMorph data. **Extraction errors** indicate flaws in UniMorph's parsing of Wiktionary inflectional paradigms. **Wiktionary errors** represent errors in the Wiktionary data itself.

Silly errors This category consists of those "bizarre" errors which defy any purely linguistic characterization. In addition to the aforementioned case of **membled*, such errors have also been reported for other language generation tasks such as machine translation (Arthur et al. 2016) and text normalization (Gorman and Sproat 2016, Sproat and Jaitly 2017, Zhang et al. 2019).

Allomorphy errors This category consists of those errors which are characterized by misapplication of existing (i.e., independently attested) allomorphic patterns in the target language. Our annotation scheme recognizes four sub-categories of allomorphy error, but we set aside their their description for reasons of space.

Spelling errors This category includes inflected forms that do not follow language-specific orthographic conventions but are otherwise correct.

4 Results

We performed full error annotation on twelve of the 52 languages. Several other languages were initially targeted for annotation but produced too few errors to draw meaningful conclusions. Annotations were performed by the authors, all specialists in computational linguistics.[4] Of these, four languages—English, Finnish, Polish, and Russian—were annotated by native

[3] This label is applied regardless of whether the predicted inflected form is correct or not, and therefore is independent of system predictions. Furthermore, it is possible that both the gold data and prediction have the same incorrect inflected form, but detecting such cases is challenging.

[4] We do not claim that this level of expertise is strictly necessary; it might be the case that linguistically naïve native speakers could be trained to produce reliable annotations.

speakers; the remaining eight were annotated by second-language speakers. In addition to the annotation guidelines, annotators were encouraged to consult authoritative dictionaries and reference grammars—such as the *Iso suomen kielioppi* (Hakulinen et al. 2008) for Finnish, the *Duden* for German, the *Oxford Latin Dictionary* (Lee 1968), or the *Diccionario de la lengua española* for Spanish—and native speakers. Table 2 reports summary statistics for fully-annotated languages.

4.1 Inter-annotator agreement

Table 3 provides raw agreement and Krippendorf's α (Artstein and Poesio 2008) for those languages known to two annotators. As mentioned above, each annotator is a specialist in computational linguistics, and annotated at least one other language as well. Raw agreement is high, and while chance-corrected agreement statistics like α are notoriously difficult to interpret, $\alpha \geq 0.8$, a threshold obtained for all three double-coded languages, is generally considered to indicate substantial reliability (Krippendorff 2004:241f.).

4.2 Errors

Table 4 provides the counts of the four major categories of error for all twelve languages and for both systems. We now proceed to describe some patterns observed within these categories.

4.2.1 Target errors

Table 5 gives counts for the three sub-categories of target errors.[5]

Free variation errors Finnish has several free variation errors, many involving vowel harmony. For example, the abessive suffix has two allomorphs, namely the the back-harmonic *-tta* and the front-harmonic *-ttä*. The lemma *progestiini* 'progestin' can take the back allomorph, giving *progestiini**tta***, but, vowel harmony often fails to apply when there are many intervening neutral vowels (*i* and *e*) between the harmonic trigger and the suffix (Hakulinen et al. 2008:§17), as is the case here. Therefore, the form *progestiini**ttä***, predicted by both systems, is grammatical, though not the form given by UniMorph. Another type of free variation error affects allomorphs of the Finnish genitive plural (gen.pl.). For instance, *omeno**iden***, *omeno**itten***, *omeno**jen***, *omen**ien*** and *omena**in*** are all possible gen.pl. forms of *omena* 'apple', but only one is present in UniMorph.

Extraction errors The comparatively low accuracy on Hungarian—CLUZH-7, the best performing system on this language, achieves 89.80% per form accuracy—appears to be due to large number of extraction errors. In most cases, the error comes from pairing one paradigm cell with another cell's inflectional bundle. For instance, UniMorph incorrectly labels **lagúnák* as the accusative plural (acc.pl.) for *lagúna* 'lagoon'; it is in fact the nominative plural (nom.pl.). In Romanian, a header for the Wiktionary paradigms reading "definite articulation" is incorrectly taken as an inflected form itself! Latin also suffers from pervasive extraction errors. This language has a robust phonemic contrast between short and long monophthongs (e.g., *malus* 'unpleasant' vs. *mālus* 'apple tree'). Long monophthongs are—at least in modern editions—indicated by the macron, a horizontal line above the vowel. UniMorph extraction has somehow removed macrons from all lemmata, though they are still present in the inflected forms. Thus, systems must attempt to predict an unpredictable phonemic contrast while mapping from lemma to inflected form. As a result, the vast majority of Latin errors concern vowel length.

Wiktionary errors Errors in the Wiktionary data itself are relatively rare and largely non-systematic. For example, in Spanish, **demarce* is given as the first person singular (1sg.) present subjunctive of *demarcar* 'to demarcate' instead of the correct form *demarque*.

4.2.2 Silly errors

Silly errors were found for all languages except English; they also appear to be somewhat more common for UE-LMU-I (59) than for CLUZH-7 (37). UE-LMU-I predicts *praes**ōs*** as the acc.pl. of the Latin noun *praesul* (a title used by Roman religious leaders); there is no obvious analogue for the *ul-ōs* stem change. In German, CLUZH-7 unexpectedly truncates the gen.pl. form of the compound noun *Schädlingsbekämpfungsmittel* 'pesticide' to produce **Schädlingsbekämpfungsmit*. For the dative plural (dat.pl.) of the Russian compound noun meaning 'forced labor', UE-LMU-I inexplicably deletes the *r* of *rabóty* 'labor', giving the bizarre **prinudítel'nym **abótam***.[6] And, in Spanish,

[5] Some analyses conducted by Richard Sproat (p.c.) suggest that sub-task 2 was also highly affected by target errors.

[6] In the shared task, Russian data is given in the standard Cyrillic orthography; we have taken the liberty of romanizing

Language	Noun	Verb	Adjective	UE-LMU-I errors	CLUZH-7 errors	Overlap
Dutch	✗	✓	✓	31	32	84%
English	✗	✓	✗	28	32	24%
Finnish	✓	✓	✓	49	65	44%
German	✓	✓	✗	70	88	48%
Hungarian	✓	✓	✗	136	132	65%
Italian	✗	✓	✗	21	24	50%
Latin	✓	✓	✓	187	190	56%
Polish	✓	✓	✓	72	79	74%
Portuguese	✗	✓	✗	9	10	73%
Romanian	✓	✓	✓	109	122	59%
Russian	✓	✓	✓	84	79	60%
Spanish	✗	✓	✗	27	25	44%

Table 2: Raw error counts out of 1,000 test examples for the target languages. Checkmarks indicate whether UniMorph data was available for a given major category in that language. Error overlap is the percentage of errors made by both systems. There were 1,701 errors in total (823 from UE-LMU-I and 878 from CLUZH-7).

Language	RA	α
Dutch	0.949	0.907
English	0.861	0.855
Spanish	0.861	0.875

Table 3: Inter-annotator agreement statistics for three double-coded languages. RA: raw agreement.

UE-LMU-I gives **at**ue**ngáis* as the second person plural present subjunctive of *atener* 'to maintain'. There is no analogue for this *e-ue* stem change.

4.2.3 Allomorphy errors

With the exception of Hungarian and Latin—which suffer from systematic extraction errors—allomorphy errors are the largest category of error in all languages.

Stem-final vowels in Finnish In Finnish nouns and adjectives, stem-final vowels commonly disappear or alternate with *e* or *o* when the plural marker *i* is added to the stem (Hakulinen et al. 2008:§45). For instance, the inessive plural of *las**i*** 'glass' is *las**e**issa*. In principle, such alternations are predictable given the syllable count of the nominal stem, the stem-final consonants and the penultimate vowel, though the exact conditions are rather complex (Hakulinen et al. 2008:§46–50). For the compound noun *pohjanpystykorva* 'norrbottenspets' (a breed of dog), CLUZH-7 predicts an incorrect gen.pl. form **pohjanpystykorv**o**jen* for intended *pohjanpystykorvien*; it has transformed the stem final *a* to *o* and then selected the wrong plural marker (**-jen* instead of *-ien*) as a result.

Ablaut in Dutch and German Stem vowel alternations in the Germanic strong verbs are known as ablaut. Ablaut is robust in Dutch and German, and in both languages, is occasionally misapplied. In Dutch, for example, both systems overapply ablaut to the 1sg. preterite indicative forms of *printen* 'to print', producing **pr**o**nt* instead of *pr**i**ntte*. Similar errors are found in German. Both systems underapply ablaut to the 1sg. preterite indicative form of *saufen* 'to drink', producing **s**au**fte* instead of the expected *s**o**ff*, and UE-LMU-I overapplies ablaut to the third person preterite subjunctive of the weak verb *versenken* 'to sink', giving **vers**ä**chten* in place of the expected *vers**e**nkten*.

Umlaut in German Another stem change seen in German inflection is umlaut, which converts a *u*, *o*, or *a* in the final syllable of a stem changes to the corresponding front vowel *ü*, *ö*, or *ä*, respectively. Umlaut applies in many different morphological contexts (Hieble 1957), but most saliently in many plural nouns. One or both systems underapply umlaut in otherwise-correct plural forms of *Aasvogel* 'carrion bird', *Augenarzt* 'eye doctor', *Brunst* 'arousal', *Chalkogenidglas* 'chalcogenide glass', *Dachschaden* 'mental issues' (lit. 'roof damage'), *Energiezustand* 'energy level', *Hang* 'slope', *Stiefvater* 'stepfather', *Tibetfuchs* 'Tibetan fox', and *Vertrag* 'treaty'. But the systems also overapply umlaut in **Einwohnerzähle* (from

it here so as to make the data accessible to a wider audience.

Language	Target	Silly		Allomorphy		Spelling	
		UE-LMU-I	CLUZH-7	UE-LMU-I	CLUZH-7	UE-LMU-I	CLUZH-7

Russian	1	5	1
Spanish	2	3	2
Total	11	272	23

Table 5: A breakdown of target errors by sub-category; counts are combined across the two systems. FV: free variation errors; Extraction: extraction errors; Wiktionary: Wiktionary errors.

Einwohnerzahl 'population', **Förmer* (from *Form* 'shape'), **Neuwähle* (from *Neuwahl* 're-vote'), and **Sprösse* (from *Spross* 'bud').

Consonant gradation in Finnish Many Finnish words undergo a set of unpredictable stem changes known as consonant gradation. Here, a "strong grade" of a consonant–normally a voiceless stop like *t*—alternates with the weak grade—a voiced stop like *d*—but the stop may also delete in the weak grade (Hakulinen et al. 2008:§41). Gradation leads to inflection errors because not all lexemes participate in gradation, and because the weak grade of the stem consonant is not predictable from the lemma. For instance, CLUZH-7 incorrectly applies the weak grade to the negated third person singular **ei kiemurda* (from *kiemurtaa* 'to crawl'); the proper gradation is *t-r* instead of the predicted *t-d*. CLUZH-7 also incorrectly produces the strong grade where the weak grade is required, failing to delete the *k* in the comitative **rikoslakein* (from *rikoslaki* 'criminal law').

Linking vowels in Hungarian The Hungarian noun plural suffix is *-k*, usually preceded by a *a*, *o*, *e*, or *ö* linking vowel. For example, the nom.pl. form of *vér* 'blood' is *vér**ek***. The choice of linking vowel is partly determined by vowel harmony: back vowel stems select *a* or *o* whereas front vowel stems select *e* or *ö*. However, for back vowel stems, it is largely unpredictable whether *a* or *o* is used (Siptár and Törkenczy 2000:224f., Vago 1980:110f.), and there are several cases where one or both systems predict an incorrect linking vowel. For example, UE-LMU-I predicts an incorrect elative plural **masszázsakból* for *masszázs* 'massage'; the correct form is *masszázs**ok**ból*.

Yers in Polish Another sub-category of allomorphy error in Polish concerns the yers, the "fleeting vowels" of Slavic. Oblique forms of the Polish nouns *klęsek* 'defeat' and *żag**ie**l* 'sail', for example lack a stem *e* or *ie*, respectively, in certain case forms, as seen in the gen.pl. *klęsk* and

żagli. Because fleeting vowels' position and quality are unpredictable, they cannot be analyzed as epenthetic. Instead, they are assumed to be present in the underlying form of certain roots and affixes, but somehow represented distinctly from the non-fleeting vowels (Lightner 1965, Rubach 1986). According to the analysis, a yer is deleted except when the following syllable also contains an yer, and the fleeting *e* and *ie* surface in the nom.sg. forms above because the masculine nom.sg. suffix is itself a yer (Gussman 1980:36f., Rubach 1984:41). It is impossible to predict the position or quality of a yer without referring to the rest of the inflectional paradigm,[7] and this indeterminacy contributes to several inflectional errors. For instance, CLUZH-7 predicts **żagieli* instead of the expected *żagli*, and both systems predict **klęsek* for of the expected *klęsk*. Similar errors are also found in Russian.

Spanish diphthongization Many Spanish verbs exhibit a stem change in which mid vowels *e* and *o* in the final syllable of the stem diphthongize to *ie* [je] and *ue* [we], respectively, when they bear primary stress. Whether or not a mid vowel participates in diphthongization is largely unpredictable (Brame and Bordelois 1974:132f., Harris 1969:74f.).[8] For example, *negar* 'to deny' undergoes diphthongization (e.g., 1sg. present indicative ***nie***gо), but *pegar* 'to stick' does not (1sg. present indicative *pego*). Both models underapply diphthongization in **despl**e**gue* (from *desplegar* 'to unfold') and **rec**o**la* (from *recolar* 'to strain again'). Interestingly, these are 1st conjugation (i.e., *-ar*) verbs, and children acquiring Spanish tend to underapply diphthongization in this class (Mayol 2007). But CLUZH-7 also overapplies diphthongization in **atañ**ie**res* (from *atañer* 'to concern') and **gañ**ie**seis* (from *gañir* 'to yelp'). Similar errors occur in Portuguese, which also exhibits a stress-conditioned stem vowel alternation.

Noun plural suffixes in German German has five major noun plural suffixes, and many errors involve the use of the wrong plural. The most frequent pattern is the overapplication of the *-(e)n* plural—traditionally regarded as the most productive plural suffix (Bech 1963, Wunderlich 1999)—as in *Eosin* 'eosin', *Fußballweltmeisterschaftsqualifikationsspiel* 'football world championship qualification game', *Hartung*, a poetic term for 'January', *Karbonatit* 'carbonatite', *Metallatom* 'metal atom', and *Vorjahr* 'last year'. Overapplication of *-e* is also common, as in *Abonnement* 'subscription', *Etat* 'budget', *Funke* 'spark', *Katholic* 'Catholic', *Königsgelb* 'yellow pigment', *Reaktorbau* 'reactor construction', *Prinzess* 'princess', *Toupet* 'toupee'. Interestingly, both types of error are produced by children acquiring German (e.g., Clahsen 1999, Marcus et al. 1995, Szagun 2001).

Genitive singular suffixes in Polish Polish has two gen.sg. suffixes, *-a* and *-u*. It is generally impossible to predict which gen.sg. allomorph a given stem will select, and there is no evidence that one is more productive than the other (Dąbrowska 2001, 2005, Kottum 1981, Maunsch 2003). This unpredictable allomorphy causes many gen.sg. errors to both systems, such as **ateusz**u*** for *ateusz**a*** 'atheist', **izotop**a*** for *izotop**u*** 'isotope', **krzyk**a*** for *krzyk**u*** 'scream', and **legar**u*** for *legar**a*** 'joist'.

Verbal prefixes in German Some verbal prefixes in German are known as "separable" because they separate (i.e., are postposed) from their host verb when tensed. Others, the "inseparable" prefixes, are always attached to their host verb without exception. Finally, some prefixes, such as *um-*, are separable or inseparable depending on the verb, and this leads to several errors. For example, both systems predict **__um__kehre* for the 1sg. present indicative of *umkehren* 'to turn around'; the correct form is the separable *kehre __um__*.

Animacy in Polish and Russian Case syncretisms in inanimate (i.e., non-personal) nouns are found in many Slavic languages. However, animacy is an inherent feature of nouns and cannot be predicted from the form of the lemma alone. In Russian, for example, CLUZH-7 wrongly predicts a syncretic acc.pl. for the animate *sadist* 'id.' and both systems incorrectly predict a distinct (i.e., non-syncretic) acc.sg. for the inanimate *magazin* 'shop'. Similarly in Polish, both systems predict incorrect syncretic accusatives for animates such as *śpiewak* 'singer' and *Żyd* 'Jew', and incorrect non-syncretic accusatives for inanimates such as *szampan* 'champagne'. Some Polish stem changes are also conditioned by animacy. For example, for the inanimate noun *katalizator* 'catalyst', both sys-

[7] Gouskova and Becker (2013) and Becker and Gouskova (2016) develop formal models of yer-deletion in Russian, but do not evaluate performance on actual held-out words.

[8] Albright et al. (2001) and Albright (2003) develop a computational model to predict Spanish diphthongization, but do not report its performance on actual held-out verb forms.

tems incorrectly predict a nom.pl. **katalizatorzy* instead of *katalizatory*; the mutation of *r* to *rz* before the nom.pl. *-y* is restricted to masculine animates (Feldstein 2001:27).

Aspect in Russian Russian verbal inflection is conditioned by an inherent feature known as aspect. For instance, the perfective verb *sorvat'* 'to pick' forms a synthetic future whereas the closely-related imperfective *sryvat'* forms a periphrastic (i.e., multi-word) future formed using future-tense forms of *byt'* 'to be'. Several errors involve the wrong future form for a verb's aspect. For example, for the perfective *sorvat'*, CLUZH-7 incorrectly predicts a periphrastic second person singular future **budeš' sorvat'* instead of the expected synthetic *sorvëš'*.

Vowel harmony in Finnish compounds In Finnish, the first stem in a noun compound does not participate in suffix harmony (Hakulinen et al. 2008:§14). For example, the partitive singular of the compound *lapinsirri* 'Temminck's stint' (a type of bird) is the *lapinsirriä*. Because this lemma is a compound of *Lapin* 'of Lapland' and *sirri* 'stint', and because all vowels in the second second stem of the compound are neutral, front harmony—the default—applies. However, CLUZH-7 generates **lapinsirria*, a form which would be correct were the lemma not a compound.

Internal inflection in Russian compounds Many Russian nouns in the shared task are adjective-noun or noun-noun compounds, and systems fail to appropriately inflect both components of the compound. The acc.pl. of *lëgkaja promyšlennost'* 'light industry' is *lëgkie promyšlennosti*, but UE-LMU-I predicts **lëgkix promyšlennosti*, incorrectly placing the adjective in the genitive case. Other adjective-noun compounds for which one or both of the systems fail to produce proper agreement morphology include *vizitnaja kartočka* 'business card' and *bulevo množestvo* 'boolean domain'. Both stems of most noun-noun compounds, particularly hyphenated compounds, are inflected. For example, the prepositional plural of *gosudarstvo-donor* 'donor state' is *gosudarstvax-donorax*, but both systems predict **gosudarstvo-donorax*, in which only the second stem is inflected. However, there are some cases in which one stem of a compound is not declined. For instance, in *sindrom Aspergera* 'Asperger's syndrome', only the head noun *sindrom* should be inflected because *Aspergera* is a nominal modifier and already in genitive case, but both systems incorrectly inflect the second stem producing the gen.pl. **sindromov Asperger*.

4.2.4 Spelling errors

Spelling errors are relatively rare overall. In Dutch, diaeresis is used to mark hiatus—adjacent vowels in consecutive syllables—and thus the past participle of *upgraden* 'to upgrade' should be *geüpgraded*, not the predicted **geupgraded*. Several English errors concern an orthographic doubling of certain final consonants; for example, both systems predict a past participle **disentered* instead of the expected *disenterred*. There are many German spelling errors, including several concerning the spelling of the gen.sg. suffix—written as *-es* or *-s* depending on context—or *s*, *ss*, and *ß*, all pronounced [s]. In Spanish, a *g* followed by *i* or *e* is read as [x], not as [g], so the verb *fungir* 'to service as' has a 1sg. future indicative spelled *funjo* rather than the predicted **fungo*. Several Portuguese and Spanish predictions omit the acute accent used to indicate exceptional primary stress; e.g., Portuguese **influisse* for the 1sg. imperfect subjunctive *influísse* (from *influir* 'to influence').

5 Discussion

5.1 Target errors

Target errors heavily impact performance for Hungarian, Latin, and Romanian. Overall, nearly one fourth of our sample's errors were target errors, and we suspect such errors also lurk in the training and development data. Clearly, the UniMorph data used in this task requires further vetting.

5.2 Allomorphy errors

Overall, silly errors were far less common than allomorphy errors. Many of the allomorphy errors appear to result from unpredictable linguistic behaviors rather than failures to extract reliable generalizations. In some cases, errors reflect systems' inability to predict inherent features such as animacy and aspect in Slavic. Such features are not encoded in UniMorph, although this information is often present on Wiktionary. Generally speaking, these features cannot be predicted from the orthographic form of lemmata,[9] but we

[9] Certain prefixes and stress patterns are cues to aspect in Russian verbs (Wade 2010:268), but this is not true of inherent features in general.

suspect that the relevant information could be induced using either contextual or type-level word embeddings. We leave this for future work.[10] Systems also appear to struggle with lemmata which are themselves internally complex due to word-formation processes like prefixation or compounding, including prefix verbs in German and compounds in Finnish and Russian. Lemma-internal structure, once again, is not currently encoded in UniMorph, though it could in principle be extracted from Wiktionary entries. Finally, we see that systems struggle with certain lexically-specific morphophonological patterns—Germanic ablaut and umlaut, Finnish consonant gradation, Hungarian linking vowels, Slavic yers, and Spanish diphthongization—and with lexically-conditioned affix selection in German and Polish. We have seemingly rediscovered what linguists have long known: certain allomorphic patterns cannot be predicted from the form of lemmata alone; they must be memorized. It is unreasonable to expect any neural network, no matter how powerful, to predict what is truly unpredictable.

Our analysis is limited to languages included the shared task, those for which the top systems have a non-trivial number of errors, and those for which we have sufficient linguistic expertise. As a result, our final sample of twelve languages only includes two major language families, Indo-European and Uralic, the latter represented by Finnish and Hungarian. However, this sample has some degree of grammatical diversity. Linguists traditionally distinguish between two types of morphological exponence. In **agglutination**, each morphological feature corresponds roughly to a single affix. For instance, in the Hungarian form *cinkosoknak*, the dat.pl. of *cinkos* 'accomplice', the *-ok* suffix marks plurality and the *-nak* suffix indicates the dative case. In **fusion**, on the other hand, single affixes may realize many morphological features at once. For instance, in the Russian form *čabrecov*, the gen.pl. of *čabrec* 'thyme', the *-ov* suffix is both genitive and plural (and its form also indirectly indicates that the stem is masculine). Agglutination is characteristic of the Uralic languages, whereas Indo-European languages makes heavy use of fusion. Furthermore, vowel harmony is limited to the two Uralic languages.

[10] Sub-task two of the SIGMORPHON 2019 Shared Task (McCarthy et al. 2019) involves lemmatization and morphological analysis in sentential context, but the applicability of this to the inflection task has not yet received much attention.

6 Conclusion

We propose an error taxonomy for morphological inflection generation and apply it to the predictions of the two best systems in the CoNLL–SIGMORPHON 2017 Shared Task. We estimate a lower bound for the percentage of "target" errors in the gold data. Over 80% of the remaining (non-target) errors can be understood as misapplication of language-specific morphological or spelling principles. One potential remedy is to enrich the input linguistic representations with, e.g., compound structure and inherent grammatical features; however, this is unlikely to avoid all errors; some morphological patterns cannot be generalized but only memorized.

The above analysis depends on manual annotation, but one might prefer to automate error classification. An automated system, for example, could be integrated into a rapid development process, or used as an additional objective during training and tuning, so long as it has reasonably high agreement with human experts. Ideally, such a system would scale to arbitrary languages, not just those for which linguistic expertise is readily available. A powerful ensemble model could help identify candidate target errors, and for certain high-resource languages, it might be possible to leverage finite-state morphological analyzers and lexicons to distinguish between silly, spelling, and allomorphy errors. We leave these and many other open questions for future work.

Acknowledgments

Ekaterina Levitskaya made substantial contributions to early stages of this project. Suzanne van der Feest assisted with Dutch annotations, and Alëna Aksënova assisted with Russian annotations. Richard Sproat provided spiritual guidance and contributed an impressionistic characterization of the sub-task 2 error profiles.

Abstract

Bilingual word embeddings have been widely used to capture the correspondence of lexical semantics in different human languages. However, the cross-lingual correspondence between sentences and words is less studied, despite that this correspondence can significantly benefit many applications such as cross-lingual semantic search and textual inference. To bridge this gap, we propose a neural embedding model that leverages bilingual dictionaries[1]. The proposed model is trained to map the lexical definitions to the cross-lingual target words, for which we explore with different sentence encoding techniques. To enhance the learning process on limited resources, our model adopts several critical learning strategies, including multi-task learning on different bridges of languages, and joint learning of the dictionary model with a bilingual word embedding model. We conduct experiments on two new tasks. In the cross-lingual reverse dictionary retrieval task, we demonstrate that our model is capable of comprehending bilingual concepts based on descriptions, and the proposed learning strategies are effective. In the bilingual paraphrase identification task, we show that our model effectively associates sentences in different languages via a shared embedding space, and outperforms existing approaches in identifying bilingual paraphrases.

1 Introduction

Cross-lingual semantic representation learning has attracted significant attention recently. Various approaches have been proposed to align words of different languages in a shared embedding space (Ruder et al., 2017). By offering task-invariant semantic transfers, these approaches critically support many cross-lingual NLP tasks including neural machine translations (NMT) (Devlin et al., 2014), bilingual document classification (Zhou et al., 2016), knowledge alignment (Chen et al., 2018b) and entity linking (Upadhyay et al., 2018).

While many existing approaches have been proposed to associate lexical semantics between languages (Chandar et al., 2014; Gouws et al., 2015; Luong et al., 2015a), modeling the correspondence between lexical and sentential semantics across different languages is still an unresolved challenge. We argue that learning to represent such cross-lingual and multi-granular correspondence is well desired and natural for multiple reasons. One reason is that, learning word-to-word correspondence has a natural limitation, considering that many words do not have direct translations in another language. For example, *schadenfreude* in German, which means *a feeling of joy that comes from knowing the troubles of other people*, has no proper English counterpart word. To appropriately learn the representations of such words in bilingual embeddings, we need to capture their meanings based on the definitions.

Besides, modeling such correspondence is also highly beneficial to many application scenarios. One example is cross-lingual semantic search of concepts (Hill et al., 2016), where the lexemes or concepts are retrieved based on sentential descriptions (see Fig. 1). Others include discourse relation detection in bilingual dialogue utterances (Jiang et al., 2018), multilingual text summarization (Nenkova et al., 2012), and educational applications for foreign language learners. Finally, it is natural in foreign language learning that a human learns foreign words by looking up their meanings in the native language (Hulstijn et al., 1996). Therefore, learning such correspondence essentially mimics human learning behaviors.

[*] Both authors contributed equally to this work.

[1]We refer the term *dictionary* to its common meaning, i.e. lexical definitions of words. Note that this is different from some papers on bilingual settings that refer dictionaries to seed lexicons for one-to-one word mappings.

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 152–162
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

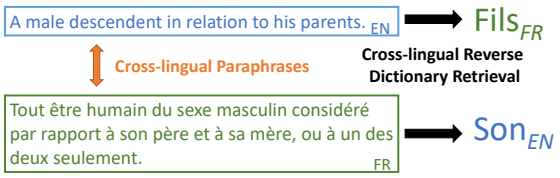

Figure 1: An example illustrating the two cross-lingual tasks. The *cross-lingual reverse dictionary retrieval* finds cross-lingual target words based on descriptions. In terms of *cross-lingual paraphrases*, the French sentence (which means *any male being considered in relation to his father and mother, or only one of them*) describes the same meaning as the English sentence, but has much more content details.

However, realizing such a representation learning model is a non-trivial task, inasmuch as it requires a comprehensive learning process to effectively compose the semantics of arbitrary-length sentences in one language, and associate that with single words in another language. Consequently, this objective also demands high-quality cross-lingual alignment that bridges between single and sequences of words. Such alignment information is generally not available in the parallel and seed-lexicon that are utilized by bilingual word embeddings (Ruder et al., 2017).

To incorporate the representations of bilingual lexical and sentential semantics, we propose an approach to capture *the mapping from the definitions to the corresponding foreign words* by leveraging *bilingual dictionaries* The proposed model `BilDRL` (**Bil**ingual **D**ictionary **R**epresentation **L**earning) first constructs a word embedding space with pre-trained bilingual word embeddings. Based on cross-lingual word definitions, a sentence encoder is trained to realize the mapping from literal descriptions to target words in the bilingual word embedding space, for which we investigate with multiple encoding techniques. To enhance cross-lingual learning on limited resources, `BilDRL` conducts multi-task learning on different directions of a language pair. Moreover, `BilDRL` enforces a joint learning strategy of bilingual word embeddings and the sentence encoder, which seeks to gradually adjust the embedding space to better suit the representation of cross-lingual word definitions.

To show the applicability of `BilDRL`, we conduct experiments on two useful cross-lingual tasks (see Fig. 1). (i) *Cross-lingual reverse dictionary retrieval* seeks to retrieve words or concepts given descriptions in another language. This task is useful to help users find foreign words based on the notions or descriptions, and is especially beneficial to users such as translators, foreigner language learners and technical writers using non-native languages. We show that `BilDRL` achieves promising results on this task, while bilingual multi-task learning and joint learning dramatically enhance the performance. (ii) *Bilingual paraphrase identification* asks whether two sentences in different languages essentially express the same meaning, which is critical to question answering or dialogue systems that apprehend multilingual utterances (Bannard and Callison-Burch, 2005). This task is challenging, as it requires a model to comprehend cross-lingual paraphrases that are inconsistent in grammar, content details and word orders. `BilDRL` maps sentences to the lexicon embedding space. This process reduces the problem to evaluate the similarity of lexicon embeddings, which can be easily solved by a simple classifier. `BilDRL` performs well with even a small amount of data, and significantly outperforms previous approaches.

2 Related Work

We discuss two lines of relevant work.

Bilingual word embeddings. Various approaches have been proposed for training bilingual word embeddings. These approaches span in two families: off-line mappings and joint training.

The off-line mapping based approach fixes the structures of pre-trained monolingual embeddings, and induces bilingual projections based on seed lexicons (Mikolov et al., 2013a). Some variants of this approach improve the quality of projections by adding constraints such as orthogonality of transforms, normalization and mean centering of embeddings (Xing et al., 2015; Artetxe et al., 2016; Vulić et al., 2016). Others adopt canonical correlation analysis to map separate monolingual embeddings to a shared embedding space (Faruqui and Dyer, 2014; Doval et al., 2018).

Unlike off-line mappings, joint training models simultaneously update word embeddings and cross-lingual alignment. In doing so, such approaches generally capture more precise cross-lingual semantic transfer (Ruder et al., 2017; Upadhyay et al., 2018). While a few such models still maintain separated embedding spaces for each language (Artetxe et al., 2017), more of them maintain a unified space for both languages. The

cross-lingual semantic transfer by these models is captured from parallel corpora with sentential or document-level alignment, using techniques such as bilingual bag-of-words distances (BilBOWA) (Gouws et al., 2015), Skip-Gram (Coulmance et al., 2015) and sparse tensor factorization (Vyas and Carpuat, 2016).

Neural sentence modeling. Neural sentence models seek to capture phrasal or sentential semantics from word sequences. They often adopt encoding techniques such as recurrent neural encoders (RNN) (Kiros et al., 2015), convolutional encoders (CNN) (Chen et al., 2018a), and attentive encoders (Rocktäschel et al., 2016) to represent the composed semantics of a sentence as an embedding vector. Recent works have focused on apprehending pairwise correspondence of sentential semantics by adopting multiple neural sentence models in one learning architecture, including Siamese models for detecting discourse relations of sentences (Sha et al., 2016), and sequence-to-sequence models for tasks like style transfer (Shen et al., 2017), text summarization (Chopra et al., 2016) and translation (Wu et al., 2016).

On the other hand, fewer efforts have been put to characterizing the associations between sentential and lexical semantics. Hill et al. (2016) and Ji et al. (2017) learn off-line mappings between monolingual descriptions and lexemes to capture such associations. Eisner et al. (2016) adopt a similar approach to capture emojis based on descriptions. At the best of our knowledge, there has been no previous approach to learn to discover the correspondence of sentential and lexical semantics in a multilingual scenario. This is exactly the focus of our work, in which the proposed strategies of multi-task learning and joint learning are critical to the corresponding learning process under limited resources. Utilizing such correspondence, our approach also sheds light on addressing discourse relation detection in a multilingual scenario.

3 Modeling Bilingual Dictionaries

We hereby begin our modeling with the formalization of bilingual dictionaries. We use $\mathcal{L}$ to denote the set of languages. For a language $l \in \mathcal{L}$, V_l denotes its vocabulary, where for each word $w \in V_l$, bold-faced $\mathbf{w} \in \mathbb{R}^k$ denotes its embedding vector. A l_i-l_j bilingual dictionary $D(l_i, l_j)$ (or simply D_{ij}) contains dictionary entries $(w^i, S_w^j) \in D_{ij}$, in which $w^i \in V_{l_i}$, and $S_w^j = w_1^j \dots w_n^j$ ($w_\cdot^j \in V_{l_j}$) is a cross-lingual definition that describes the word w^i with a sequence of words in language l_j. For example, a French-English dictionary $D(\mathrm{Fr}, \mathrm{En})$ could include a French word *appétite* accompanied by its English definition *desire for, or relish of food or drink*. Note that, for a word w^i, multiple definitions in l_j may coexist.

`BilDRL` is constructed and improved through three stages, as depicted in Fig. 2. A sentence encoder is first used to learn from a bilingual dictionary the association between words and definitions. Then in a pre-trained bilingual word embedding space, multi-task learning is conducted on both directions of a language pair. Lastly, joint learning with word embeddings is enforced to simultaneously adjust the embedding space during the training of the dictionary model, which further enhances the cross-lingual learning process.

It is noteworthy that, NMT (Wu et al., 2016) is considered as an ostensibly relevant method to ours. NMT does not apply to our problem setting bacause it has major differences from our work in those perspectives: (i) In terms of data modalities, NMT has to bridge between corpora of the same granularity, i.e. either between sentences or between lexicons. This is unlike `BilDRL` that captures multi-granular correspondence of semantics across different modalities, i.e. sentences and words; (ii) As for learning strategies, NMT relies on an encoder-decoder architecture using end-to-end training (Luong et al., 2015b), while `BilDRL` employs joint learning of a dictionary-based sentence encoder and a bilingual embedding space.

3.1 Encoders for Lexical Definitions

`BilDRL` models a dictionary using a neural sentence encoder $E(S)$, which composes the meaning of the sentence into a latent vector representation. We hereby introduce this model component, which is designed to be a GRU encoder with self-attention. Besides that, we also investigate other widely-used neural sequence encoders.

3.1.1 Attentive GRU Encoder

The GRU encoder is a computationally efficient alternative of the LSTM (Cho et al., 2014). Each unit consists of a reset gate $\mathbf{r}_t$ and an update gate $\mathbf{z}_t$ to track the state of the sequence. Given the vector representation $\mathbf{w}_t$ of an incoming item w_t, GRU updates the hidden state $\mathbf{h}_t^{(1)}$ as a linear combination of the previous state $\mathbf{h}_{t-1}^{(1)}$ and the candidate

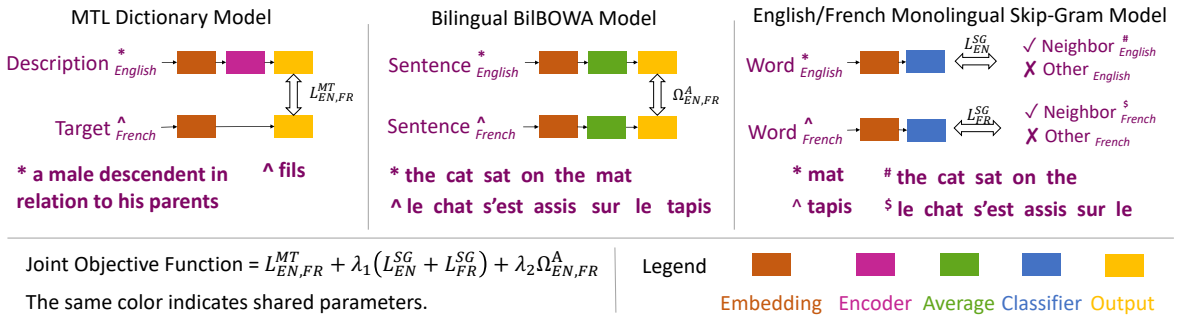

Figure 2: Joint learning architecture of BilDRL.

state $\tilde{\mathbf{h}}_t^{(1)}$ of the new item w_t as below.

$$\mathbf{h}_t^{(1)} = \mathbf{z}_t \odot \tilde{\mathbf{h}}_t^{(1)} + (1 - \mathbf{z}_t) \odot \mathbf{h}_{t-1}^{(1)}.$$

The update gate $\mathbf{z}_t$ balances between the information of the previous sequence and the new item, where $\mathbf{M}_z$ and $\mathbf{N}_z$ are two weight matrices, $\mathbf{b}_z$ is a bias vector, and σ is the sigmoid function.

$$\mathbf{z}_t = \sigma\left(\mathbf{M}_z\mathbf{x}_t + \mathbf{N}_z\mathbf{h}_{t-1}^{(1)} + \mathbf{b}_z\right).$$

The candidate state $\tilde{\mathbf{h}}_t^{(1)}$ is calculated similarly to those in a traditional recurrent unit as below. The reset gate $\mathbf{r}_t$ thereof controls how much information of the past sequence should contribute to the candidate state.

$$\tilde{\mathbf{h}}_t^{(1)} = \tanh\left(\mathbf{M}_s\mathbf{w}_t + \mathbf{r}_t \odot (\mathbf{N}_s\mathbf{h}_{t-1}^{(1)}) + \mathbf{b}_s\right)$$
$$\mathbf{r}_t = \sigma\left(\mathbf{M}_r\mathbf{w}_t + \mathbf{N}_r\mathbf{h}_{t-1}^{(1)} + \mathbf{b}_r\right).$$

While a GRU encoder can stack multiple of the above GRU layers, without an attention mechanism, the last state $\mathbf{h}_S^{(1)}$ of the last layer represents the overall meaning of the encoded sentence S.

The self-attention mechanism (Conneau et al., 2017) seeks to highlight the important units in an input sentence when capturing its overall meaning, which is calculated as below:

$$\mathbf{u}_t = \tanh\left(\mathbf{M}_a\mathbf{h}_t^{(1)} + \mathbf{b}_a\right)$$
$$a_t = \frac{\exp\left(\mathbf{u}_t^\top \mathbf{u}_S\right)}{\sum_{w_m \in S} \exp\left(\mathbf{u}_m^\top \mathbf{u}_S\right)}$$
$$\mathbf{h}_t^{(2)} = |S| a_t \mathbf{u}_t.$$

$\mathbf{u}_t$ is the intermediary representation of GRU output $\mathbf{h}_t^{(1)}$, and $\mathbf{u}_S = \tanh(\mathbf{M}_a\mathbf{h}_S^{(1)} + \mathbf{b}_a)$ is that of the last GRU output $\mathbf{h}_S^{(1)}$. $\mathbf{u}_S$ can be seen as a high-level representation of the input sequence. By measuring the similarity of each $\mathbf{u}_t$ with $\mathbf{u}_S$, the normalized attention weight a_t, which highlights an input that contributes significantly to the overall meaning, is produced through a softmax. Note that a scalar $|S|$ is multiplied along with a_t to $\mathbf{u}_t$, so as to keep the weighted representation $\mathbf{h}_t^{(2)}$ from losing the scale of $\mathbf{h}_t^{(1)}$. The sentence encoding is calculated as the average of the last attention layer $E^{(1)}(S) = \frac{1}{|S|}\sum_{t=1}^{|S|} a_t\mathbf{h}_t^{(2)}$.

3.1.2 Other Encoders

We also experiment with other widely used neural sentence modeling techniques[2], which are however outperformed by the attentive GRU in our tasks. These techniques include the vanilla GRU, CNN (Kalchbrenner et al., 2014), and linear bag-of-words (BOW) (Hill et al., 2016). We briefly introduce the later two techniques in the following.

A convolutional encoder applies a kernel $\mathbf{M}_c \in \mathbb{R}^{h\times k}$ to produce the latent representation $\mathbf{h}_t^{(3)} = \tanh(\mathbf{M}_c\mathbf{w}_{t:t+h-1} + \mathbf{b}_c)$ from each h-gram of the input vector sequence $\mathbf{w}_{t:t+h-1}$, for which h is the kernel size and $\mathbf{b}_c$ is a bias vector. A sequence of latent vectors $\mathbf{H}^{(3)} = [\mathbf{h}_1^{(3)}, \mathbf{h}_2^{(3)}, ..., \mathbf{h}_{|S|-h+1}^{(3)}]$ is produced from the input, where each latent vector leverages the significant local semantic features from each h-gram. Following convention (Liu et al., 2017), we apply dynamic max-pooling to extract robust features from the convolution outputs, and use the mean-pooling results of the last layer to represent the sentential semantics.

The Linear bag-of-words (BOW) encoder (Ji et al., 2017; Hill et al., 2016) is realized by the

[2]Note that recent advances in monolingual contextualized embeddings like multilingual ELMo (Peters et al., 2018; Che et al., 2018) and M-BERT (Pires et al., 2019; Devlin et al., 2018) can also be supported to represent sentences for our setting. We leave them as future work, as they require non-trivial adaption to both multilingual settings and joint training, and extensive pre-training on external corpora.

sum of projected word embeddings of the input sentence, i.e. $E^{(2)}(S) = \sum_{t=1}^{|S|} \mathbf{M}_b \mathbf{w}_t$.

3.2 Basic Learning Objective

The objective of learning the dictionary model is to map the encodings of cross-lingual word definitions to the target word embeddings. This is realized by minimizing the following L_2 loss,

$$L_{ij}^{\mathrm{ST}} = \frac{1}{|D_{ij}|} \sum_{(w^i, S_w^j) \in D_{ij}} \left\| E_{ij}(S_w^j) - \mathbf{w}^i \right\|_2^2$$

in which E_{ij} is the dictionary model that maps from descriptions in l_j to words in l_i.

The above defines the basic model variants of `BilDRL` that learns on a single dictionary. For word representations in the learning process, `BilDRL` initializes the embedding space using pre-trained word embeddings. Note that, without adopting the joint learning strategy in Section 3.4, the learning process does not update word embeddings that are used to represent the definitions and target words. While other forms of loss such as cosine proximity (Hill et al., 2016) and hinge loss (Ji et al., 2017) may also be used in the learning process, we find that L_2 loss consistently leads to better performance in our experiments.

3.3 Bilingual Multi-task Learning

In cases where entries in a bilingual dictionary are not amply provided, learning the above bilingual dictionary on one ordered language pair may fall short in insufficiency of alignment information. One practical solution is to conduct a bilingual multi-task learning process. In detail, given a language pair (l_i, l_j), we learn the dictionary model E_{ij} on both dictionaries D_{ij} and D_{ji} with shared parameters. Correspondingly, we rewrite the previous learning objective function as below, in which $D = D_{ij} \cup D_{ji}$.

$$L_{ij}^{\mathrm{MT}} = \frac{1}{|D|} \sum_{(w, S_w) \in D} \left\| E_{ij}(S_w) - \mathbf{w} \right\|_2^2 .$$

This strategy non-trivially requests the same dictionary model to represent semantic transfer in two directions of the language pair. To fulfill such a request, we initialize the embedding space using the BilBOWA embeddings (Gouws et al., 2015), which provide a unified embedding space that resolves both monolingual and cross-lingual semantic relatedness of words. In practice, we find this simple multi-task strategy to bring significant improvement to our cross-lingual tasks. Note that, besides BilBOWA, other joint-training bilingual embeddings in a unified space (Doval et al., 2018) can also support this strategy, for which we leave the comparison to future work.

3.4 Joint Learning Objective

While above learning strategies are based on a fixed embedding space, we lastly propose a joint learning strategy. During the training process, this strategy simultaneously updates the embedding space based on both the dictionary model and the bilingual word embedding model. The learning is through asynchronous minimization of the following joint objective function,

$$J = L_{ij}^{\mathrm{MT}} + \lambda_1 (L_i^{\mathrm{SG}} + L_j^{\mathrm{SG}}) + \lambda_2 \Omega_{ij}^{\mathrm{A}},$$

where λ_1 and λ_2 are two positive hyperparameters. L_i^{SG} and L_j^{SG} are the original Skip-Gram losses (Mikolov et al., 2013b) to separately obtain word embeddings on monolingual corpora of l_i and l_j. Ω_{ij}^{A}, termed as below, is the alignment loss to minimize bag-of-words distances for aligned sentence pairs (S^i, S^j) in parallel corpora C_{ij}.

$$\Omega_{ij}^{\mathrm{A}} = \frac{1}{|C_{ij}|} \sum_{(S^i, S^j) \in C_{ij}} d_{\mathrm{S}}(S^i, S^j)$$

$$d_{\mathrm{S}}(S^i, S^j) = \left\| \frac{1}{|S^i|} \sum_{w_m^i \in S^i} \mathbf{w}_m^i - \frac{1}{|S^j|} \sum_{w_n^j \in S^j} \mathbf{w}_n^j \right\|_2^2$$

The joint learning process adapts the embedding space to better suit the dictionary model, which is shown to further enhance the cross-lingual learning of `BilDRL`.

3.5 Training

To initialize the embedding space, we pre-trained BilBOWA on the parallel corpora Europarl v7 (Koehn, 2005) and monolingual corpora of tokenized Wikipedia dump (Al-Rfou et al., 2013). For models without joint learning, we use AMSGrad (Reddi et al., 2018) to optimize the parameters. Each model without bilingual multi-task learning thereof, is trained on batched samples from each individual dictionary. Multi-task learning models are trained on batched samples from two dictionaries. Within each batch, entries of different directions of languages can be mixed together. For joint learning, we conduct an efficient

multi-threaded asynchronous training (Mnih et al., 2016) of AMSGrad. In detail, after initializing the embedding space based on pre-trained BilBOWA, parameter updating based on the four components of J occurs across four worker threads. Two monolingual threads select batches of monolingual contexts from the Wikipedia dump of two languages for Skip-Gram, one alignment thread randomly samples parallel sentences from Europarl, and one dictionary thread extracts samples of entries for a bilingual multi-task dictionary model. Each thread makes a batched update to model parameters asynchronously for each term of J. The asynchronous training of all threads keeps going until the dictionary thread finishes its epochs.

4 Experiments

We present experiments on two multilingual tasks: the cross-lingual reverse dictionary retrieval task and the bilingual paraphrase identification task.

4.1 Datasets

The experiment of cross-lingual reverse dictionary retrieval is conducted on a trilingual dataset *Wikt3l*. This dataset is extracted from Wiktionary[3], which is one of the largest freely available multilingual dictionary resources on the Web. Wikt3l contains dictionary entries of language pairs (English, French) and (English, Spanish), which form En-Fr, Fr-En, En-Es and Es-En dictionaries on four bridges of languages in total. Two types of cross-lingual definitions are extracted from Wiktionary: (i) cross-lingual definitions provided under the *Translations* sections of Wiktionary pages; (ii) monolingual definitions for words that are linked to a cross-lingual counterpart with a inter-language link[4] of Wiktionary. We exclude all the definitions of stop words in constructing the dataset, and list the statistics in Table 1.

Since existing datasets for paraphrase identification are merely monolingual, we contribute with another dataset *WBP3l* for cross-lingual sentential paraphrase identification. This dataset contains 6,000 pairs of bilingual sentence pairs respectively for En-Fr and En-Es settings. Within each bilingual setting, positive cases are formed as pairs of descriptions aligned by inter-language links, which exclude the word descriptions in Wikt3l for training `BilDRL`. To generate negative examples, given a source word, we first find its 15 nearest neighbors in the embedding space. Within the nearest neighbors, we use ConceptNet (Speer et al., 2017) to filter out the synonyms of the source word, so as to prevent from generating false negative cases. Then we randomly pick one word from the filtered neighbors and pair its cross-lingual definition with the English definition of the source word to create a negative case. This process ensures that each negative case is endowed with limited dissimilarity of sentence meanings, which makes the decision more challenging. For each language setting, we randomly select 70% for training, 5% for validation, and the rest 25% for testing. Note that each language setting of this dataset thereof, matches with the quantity and partitioning of sentence pairs in the widely-used Microsoft Research Paraphrase Corpus benchmark for monolingual paraphrase identification (Yin et al., 2016; Das and Smith, 2009). Several examples from the dataset are shown in Table 2. The datasets and the processing scripts are available at `https://github.com/muhaochen/bilingual_dictionaries`.

Dictionary	En-Fr	Fr-En	En-Es	Es-En
#Target words	15,666	16,857	8,004	16,986
#Definitions	50,412	58,808	20,930	56,610

Table 3: Cross-lingual reverse dictionary retrieval results by BilDRL variants. We report $P@1$, $P@10$, and MRR on four groups of models: (i) basic dictionary models that adopt four different encoding techniques (BOW, CNN, GRU and ATT); (ii) models with the two best encoding techniques that enforce the monolingual retrieval approach by Hill et al. (2016) (GRU-mono and ATT-mono); (iii) models adopting bilingual multi-task learning (GRU-MTL and ATT-MTL); (iv) joint learning that employs the best dictionary model of ATT-MTL (ATT-joint).

gies, we also compare with the monolingual retrieval approach proposed by Hill et al. (2016). Instead of directly associating cross-lingual word definitions, this approach learns definition-to-word mappings in a monolingual scenario. When it applies to the multilingual setting, given a lexical definition, it first retrieves the corresponding word in the source language. Then, it looks for semantically related words in the target language using bilingual word embeddings. As discussed in Section 3, NMT does not apply to this task due that it cannot capture the multi-granular correspondence between a sentence and a word.

Evaluation Protocol. Before training the models, we randomly select 500 word definitions from each dictionary respectively as test cases, and exclude these definitions from the training data. Each of the basic BilDRL variants are trained on one bilingual dictionary. The monolingual retrieval models are trained to fit the target words in the original languages of the word definitions, which are also provided in Wiktionary. BilDRL variants with multi-task or joint learning use both dictionaries of the same language pair. In the test phase, for each test case $(w^i, S_w^j) \in D_{ij}$, the prediction performs a kNN search from the definition encoding $E_{ij}(S_w^j)$, and record the rank of w^i within the vocabulary of l_i. We limit the vocabularies to all words that appear in the Wikt3l dataset, which involve around 45k English words, 44k French words and 36k Spanish words. To prevent the surface information of the target word from appearing in the definition, we have also masked out any translation of the target word occurring in the definition using a wildcard token <concept>. We aggregate three metrics on test cases: the accuracy $P@1$ (%), the proportion of ranks no larger than 10 $P@10$ (%), and mean reciprocal rank MRR.

We pre-train BilBOWA based on the original configuration by Gouws et al. (2015) and obtain 50-dimensional initialization of bilingual word embedding spaces respectively for the English-French and English-Spanish settings. For CNN, GRU, and attentive GRU (ATT) encoders, we stack five of each corresponding encoding layers with hidden-sizes of 200, and two affine layers are applied to the final output for dimension reduction. This encoder architecture consistently represents the best performance through our tuning. Through comprehensive hyperparameter tuning, we fix the learning rate α to 0.0005, the exponential decay rates of AMSGrad β_1 and β_2 to 0.9 and 0.999, coefficients λ_1 and λ_2 to both 0.1, and batch size to 64. Kernel-size and pooling-size are both set to 2 for CNN. Word definitions are zero-padded (short ones) or truncated (long ones) to the sequence length of 15, since most definitions (over 92%) are within 15 words in the dataset. Training is limited to 1,000 epochs for all models as well as the dictionary thread of asynchronous joint learning, in which all models are able to converge.

Results. Results are reported in Table 3 in four groups. The first group compares four different encoding techniques for the basic dictionary models. GRU thereof consistently outperforms CNN and BOW, since the latter two fail to capture the important sequential information for descriptions. ATT that weighs among the hidden states has notable improvements over GRU. While we equip the two better encoding techniques with the monolingual retrieval approach (GRU-mono and ATT-mono), we find that the way of learning the dictionary models towards monolingual targets and

retrieving cross-lingual related words incurs more impreciseness to the task. For models of the third group that conduct multi-task learning in two directions of a language pair, the results show significant enhancement of performance in both directions. For the final group of results, we incorporate the best variant of multi-task models into the joint learning architecture, which leads to compelling improvement of the task on all settings. This demonstrates that properly adapting the word embeddings in joint with the bilingual dictionary model efficaciously constructs the embedding space that suits better the representation of both bilingual lexical and sentential semantics.

In general, this experiment has identified the proper encoding techniques of the dictionary model. The proposed strategies of multi-task and joint learning effectively contribute to the precise characterization of the cross-lingual correspondence of lexical and sentential semantics, which have led to very promising capability of cross-lingual reverse dictionary retrieval.

4.3 Bilingual Paraphrase Identification

The bilingual paraphrase identification problem[5] is a binary classification task with the goal to decide whether two sentences in different languages express the same meanings. BilDRL provides an effective solution by transferring sentential meanings to word-level representations and learning a simple classifier. We evaluate three variants of BilDRL on this task using WBP3l: the multi-task BilDRL with GRU encoders (BilDRL-GRU-MTL), the multi-task BilDRL with attentive GRU encoders (BilDRL-ATT-MTL), and the joint learning BilDRL with with attentive GRU encoders (BilDRL-ATT-joint). We compare against several baselines of neural sentence pair models that are proposed for monolingual paraphrase identification. These models include Siamese structures of CNN (BiCNN) (Yin and Schütze, 2015), RNN (BiLSTM) (Mueller and Thyagarajan, 2016), attentive CNN (ABCNN) (Yin et al., 2016), attentive GRU (BiATT) (Rocktäschel et al., 2016), and BOW (BiBOW). To support the reasoning of cross-lingual semantics, we provide the baselines with the same BilBOWA embeddings.

[5]Paraphrases have similar meanings, but can largely differ in content details and word orders. Hence, they are essentially different from translations. We have found that even the well-recognized Google NMT frequently caused distortions to short sentence meanings, and led to results that were close to random guess by the baseline classifiers after translation.

Languages	En&Fr		En&Es	
Metrics	*Acc.*	*F1*	*Acc.*	*F1*
BiBOW	54.93	0.622	56.27	0.623
BiCNN	54.33	0.625	53.80	0.611
ABCNN	56.73	0.644	58.83	0.655
BiLSTM	59.60	0.662	57.60	0.637
BiATT	61.47	0.699	61.27	0.689
BilDRL-GRU-MTL	64.80	0.732	63.33	0.722
BilDRL-ATT-MTL	65.27	0.735	66.07	0.735
BilDRL-ATT-joint	**68.53**	**0.785**	**67.13**	**0.759**

Table 4: Accuracy and F1-scores of bilingual paraphrase identification. For BilDRL, the results by three model variants are reported: BilDRL-GRU-MTL and BilDRL-ATT-MTL are models with bilingual multi-task learning, and BilDRL-ATT-joint is the best ATT-based dictionary model variant deployed with both multi-task and joint learning.

Evaluation protocol. BilDRL transfers each sentence into a vector in the word embedding space. Then, for each sentence pair in the train set, a Multi-layer Perceptron (MLP) with a binary softmax loss is trained on the subtraction of two vectors as a downstream classifier. Baseline models are trained end-to-end, each of which directly uses a parallel pair of encoders with shared parameters and an MLP that is stacked to the subtraction of two sentence vectors. Note that some works use concatenation (Yin and Schütze, 2015) or Manhattan distances (Mueller and Thyagarajan, 2016) of sentence vectors instead of their subtraction (Jiang et al., 2018), which we find to be less effective on small amount of data.

We apply the configurations of the sentence encoders from the last experiment to corresponding baselines, so as to show the performance under controlled variables. Training of a classifier is terminated by early-stopping based on the validation set. Following convention (Hu et al., 2014; Yin et al., 2016), we report the accuracy and F1 scores.

Results. This task is challenging due to the heterogeneity of cross-lingual paraphrases and limitedness of learning resources. The results in Table 4 show that all the baselines, where BiATT consistently outperforms the others, merely reaches slightly over 60% of accuracy on both En-Fr and En-Es settings. We believe that it comes down to the fact that sentences of different languages are often drastically heterogenous in both lexical semantics and the sentence grammar that governs the composition of words. Hence, it is not surprising that previous neural sentence pair models, which capture the semantic relation of bilingual sentences directly from all participating words, fall short at the multilingual task. BilDRL, how-

ever, effectively leverages the correspondence of lexical and sentential semantics to simplify the task to an easier entailment task in the lexicon space, for which the multi-task learning BilDRL-ATT-MTL outperforms the best baseline respectively by 3.80% and 4.80% of accuracy in both language settings, while BilDRL-ATT-joint, employing the joint learning, further improves the task by another satisfying 3.26% and 1.06% of accuracy. Both also show notable increment in F1.

5 Conclusion and Future Work

In this paper, we propose a neural embedding model BilDRL that captures the correspondence of cross-lingual lexical and sentential semantics. We experiment with multiple forms of neural models and identify the best technique. The two learning strategies, bilingual multi-task learning and joint learning, are effective at enhancing the cross-lingual learning with limited resources, and also achieve promising performance on cross-lingual reverse dictionary retrieval and bilingual paraphrase identification tasks by associating lexical and sentential semantics. An important direction of future work is to explore whether the word-sentence alignment can improve bilingual word embeddings. Applying BilDRL to bilingual question answering and semantic search systems is another important direction.

Abstract

Recently, language models (LMs) or language representation models are widely used in natural language understanding (NLU) tasks. However, these LMs are usually trained on large unlabeled text corpora, while the fine-tuning process simply takes words or word-pieces as model input. Because of the differences between language model and NLU task objectives, the problem of lack of concern on some key words exists. Thus in this paper, we propose a method called reverse mapping bytepair encoding, which maps named-entity information and other word-level linguistic features back to subwords during the encoding procedure of bytepair encoding (BPE). We employ this method to the Generative Pre-trained Transformer (OpenAI GPT) (Radford et al., 2018) by adding a weighted linear layer after the embedding layer. We also propose a new model architecture named as the multi-channel separate transformer to evaluate the effectiveness of the newly introduced information by employing a training process without parameter-sharing. Experiments on Story Cloze, RTE, SciTail and SST-2 datasets demonstrate the effectiveness of our approach. Compared with the original results in GPT, our approach gains 1.58% absolute increase on Stories Cloze, 6.4% on RTE, 0.69% on SciTail and 0.8% on SST-2.

1 Introduction

Recently, language models are widely used as the feature extractor for many NLU tasks. Statistical language models learn the joint probability function of sequences of words in a language (Bengio et al., 2003). Trained on large corpora and different domains give LMs generalization abilities, and enable them to capture latent or deep senmantics. Normally, statistical language models take the following objective to maximize:

$$L_1(u) = \sum_i \log P(u_i | u_{i-k}, ..., u_{i-1}; \Theta) \quad (1)$$

where k is the size of the context window, and the conditional probability P is modeled using a neural network with parameters Θ.

However, this formal simplicity determines that they can not deal well with the ambiguity of words nor low-frequency words. In fact, low-frequency words may appear once or little times in the whole corpus, thus the embeddings of them may overfit or underfit the corpus. In practice, we usually truncate them from the vocabulary and replace them with an "UNK" label. In this situation, we partially lose their meanings. For example, in "15 million tonnes of rubbish are produced daily in Cairo.", the number "15" can hardly be trained to gain its proper representation even if it is replaced by a specific label representing numbers. Besides, out of vocabulary (OOV) is a big problem while predicting. Some kinds of word segmentation technologies have been proposed (Joulin et al., 2017; ray Su and yi Lee, 2017) to solve these problems.

BPE (Sennrich et al., 2016) has been proposed to handle these problems as well. It shows its powerful effectiveness in many works (Sennrich and Haddow, 2016; Radford et al., 2018; Devlin et al., 2018). However, it is originally designed to handle open-vocabulary problem in machine translation, basing on the intuition that various word classes are translatable via smaller units than words, for instance names (via character copying or transliteration), compounds (via compositional translation), and cognates and loanwords (via phonological and morphological transformations). Thus compared with semantic characteristics, morphological and compounding characteristics are more considered. The unique meanings of some proper

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 163–173
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

nouns are missing while simply applying it to some NLU tasks. Consider the following textual entailment example:

Example 1. t. *Traditionally, the* ***Brahui*** *of the* ***Raisani*** *tribe are in charge of the law and order situation through the Pass area. This tribe is still living in present day* ***Balochistan*** *in Pakistan.*

h. *The* ***Raisani*** *tribe resides in Pakistan.*

$t \rightarrow h$: *entailment*

BPE:

Brahui: bra hu i

Raisani: rai san i

Balochistan: bal o chi stan

In this example, proper nouns play an important role, but they are divided into wordpieces shared with other words. Especially they have common pieces such as "i" and "o". Therefore, inferring from the encoded sequence can be quite difficult.

Apart from this, let us motivate the lack of concern on some key words or phrases of such method. Here is another example:

Example 2. t. *Cairo is now home to* ***some 15 million*** *people - a burgeoning population that produces* ***approximately 10,000 tonnes*** *of rubbish per day, putting an enormous strain on public services...*

h. ***15 million tonnes*** *of rubbish are produced* ***daily*** *in Cairo.*

$t \rightarrow h$: *not_entailment*

In this case, "15 million tonnes" is the key phrase while "15", "million" and "tonnes" also appear in the context. Word-level or subword-level information is obviously not enough.

To alleviate these issues, we propose a reverse mapping bytepair encoding method to integrate prior knowledge into subwords. The prior knowledge mentioned here includes named-entity information, part-of-speech (POS) tags and dependency parsing labels. Our method has two forms and both of them modify the encoding procedure of BPE. In the conventional form, firstly we tag and parse the target sentence which needs to be tagged with NER, POS taggers as well as a dependency parser. After that, we handle the target sentence with the original BPE algorithm. Note that the taggers and the parser work on the word-level while BPE works on the wordpiece-level. Finally, we encode every wordpiece as a combination of linguistic features of its parent word and itself. To avoid over-reliance on the performance of external tools and error propagation, we modify the former as named-entity phrase based reverse mapping, which adds named-entity phrases to the vocabulary during the scanning process of the whole corpus and encodes a wordpiece as the combination of the named-entity phrase where the wordpiece comes from and itself. We evaluate our method on a set of NLU tasks by applying it to GPT. More specifically, we add a weighted layer after the embedding layer to get different weighted combinations of the inputs. We also propose a new model architecture named as the multi-channel separate transformer to employ a training process without parameter-sharing for wordpieces and additional features. We evaluate our approach on two natural language inference tasks (RTE, SciTail), a question answering task (Story Cloze Test) and a classification task (SST-2), showing the benifits of our approach.

2 Related Work

Improving natural language understanding requires better techniques for modeling natural language. There have been many researchers working on better capturing semantic and morphological information of word vectors (Mikolov et al., 2013a,b; Huang et al., 2012; Levy and Goldberg, 2014b; Pennington et al., 2014). Utilizing internal information has been widely studied, and most of these works employed structural information between words and smaller units (Chen et al., 2015; Iacobacci et al., 2015; Bojanowski et al., 2017; Yu et al., 2017; Xu et al., 2018). Another relative research direction is to use external knowledge. The researchers in Microsoft (Song et al., 2011) employed a big and rich probabilistic knowledge-base to machine learning algorithms, and got significant improvement in terms of tweets clustering accuracy. However, such method needs huge human and material resources to build up a high-quality and extremely wide-coverage knowledge base. Recently, a novel language representation model called ERNIE (Zhang et al., 2019) has been proposed. ERNIE introduces knowledge-related tasks in the pre-training process. Besides, it utilizes graph embedding methods to get the embedded representation of entities. Compared with it, our method does not rely upon external knowledge bases and it can be a double-edged sword. In addition, our method provides syntactic information integration and allows principled integration of named-entity information in an easier way.

There is also a class of method, instead of relying a lot on external knowledge, it takes advantage of the linguistic features that exist in natural language. Levy (Levy and Goldberg, 2014a) generalized the skip-gram model to include arbitrary contexts by dependency parsing. The dependency-based embeddings are less topical and exhibit more functional similarity than the original skip-gram embeddings. Multimodal representations of chinese characters (ray Su and yi Lee, 2017) have also been studied, and the research showed the effectiveness of glyph features in some cases. Sennrich (Sennrich and Haddow, 2016) proposed an approach to employ linguistic features for neural machine translation (NMT). These features include lemmas, subword tags, morphological features, POS tags and dependency labels. Different from us, they paid more attention on how to improve NMT from the morphological level. Besides, they did not consider named entities. Another work relevant to us is (Nallapati et al., 2016). They proposed a feature-rich encoder to capture keywords in summarization. Their model employs a word-level vocabulary, and the words are embedded by concatenating all kinds of features including POS, NER tags and discretized TF and IDF values. Different from them, our approach works on the subword level and leverages linguistic features at the semantic level.

There are many kinds of neural networks that can deal with NLU tasks. Recently, pre-trained language models or language representation models have been widely used and these works got significant improvements (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2018). Trained on large corpora will inevitably face the big-vocabulary problem and the OOV problem. Thus researchers have proposed several methods to handle them. FastText (Joulin et al., 2017) employed n-grams thus it could predict the zero-shot word embeddings. However, n-gram is an arbitrary method of word segmentation. Sennrich (Sennrich et al., 2016) adapted the original byte pair encoding (BPE) compression algorithm to NMT and got significant success. This method iteratively merges most frequent adjacent characters or character sequences in a word until it can not be done, based on the well learned token rank. Therefore it can encode any word with a pre-learned token vocalulary. We give an illustration as Figure 1, showing the ranking process of BPE. GPT (Radford et al., 2018) applied BPE to its training process and got impressive achievements in a series of NLU tasks. Due to the greedy nature of BPE algorithm, the results produced by BPE are deterministic, resulting in insufficient robustness in machine translation. Kudo (Kudo, 2018) located this problem and proposed a subword regularization method to handle it. He trained the NMT model with multiple subword segmentations generated in a probability manner and got improvements especially on low resource and out-of-domain settings. This study provides an interesting insight, but we argue that it may not bring significant improvement in NLU tasks. In fact, BPE is proposed to model open-vocabulary translation in NMT, which is inconsistent with the goal of some natural language understanding tasks. That motivates us to start our work.

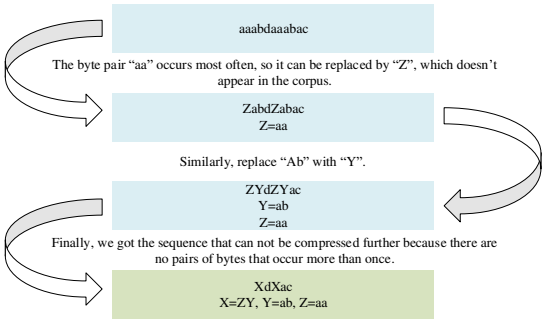

Figure 1: Ranking process of bytepair encoding.

3 Methods

In this section, we introduce our reverse mapping bytepair encoding method and the procedure of applying it to GPT. The reverse mapping bytepair encoding has two forms: label based (LB-BPE) and named-entity phrase based (NPB-BPE). Figure 2 provides a visual illustration. We employ them to the fine-tuning process of GPT by adding a weighted layer after the embedding layer. Besides, we propose a multi-channel separate transformer (MCST) to evaluate the utility of introduced features and give some insights into the semantic capture capabilities of the transformer. The model architecture is shown in Figure 3.

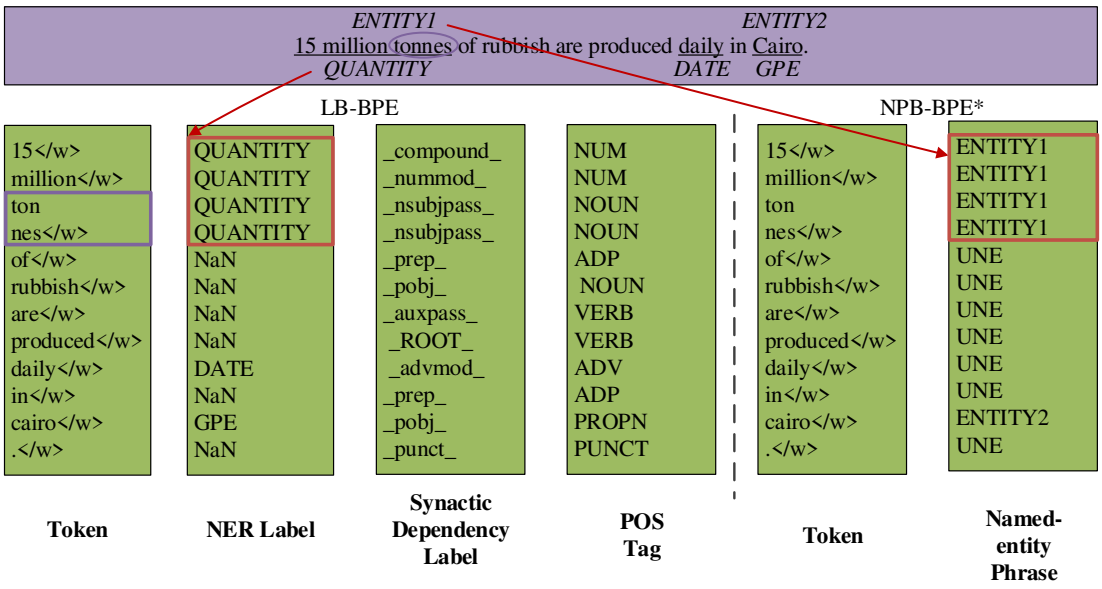

Figure 2: "tonnes" is encoded to be two tokens: "ton", "nes⟨/w⟩". **(Left)** LB-BPE result. Each token consists of four parts: token, NER label, synactic dependency label and POS tag. Words in the original text pass their linguistic features to the tokens generated from them. **(Right)** NPB-BPE* result. Each token consists of two parts: token and corresponding entity.

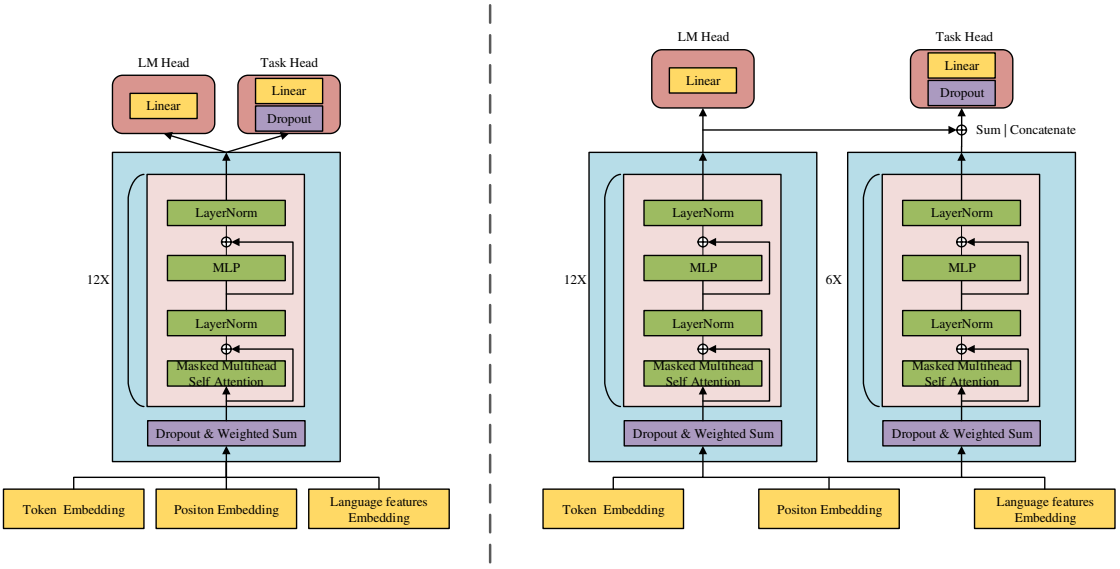

Figure 3: **(Left)** Parameter-sharing training procedure. **(Right)** Multi-channel separate transformer. Language model loss is only generated by the left transformer. The input of the task specific head is the sum or concatenation of both transformers outputs.

3.1 Label Based Reverse Mapping Bytepair Encoding

We extend a token t generated by BPE to four parts $\{t, t_{pos}, t_{ner}, t_{dep}\}$, where t is the same as the original encoded token in BPE, t_{pos} is the POS tag of the word which generates this token, similar with t_{ner} and t_{dep}. Not all words are tagged with named-entity labels, therefore we tag these tokens without NER labels as "NaN". We regard t_{pos}, t_{ner}, t_{dep} as additional features that could not be captured fully by language models. Table 1 shows the amount of features of various types.

Feature type	Amount
NER	20
POS	19
DEP	51

Table 1: Amount of different types of features.

Schemes come from *Spacy Annotation Specifications*[1]. We use *spaCy*[2] to tokenize, tag and parse the datasets during our experiments. We simply use the dependency labels instead of the whole dependency parsing tree because of two reasons: one is it brings complex changes to the input architecture, the other is that we assume the transformer architecture has the ability to establish some kinds of patterns to capure the dependencies between tokens generated by BPE.

3.2 Named-entity Phrase Based Bytepair Encoding

Algorithm 1: Encoding process for NPB-BPE

Input :
Given sentence S;
Pretrained lookup table T for tokens;
Lookup table T_{ne} for named-entity phrases;
NER Scheme Θ := {B,I,O};
Output:
Encoded sequence S';

Current named-entity token array e;
for *each word* $w \in S$ **do**
  Step1. **if** *NER*(w_i) $\in$ {*B,I*} **then**
    Append w_i to e;
    i++;
    Back to Step1;
  end
  else
    e_str := ARR2STR(e)
    if $e_str \notin T_{ne}$ **then**
      Append e_str to T_{ne};
    end
    for $t' \in$ *BPE*(e_str) **do**
      Append (t', e_str) to S';
    end
    Empty e;
    for $t \in$ *BPE*(w) **do**
      Append (t, "_UNE_") to S';
    end
  end
end

As we mentioned in Introduction 1, some key words are low-frequency. Such as a person name "Kevin Federline", it can be encoded as "kevin⟨/w⟩", "feder" and "line⟨/w⟩", and the meaning will be changed. Passing the keyword information to tokens is a simple and feasible approach to solve this problem. There are many ways of defining which words are key words and thus the problem can be defined as following:

Definition 1. Find an algorithm $A, \forall k \in S$, $A(k) = 1$ if k is a key word, else $A(k) = 0$.

where S represents a sentence.

This is a two-category classification problem. In fact, these key words usually perform as people's names, organizations or other types of named entities. Therefore, we choose a NER algorithm[3] as algorithm A and we modify the encoding process of BPE algorithm as algorithm 1 to pass the entity attribute to tokens. By reverse mapping named-entity words or phrases appeared in the corpus back to BPE tokens, key information has a way to be preserved. Some kinds of named entities (ep. DATE, TIME, PERCENT, MONEY, QUANTITY, ORDINAL, etc) contain numbers and they usually express general attributes, such as "22-year-old". We add a switch in practice to control whether processing these words with NPB-BPE or not.

The main difference between LB-BPE and NPB-BPE is that LB-BPE makes ordinary use of additional semantic information that can not be easily captured by statistical language models in a specific language, while NPB-BPE provides a way to share important concepts within a corpus.

3.3 Training Process

GPT is followed by many studies for its excellent generalization performance and we will give a brief introduction to it in the first subsubsection. Due to the expensive cost of pre-training, we reuse the OpenAI pre-trained language model[4] parameters, and we train new embeddings and fine-tune all parameters during the fine-tuning process. Figure 4 shows the modified preprocess procedure. Considering the input is enhanced by different kinds of new features, we propose two different processes for training.

Generative Pre-trained Transformer

The Generative Pre-trained Transformer (Radford et al., 2018), also known as OpenAI GPT or called as GPT, is a language representation model which

[1] https://spacy.io/api/annotation#_title
[2] https://spacy.io/
[3] https://spacy.io/api/entityrecognizer
[4] https://github.com/openai/finetune-transformer-lm

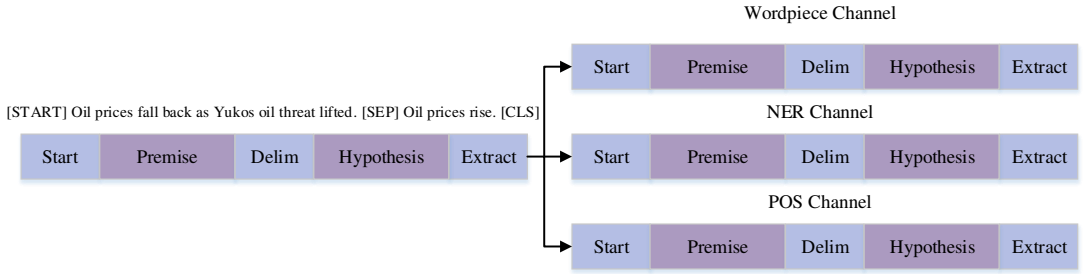

Figure 4: The preprocess procedure of RTE dataset by LB-BPE (NER+POS). Others are similar with this example.

is pre-trained on large corpora and fine-tunes all pre-trained parameters on the downsteam tasks. Its main architechture was originally described in (Vaswani et al., 2017). Unless otherwise stated, the GPT mentioned in this paper refers to a 12-layer decoder-only transformer with masked self-attention heads (768 dimensional states and 12 attention heads). For the position-wise feed-forward networks, we use 3072 dimensional inner states. Other hyperparameters are set as well as the GPT paper (Radford et al., 2018) for comparison.

Sharing Parameters

With this method, we treat additional features like positional encoding. We add these tags to the vocabulary and random initialize their embeddings in the embedding layer, thus the input can be described as following:

$$h_0 = w_{wt}E_t + w_{wp}E_p + \sum_{i \in \mathcal{C}_{lf}} w_{wli}E_{li} \quad (2)$$

where E_t, E_p, E_{li} represent the token embedding matrix, position embedding matrix and linguistic feature embedding matrix, $\mathcal{C}_l$ is the collection of all types of linguistic features and w_{wt}, w_{wp}, w_{wli} are the corresponding weight scalars. The following data flow is the same as GPT (Liu et al., 2018). We use the following objective to minimize:

$$L_3(\mathcal{C}) = L_2(\mathcal{C}) + \lambda L_1(\mathcal{C}) \quad (3)$$

where $\mathcal{C}$ represents the labeled dataset, $L_2(\mathcal{C})$ is the cross entropy loss of classification got on $\mathcal{C}$, $L_1(\mathcal{C})$ is the cross entropy loss of the language model got on $\mathcal{C}$ and λ is a weight parameter between 0 and 1.

Multi-channel Separate Transformer

GPT uses a multi-layer transformer decoder as the language model, and it learns patterns in the language by simply observing the token-level sequences. In this part, we use LB-BPE to encode sequences and with this method we have multiple input channels. We employ two stand-alone multi-layer transformer decoder to separate the parameters learned on different perspectives. One is the 12-layer pre-trained transformer released by OpenAI GPT, and the other is an entirely new one which has different amount of layers with the former and takes responsibility for linguistic features.

4 Experiments and Analysis

4.1 Setup

We follow the model hyperparameters mentioned in the GPT (Liu et al., 2018) paper. We use learned position embeddings with variable length depending on downstream tasks. We perform a pilot experiment and the result shows that it is almost the best to set the weighted layer as 1.0 for each channel. We use a 16G *ASPEED Graphics Family (rev 30)* card for training.

4.2 Supervised Fine-tuning

Datasets

Story Cloze Test Story Cloze Test (Mostafazadeh et al., 2017) is a new commonsense reasoning framework for evaluating story understanding, story generation, and script learning. This test requires a system to choose the correct ending to a four-sentence story. We choose it as a part of our evaluation corpora because it requires the model to capture rich linguistic phenomena.

RTE and SciTail RTE (Bentivogli et al., 2009) and SciTail (Khot et al., 2018) are language in-

Model	Story Cloze(Acc%)	RTE(Acc%)	SciTail(Acc%)	SST-2(Acc%)
jose.fonollosa's model	87.60	-	-	-
BiLSTM+ELMo+Attn	-	58.9	-	90.4
BigBird	-	-	**93.84**	-
GPT	86.5	56.0	88.3	91.3
NER	**87.39**	**61.6**	**88.90**	91.2
NER+POS	**88.08**	**62.1**	**88.33**	91.1
NER+DEP	**87.55**	**62.0**	**88.99**	90.2
NER+POS+DEP	**87.07**	**60.4**	87.54	**92.1**
POS	84.07	**62.4**	88.15	**92.1**
POS+DEP	86.05	**61.5**	87.63	**91.7**
DEP	86.48	**62.0**	87.82	91.3
NPB-BPE	**87.76**	**58.8**	**88.43**	91.1
NPB-BPE*	**87.39**	**62.3**	87.16	**91.9**

The details of the models for comparison in this table can be found in the leaderboards of the corresponding dataset official websites. Each row in the second block represents a LB-BPE result with different combination of features. NER represents using named-entity labels, POS represents part of speech tags and DEP represents synactic dependency parsing tags. NPB-BPE* represents filtering out named entities within these types (DATE, TIME, PERCENT, MONEY, QUANTITY, ORDINAL).

Table 2: Reverse mapping bytepair encoding results on Story Cloze Test, RTE, SciTail and SST-2.

ference also called textual entailment tasks which given a text t and a hypothesis h, t entails h, if, typically, a human reading t would infer that h is most likely true. The relation is directional. These two datasets differ from each other in size and domain.

SST-2 SST-2 (Socher et al., 2013) is related to sentiment analysis, containing 56.4k movie reviews and each of them has a binary label.

Evaluation of Label Based Reverse Mapping Bytepair Encoding

We evaluate LB-BPE on these datatsets and conduct multiple controlled trials based on different combinations of linguistic features by employing the parameter-sharing training procedure. Details is described in Table 2. The result shows that incorporating named-entity features usually works well, while utilizing POS tags sometimes can bring significant performance improvement. Besides, it is not a good way to use external features as many as possible, most likely because of the error propagation. However, combinations of named-entity information and others may bring a small boost. Compared with GPT, we achieved an absolute increase of 1.58% on Story Cloze Test, 6.4% on RTE, 0.69% on SciTail and 0.8% on SST-2 at our best.

Evaluation of Named-entity Phrase Based Bytepair Encoding

We evaluate NPB-BPE with the parameter-sharing training procedure. Details are shown in Table 2. Overall, NPB-BPE improves the performances for all datasets while not overly relying on external features. On Story Cloze Test, both kinds of NPB-BPE are not worse than LB-BPE (NER). On RTE, NPB-BPE* nearly achieves the best performance of LB-BPE. Little performance boost is shown on SciTail, probably because sentences in SciTail are more focused on the expressions of concepts and knowledge, and thus key words are more about verbs and nouns rather than named entities. However, as we unexpected, applying NPB-BPE* to SST-2 gains a 0.6% absolute increase. We also collect the statistics of named entities on these datasets. Details is shown in Table 3. We observe that there is a positive correlation between named entities percentage and performance improvement.

Evaluation of Different Training Processes

The parameters in GPT are all the same for all wordpiece embeddings in the vocabulary. However, linguistic features contain different levels of information compared with words and wordpieces. Thus we evaluate two different training processes mentioned in Section 3.3. As for MCST,

Dataset	Amount	Percentage(%)	Top10(non-numeric)
Story Cloze	2354	7.3	(“One day”, 241), (“John”, 196), (“Amy”, 195), (“Bob”, 189), (“Joe”, 156), (“Tom”, 152), (“Tim”, 148), (“Sam”, 114), (“Gina”, 101), (“Jim”, 95)
RTE	15548	21.9	(“U.S.”, 294), (“Iraq”, 262), (“US”, 243), (“the United States”, 180), (“China”, 166), (“today”, 150), (“France”, 148), (“Monday”, 144), (“American”, 144), (“Bush”, 142)
SciTail	7631	4.8	(“Earth”, 670), (“earth”, 632), (“Sun”, 358), (“Mercury”, 262), (“Oxygen”, 139), (“Hydrogen”, 134), (“Venus”, 103), (“Jupiter”, 101), (“Weight”, 101), (“Mars”, 92)
SST-2	728	1.6	(“american”, 141), (“years”, 128), (“summer”, 122), (“the year”, 119), (“year”, 90), (“today”, 87), (“2002”, 60), (“this year”, 54), (“two hours”, 53), (“saturday”, 51)

Table 3: Statistics of named entities on Story Cloze Test, RTE, SciTail, SST-2.

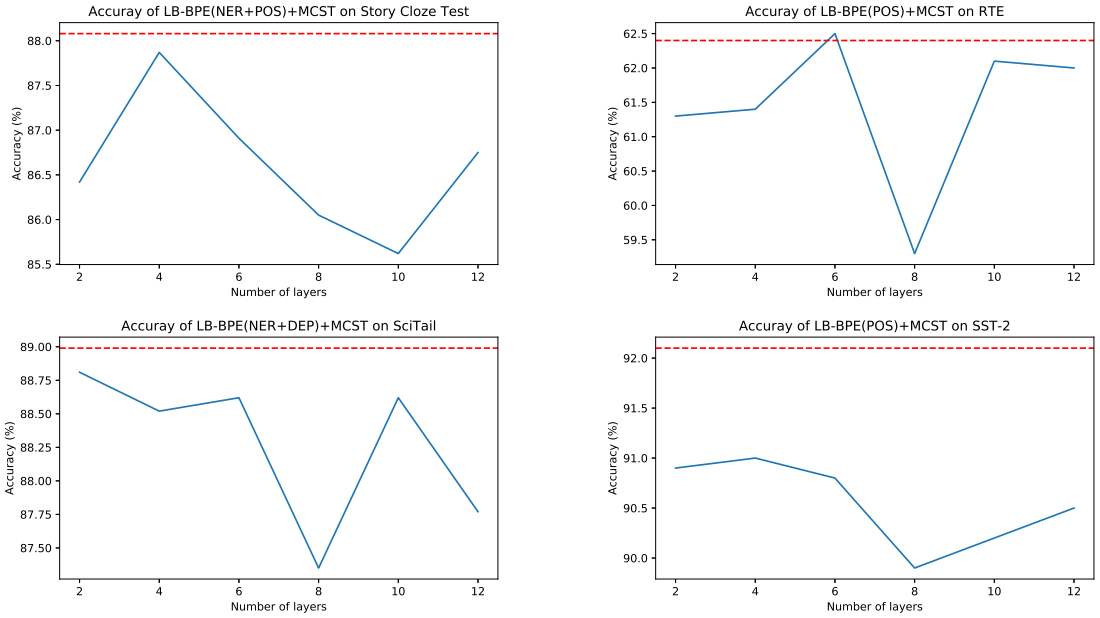

Figure 5: Accuracy of LB-BPE+MCST on all datasets. The red dotted line in each subgraph represents the best result of LB-BPE+GPT got on that dataset.

we perform a series of experiments based on different amount of blocks in the new transformer. As shown in Figure 5, employing non-parameter-sharing training process will generally reduce the performance. We infer that it is probably due to the lack of pre-training procedure for newly introduced features. However, MCST predicts labels based on both transformers while the accuracy rates do not drop too much, which suggests that the newly introduced linguistic features work at least to some extent and the transformer architecture can capture some potential semantic information from them independently. Besides, MCSTs trained with 2, 4, 6 layers in the new transformer perform best in our experiments, and they gain similar or even better results compared with the parameter-sharing training process, which means training newly introduced features doesn't need as many parameters as the original transformer. The main reason is that linguistic features act at a higher level compared with words and wordpieces.

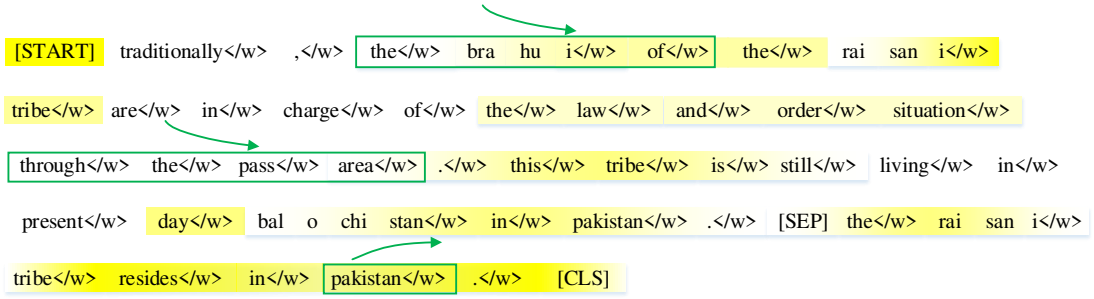

Figure 6: Attention weights of a textual entailment case in RTE. Yellow parts represent the attention weights of our approach. Green arrows and boxes represent the weight changes compared with GPT.

4.3 Case Study

We compare the attention weights of GPT and our LB-BPE (NER+POS) approach in a textual intailment example as shown in Figure 6. GPT labels it as *not_entailment* while our approach labels it as *entailment* which is the right answer. The attention weights come from the same attention head in the last transformer block. Changes in some parts lead to the correct answer.

5 Conclusion and Future Work

In this paper, we introduce a simple approach called reverse mapping bytepair encoding to improve natural language understanding based on pre-trained language models. The reverse mapping bytepair encoding has two forms: One is label based and the other is named-entity phrase based. Both forms introduce extra information to the tokens generated by BPE while the former ordinarily employs linguistic features, and the latter provides a way to share concepts through named-entity phrases. In addition, in the second form, we summarize the problem we are trying to solve into a two-category problem that judges whether a word is a key word. By applying them to the fine-tuning process of GPT, we gain about 1-6% improvement on downsteam NLU tasks. We also propose a new model architecture named as MCST and experiments based on it shows its effectiveness in some cases. Besides, the experimental results show that linguistic features usually perform at a higher level compared with words and wordpieces. It is quite easy to apply our method to the existing language models.

There could be several directions to be explored for future works. Language models have many forms, we only test our approach on GPT, a follow up direction is finding if it is generic enough. In this paper, we don't employ pre-training for linguistic features, it might be better by doing this. There are several researches focusing on incorporating knowledge into systems to improve their performances, thus we are looking forward to finding a smooth way to utilize named entities with prior knowledge or knowledge graphs.

Abstract

Universal Conceptual Cognitive Annotation (UCCA; Abend and Rappoport, 2013) is a typologically-informed, broad-coverage semantic annotation scheme that describes coarse-grained predicate-argument structure but currently lacks semantic roles. We argue that lexicon-free annotation of the semantic roles marked by prepositions, as formulated by Schneider et al. (2018), is complementary and suitable for integration within UCCA. We show empirically for English that the schemes, though annotated independently, are compatible and can be combined in a single semantic graph. A comparison of several approaches to parsing the integrated representation lays the groundwork for future research on this task.

1 Introduction

A common thread in many approaches to meaning representation is the idea that abstract structures can describe semantic invariants that hold across paraphrasing or translation: for example, semantic dependency relations capturing predicate-argument structures or other types of semantic relations that can be annotated within sentences (e.g., Böhmová et al., 2003; Oepen et al., 2015; Banarescu et al., 2013). These annotation schemes can be distinguished by various design principles such as language-specificity; the level of granularity of meaning elements; the reliance on morphosyntactic criteria to define the units of semantic annotation; the extent to which human annotators specify semantics from scratch; and many others (Abend and Rappoport, 2017).

In this work, we seize an opportunity to unite two previously unrelated—yet complementary—meaning representations in NLP. On the one hand, Universal Conceptual Cognitive Annotation (UCCA; Abend and Rappoport, 2013) provides

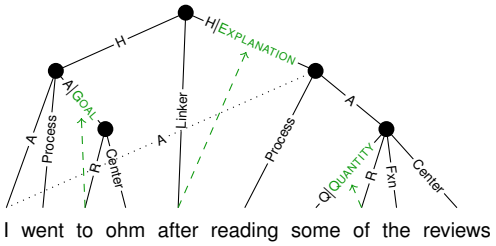

Figure 1: Semantic parse illustrating the integrated representation proposed here. Solid edges are the UCCA parse's *primary edges*, and the dotted edge is a *remote edge*. Dashed arrows show how SNACS labels (green small caps) have been mapped onto edges of the UCCA structure from the prepositions on which they were originally annotated. The following UCCA categories are abbreviated: A = Participant, R = Relator, H = Parallel scene, Q = Quantifier, Fxn = Function.

a skeletal structure of semantic units and relations, with typologically-based criteria for marking predicate-argument structures, based on "Basic Linguistic Theory", an established framework for typological description (Dixon, 2010/2012). On the other hand, a recent approach to annotation of English prepositions and possessives (SNACS; Schneider et al., 2018) provides an inventory of labels that characterize semantic relations. UCCA and SNACS follow similar design principles: they are both *language-neutral*, with general-purpose coarse-grained labels rather than lexically-specific senses or roles; and they are both designed for *direct* semantic annotation, without requiring a syntactic parse as a foundation. The philosophy is that these properties will facilitate annotation in many languages and domains that may lack detailed lexicons. But UCCA makes only the most rudimentary role distinctions, while SNACS annotations thus far have not made explicit which elements are being brought into a semantic relation (§2).

We propose a design that achieves the best of both worlds, as illustrated for an English example in figure 1. Taking advantage of an English corpus

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 174–185
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

that has been separately annotated for both UCCA and SNACS, as well as dependency syntax, we show that the SNACS role labels can be automatically integrated within UCCA structures over a range of syntactic constructions (§3). Then, we use this corpus to test pipelined, multitask, and joint approaches to parsing the integrated representation (§4). Our findings (§5) set the stage for future English parsers as well as multi- and cross-lingual extensions. §6 situates this work in the broader landscape of computational meaning representations.

Our main contributions are:

- a typologically-oriented broad-coverage linguistic **representation** that captures predicate-argument structure and semantic roles, without reference to any lexicon;
- a procedure to **integrate** UCCA and (token-level) SNACS annotations for particular sentences, mapping the SNACS labels to the appropriate edge in the UCCA structure, by which we create an integrated gold standard; and
- initial results for the **integrated parsing task**, comparing several alternatives that couple the learning/prediction of UCCA and SNACS in various ways. We find that optimizing for the two objectives jointly works best.

Data and code from these experiments are open-sourced to facilitate future work on this task.[1]

2 Background

To better understand the distinctions that we expect to be captured by such a framework, consider the following examples:

(1) a. Her picture was on the wall.
b. Her speech was on security.

Despite parallel syntax and overlapping vocabulary, the sentences above vary in numerous aspects of meaning:

- The NPs *her picture* and *the wall* denote entities that stand in a certain locative relation to each other, as signaled by the preposition *on*.
- In contrast, the relation between *her speech* (which is an event, not an entity) and *security* is a different one, TOPIC, despite being signaled by the same preposition.

This is made explicit in the German translations of these sentences:

(2) a. Ihr Bild hing **an** der Wand .
Her picture hung **at** the wall .
b. Ihre Rede war **über** Sicherheit .
Her speech was **over** security .

In addition, the possessive pronoun *her* (*ihr*/*ihre*) signals a prototypical POSSESSION relation in (1a)/(2a), but the core role of AGENT in (1b)/(2b).

As we can see, the natural lexical choices for expressing the LOCATION relation between the picture and the wall and the TOPIC relation in German have diverging literal translations to English. Thus, the empirical study of cross-linguistic commonalities and differences between form and meaning calls for a common metalanguage to describe the relations between mentioned events and entities, as marked by case and adpositions.

Our approach to such a representation consists of utilizing two existing semantic representations. UCCA (§2.1) captures the structure of predicate-argument and head-modifier relations at a high level, crucially distinguishing units that evoke a **scene** (event or state) from other units. SNACS (§2.2) disambiguates semantic roles as signaled by adpositions and possessives, but only directly annotates a function word, without formalizing the semantic relation that it mediates.[2] Both of these schemas have the guiding principle to be language-independent, eschewing a lexicon and defining a closed inventory of semantic categories.

2.1 UCCA

UCCA is a semantic annotation scheme rooted in typological and cognitive linguistic theory. It aims to represent the main semantic phenomena in the text, abstracting away from syntactic forms. UCCA's foundational layer, which is the only layer annotated over text so far,[3] reflects a coarse-grained level of semantics that has been shown to be preserved remarkably well across translations (Sulem et al., 2015). It has also been successfully used for improving text simplification (Sulem et al., 2018b),

[1] Integrated data: https://github.com/jakpra/ucca-streusle; parser code: https://github.com/jakpra/tupa; the integration routine and evaluation scripts are being released as part of the UCCA PyPI package and under https://github.com/jakpra/ucca.

[2] Note that mapping between syntactic and semantic relations varies by construction: in *She spoke on security*, the semantic head of the relation between *spoke* and *security* corresponds to the syntactic head (the verb), whereas in *Her speech was on security*, UD treats *security* as the syntactic head (§3).

[3] Prange et al. (2019) have proposed and piloted a coreference layer that sits above the foundational layer.

as well as to the evaluation of a number of text-to-text generation tasks (Birch et al., 2016; Sulem et al., 2018a; Choshen and Abend, 2018).

Formally, UCCA structures are directed acyclic graphs over **units** (nodes covering a subset of tokens). Atomic units are the leaves of the graph: individual tokens or unanalyzable MWEs. Nonterminal units represent larger semantic constituents, such as scenes and compositional participants/modifiers. The example in figure 1 has 5 nonterminal units. Each unit (save for the root) has a single incoming **primary** edge, and may also have incoming reentrant **remote** edges to express shared argumenthood. The primary edges of a UCCA structure thus form a tree, which along with the remote edges, forms a DAG.[4]

Edges are labeled with one or more **categories** indicating a kind of semantic relationship. The small set of categories includes State and Process for static or dynamic scene predicates, respectively; Participant, Time, and Adverbial for dependents of scenes; Center for the head of a non-scene unit (usually an entity); and Elaborator and Quantity for modifiers of entities. Scenes can be semantic dependents (Participant of another scene, Elaborator of a non-scene). Multiple scenes at the same level are called Parallel Scenes, and connectives between them are Linkers.

UCCA makes a distinction between different functions of prepositions, the most common cases of which are: (1) phrasal verbs (e.g., "give **up**"), annotated as internally unanalyzable; (2) linkers between scenes; e.g., in figure 1, "after" links the going to ohm scene, and the reading scene); (3) main relations in scenes (e.g., "The apple tree is **in** the garden"); and (4) case markers within a scene or a participant, or *Relators* in UCCA terms (e.g., in figure 1, "to" and "of" are such markers).

However, apart from distinguishing temporal modifiers, the UCCA scheme does not provide any **semantic role** information: thus the analyses of "the dark wizard defeated by Gandalf" and "the dark wizard's defeat of Gandalf" are nearly isomorphic—obliterating the distinction between agents and patients in the semantics—though the grammatical encoding of the noun phrases in question (subject, by-PP, possessive, of-PP) leaves no ambiguity about the intended roles to a human reader.

[4]There is also the capability to annotate implicit units, but these are ignored in the standard evaluation and we do not address them here.

2.2 SNACS

SNACS is an inventory of 50 roles/relations used to disambiguate adpositions and possessives in multiple languages, including English (Schneider et al., 2018, 2019), Mandarin Chinese (Zhu et al., 2019), and to a lesser extent, Korean, Hindi, and Hebrew (Hwang et al., 2017). Many of the SNACS labels, such as AGENT, THEME, and TOPIC, are derived from VerbNet's (Kipper et al., 2008) core roles of predicates. (Others, such as QUANTITY and WHOLE, are for entity modification.) But unlike VerbNet, FrameNet (Fillmore and Baker, 2009), and PropBank (Palmer et al., 2005), SNACS does not require a language-specific predicate lexicon (hence Schneider et al. (2018) use the term "supersenses", which we adopt in the remainder of this paper)—and is therefore compatible with UCCA's design principle of crosslinguistic applicability.[5]

Currently, SNACS labels are applied directly to lexical items, without marking up underlying structure on either the subword (morphological) or the sentence-structure level.

3 Automatically Integrating Semantic Roles with UCCA

With the benefit of a jointly annotated corpus, we examined the data and determined that the proper placement of adpositional semantic role labels is fairly deterministic given certain syntactic patterns and their structural counterparts in UCCA. Here we present a rule-based method for automatically integrating token-based semantic role annotations from SNACS into an UCCA graph as edge refinements. We use these rules to construct a gold standard for analysis and parsing of the integrated representation. The rules we use, though empirically grounded in the English Web Treebank corpus (Bies et al., 2012), make no specific assumptions about language or lexicon, as they solely depend on UCCA, SNACS, and Universal Dependencies (UD; Nivre et al., 2016) annotation, all of which are frameworks designed to be cross-linguistically applicable. Thus, we expect the rules could be adapted to other languages with only minor changes if the underlying annotations are applied consistently, though this will require testing in future work.

[5]SNACS also annotates the **function** of a preposition token—its lexical semantics which may be distinct from its semantic role (Hwang et al., 2017). Only scene roles are taken into account in the present analysis.

	scene	non-scene
verb	I *went* [**to** ohm]	*Quit* [**with** the overstatements] !
noun	Wonderful *service* [**for** large group]	Cheapest *drinks* [**in** Keene]
	[10 minutes] **of** *paperwork*	[No amount] **of** *sugar* and milk can mask it .

Table 1: Syntactic and semantic dimensions of canonical adpositional phrase constructions. The adposition is **bolded**, the semantic head is *italicized*, and the semantic dependent is [bracketed]. Rows indicate whether the semantic head is nominal or verbal, while columns differentiate between scene-evoking and non-scene-evoking heads. Scene-evokers are underlined.

3.1 Data

We use the STREUSLE 4.0 corpus (Schneider and Smith, 2015; Schneider et al., 2018), which covers the reviews section from the English_EWT treebank of UD 2.3, and lexical semantic annotations for the same text.[6] The same corpus has been annotated with UCCA by Hershcovich et al. (2019a). We use the standard train/dev/test split for this dataset (table 2). §3.3 shows the distribution of linguistic phenomena at issue here.

3.2 Procedure

Given an UCCA graph with annotated terminals, the integration routine projects a SNACS annotation of a token onto the appropriate edge representing a semantic relation. This is illustrated by dashed arrows in figure 1. The procedure starts with a single terminal node, traversing the graph upwards until it finds an edge that satisfies the criteria given by the rules. The rules concern canonical prepositional phrase modifiers, plus a variety of syntactically or otherwise anomalous constructions, such as copulas and adverbs.

3.2.1 Canonical PPs

The adpositional constructions annotated in STREUSLE can be adnominal or adverbial modifiers and arguments, where both the nouns and verbs that are being elaborated on can evoke either scenes or non-scene units in UCCA (table 1). First, we take a look at expressions marked with Relators in UCCA, which generally correspond to prototypical syntactic PPs.

Modifiers of scenes. In general, if the adposition marks a modifier of a scene—i.e., the adposition is the first or last terminal in the modifier unit's yield—the supersense should refine the role of that dependent. The adposition's parent unit is refined by the supersense ("to ohm" in figure 1 and table 1; "for large group" in table 1).

	train	dev	test	total
sentences	2,723	554	535	3,812
tokens	44,804	5,394	5,381	55,579
SNACS-annotated	4,522	453	480	5,455
successful integ.	4,435	447	473	5,355
matches synt. obj	3,924	403	438	4,765

Table 2: Quantitative analysis of adpositional constructions in the corpus.

Modifiers of non-scenes. Where the adposition relates a modifying (elaborating or quantifying) unit to a non-scene unit, the supersense refines the modifying unit. If the adposition is the first or last terminal in a non-Center unit, that unit gets refined ("in Keene" in table 1). This includes the case when the adposition marks the predicate evoking the scene of which the syntactic governor is a modifier ("with the overstatements": "Quit" is treated as an aspectual modifier of the "overstatements" event).

For partitive constructions like "the top **of** the mountain", both the syntactic governor and object of the adposition are marked as UCCA Centers, indicating that they are on a *semantically equal* level—neither one is clearly only modifying or being modified by the other. In this case, the supersense refines the syntactic object of the adposition.

Quantities. Another special case is where the adposition is labeled as QUANTITY, in which case the unit for its syntactic governor[7] ("10 minutes" in table 1) receives the refinement: e.g., "[some] **of** the reviews" in figure 1; in table 1, "[10 minutes] **of** paperwork" and "[no amount] **of** sugar" (the bracketed expression is the QUANTITY).

3.2.2 Non-canonical phenomena

For other, less prototypical constructions involving SNACS-annotated expressions, such as copulas, linked parallel scenes, possessive pronouns, and idiomatic PPs, we have additional rules, summarized in supplementary material (appendix A).

[6] UD: https://github.com/UniversalDependencies/UD_English-EWT; however, as described in §5.1, we use automatic dependency parses in all experiments, to emphasize generalizability.

[7] We determine the head noun of the syntactic governor and object using a script released together with the STREUSLE corpus: https://github.com/nert-nlp/streusle/blob/master/govobj.py. Since semantic UCCA units do not always align with syntactic phrases, we choose the UCCA unit containing the head token of the syntactic governor or object in its yield.

Table 3: Refined UCCA edges by construction type, according to our heuristic. (The non-canonical subcategories are mutually exclusive.)

3.3 Quantitative Analysis

We run the integration routine on our dataset and report statistics in tables 2 and 3. The heuristic rules have a coverage of 98% – 99% (row 'successful integ.' divided by row 'SNACS-annotated' in table 2). 88.5% (train) – 92.6% (test) of refined units contain the syntactic complement[8] (table 2), indicating that while syntax may often give a good approximation to the semantic relations marked by adpositions, a direct mapping from syntactic into semantic structure is not always trivial.

In table 3, we see that among the canonically adpositional SNACS targets, the vast majority mark scene modifiers (including participants). The various non-canonical targets modify both scenes and non-scenes, except for linkages and predications, which naturally only operate at the scene-level, and approximators, which only elaborate on non-scenes. Similar to canonical adpositional constructions, possessive pronouns and intransitive adpositions have a tendency to modify scenes rather than non-scenes. Those infinitivals that are not inter-scene Linkers (which are counted under *linkage*) are mostly non-scene modifiers.

Remote edges are only rarely affected by the SNACS integration, so we exclude them from evaluation in §5.

[8]We use the term 'syntactic complement' to include head tokens of prepositional objects and subordinate clauses, as determined by the script mentioned above. If no prepositional object is given in the STREUSLE corpus, we consider the adposition itself and only count towards this metric if the refined edge is its incoming preterminal edge.

3.4 Difficult Cases & Limitations

Our heuristics are based solely on universal semantic and syntactic annotations, with no assumptions about the grammar or lexicon of any specific language. However, there are some limitations to the rules that deserve discussion. Most importantly, as many rules are highly sensitive to UCCA structure and categories, errors or inconsistencies in human and automatic UCCA annotation are likely to throw the system off. This can be mitigated with strict constraints and careful reviewing during manual annotation, but cannot be fully avoided when applying the rules to automatically generated UCCA.

Multiword expressions (MWEs) are another source of difficulty. Both UCCA and STREUSLE mark idiomatic MWEs, but follow slightly different guidelines. The heuristic rules actually recover from most MWE misalignments; however, constructions that are MWEs in UCCA and contain multiple SNACS targets, such as *as-as* comparatives, are not fully resolved by our heuristic, as we cannot assign individual edge refinements for the adpositions' competing supersenses, given that we start traversing the UCCA graph from the shared preterminal node.

4 Models

We hypothesize that our combined (lexical and structural) semantic representation is not only linguistically plausible, but also useful in practice, as the annotations on both levels should be informative predictors for each other. That is, we expect that knowing what semantic role is signaled by an adposition informs the underlying semantic structure of the sentence, and vice versa.

In order to test this hypothesis, we use our annotated corpus to parse into the integrated representation. We consider several different ways of orchestrating the prediction of the foundational UCCA structure and the prediction of SNACS roles: modeling SNACS and UCCA in (i) a pipeline, (ii) a multitask setup with shared parameters, (iii) a single joint model.

4.1 Baseline: TUPA

We choose the neural transition-based graph parser TUPA (Hershcovich et al., 2017, 2018) as a strong baseline for UCCA parsing. It was the official baseline in the recent SemEval shared task on UCCA parsing (Hershcovich et al., 2019b).

TUPA's transition system is defined to address

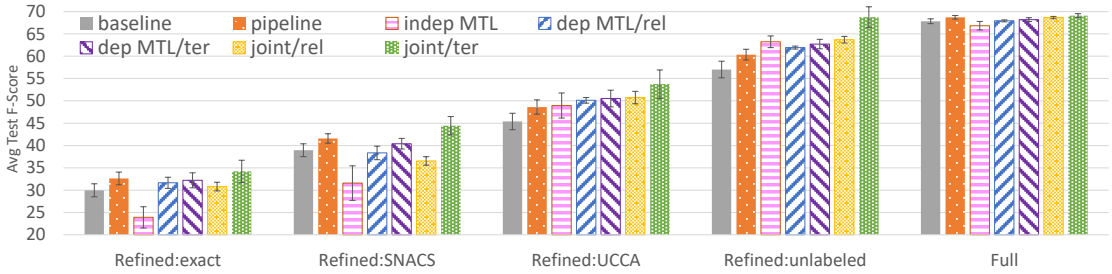

Figure 2: Average F1-score on the test set over 5 random restarts with error bars indicating standard deviation. *ter* stands for terminal-level and *rel* for relation-level SNACS refinement (prediction or features).

the different formal structural phenomena exhibited by UCCA structures, notably reentrancies and discontiguous units. There are transitions for creating nonterminal nodes, and for attaching terminal and nonterminal nodes to a primary or remote (reentrant) parent with an UCCA category label on the edge. The transition system is general enough to be able to tackle parsing into a variety of formalisms, including SDP (Oepen et al., 2015) and a simplified form of AMR (Banarescu et al., 2013); Hershcovich et al. (2018) take advantage of this flexibility in their multitask learning framework.

TUPA's learning architecture largely follows that of Kiperwasser and Goldberg (2016). It encodes the parser's configuration (buffer, stack and intermediate graph structure) using BiLSTMs, and predicts the next transition using an MLP, stacked on top of them. Token-based features, including POS tags, dependency parses, as well as NER and orthographic features, are embedded in the BiLSTM. Another set of features, taking into account the partially constructed graph and previously predicted transition types, is fed into the MLP directly.

4.2 Pipeline

We extend TUPA by providing the SNACS label as a feature on the adposition token.[9] This is added in preprocessing in the same way as the syntactic features listed above (including the BiLSTM encoding). At testing time, we obtain SNACS labels for automatically identified targets from the SVM model of Schneider et al. (2018).

4.3 Multitask

Hershcovich et al. (2018) showed that UCCA parsing performance can be improved with multitask learning (MTL; Caruana, 1997) on several semantic and syntactic parsing tasks. We examine whether alternately optimizing two objectives, one for UCCA and one for SNACS, leads to mutually favorable biases via shared parameters. There are multiple ways the two tasks can be orchestrated:

Independent MTL. This is the multitask learning (MTL) setup from Hershcovich et al. (2018), where separate transition classifiers are trained on different tasks simultaneously, sharing and mutually updating the BiLSTM encoding.[10] We consider as auxiliary tasks (a) SNACS scene role classification and (b) the decision of which UCCA unit is refined by a SNACS-annotated token. We encode these tasks as parsing tasks analogous to UCCA parsing as follows: for each training item in (a), we create a graph consisting of a root and up to 4 children: the syntactic governor (if available), the preposition token, the syntactic object (if available)—all of which have dummy edge labels—as well as a dummy terminal carrying the SNACS supersense. For each training item in (b), we consider the full UCCA structure, but the edge labels are simply boolean values indicating whether an edge is refined or not.

We also train a separate model with SNACS classification as the primary task and UCCA parsing and SNACS integration as auxiliary tasks, whose predictions are integrated in postprocessing for the combined evaluation (table 4), and which is evaluated independently in table 5.

Dependent MTL. Here we train the SNACS task in direct interaction with the UCCA parsing task.

[9] We report here only results for the setting in which a supersense is added as a feature of the *preposition* token. We also experimented with using it as a feature of the syntactic object token—which often, but not always, heads the semantic object (cf. table 2)—but got similar or worse results.

[10] Note that our setup differs from that of Hershcovich et al. (2018) in two key points: In contrast to the auxiliary tasks used in the aforementioned work, SNACS prediction as formulated by Schneider et al. (2018) is not a structured, but a (per-token) classification task (however, as described above, we transform it into an artificially structured task to make it conform with the input format expected by TUPA). Furthermore, we are interested in both UCCA and SNACS performance, expecting both tasks to benefit from each other's complementary semantic content.

Table 4: Experimental results, averaged over 5 random restarts. The baseline system (BL) for UCCA is TUPA version 1.3.9 without any modifications, retrained on our data. For the sake of generalizability and consistency with our own preprocessing, we use system-predicted SNACS categories from the auto-id/auto-syntax setting from (Schneider et al., 2018) in the BL and pipeline setups. Results where the system has access to gold SNACS annotations on adposition tokens are shown in small font.

We enhance TUPA with a separate MLP that, given an edge, classifies its supersense refinement (a null category can be chosen to indicate an unrefined edge). This network is run after each edge-creating transition. Its input features are the same as for the transition classifier, including the BiLSTM encoding. Since the two classifiers alternate in making forward passes and updating the shared BiLSTM, they indirectly contribute to each other's input. Here we have an option of where in the UCCA structure to initially predict the supersense label. In the **terminal-level (ter)** setting, we predict supersense refinements only on preterminal edges, and then apply the integration rules (§3) as postprocessing. In the **relation-level (rel)** setting, we parse directly into the integrated representation. To do this, we preprocess the training data with our integration routine. However, during parsing, there is no explicit restriction that supersense-refined edges must have an adposition token in their yield—thus the model could, in theory, learn to predict adequate role supersenses even when it is not signaled by a lexical marker (though it will get penalized for that in our current evaluation).

4.4 Joint

Finally, we train a single classifier on the integrated data, concatenating UCCA and SNACS categories, to predict parsing transitions using the new compound categories. We revisit the terminal-level and the relation-level settings introduced in §4.3.

5 Experiments

5.1 Experimental Setup

Preprocessing. We follow Hershcovich et al. (2018) in obtaining automatic POS and NE tags, as well as syntactic dependency relations using SpaCy 2.0, and pretrained word vectors from fastText.[11] For all setups that use or predict SNACS supersenses, we include the gold standard scene role categories for pre-identified targets from the STREUSLE 4.0 corpus in our training and development data. In the test data we identify adposition targets using the heuristics introduced in Schneider et al. (2018). For the joint prediction setup (§4.3), we also include the head terminal of the syntactic governor and object for each adposition as features, using the same heuristics as in §3.

Architecture and hyperparameters. For classifying the next transition, TUPA uses a multi-layer perceptron (MLP) with 2 hidden layers and a softmax output layer, on top of a 2-layer BiLSTM (Kiperwasser and Goldberg, 2016). Building on previous work, we train for 100 epochs, using the stochastic gradient descent optimizer for the first 50, and AMS-grad (Reddi et al., 2018) for the remaining 50 epochs,[12] and apply early stopping post-hoc by keeping the model with the highest performance on the dev set as the final model.

Evaluation. For our main evaluation in §5.2, we compare our systems along five new metrics: a **full structure** score which evaluates precision and recall of all units and requires both the UCCA and SNACS categories to be correct, where applicable; and **refined UCCA**, **SNACS**, **exact**, and **unlabeled** scores which only consider SNACS-refined units. Here, the integrated representation obtained via the rule-based integration (§3.2) serves as the ground truth. We also report the standard labeled and unlabeled UCCA scores.[13] In addition, for sys-

[11] https://spacy.io/; https://fasttext.cc/

[12] Except for the independent MTL setting, where we stop training after the first 50 epochs.

[13] All of the above metrics are F-scores over the edges, as in Hershcovich et al. (2017).

Table 5: Results on the respective tasks of UCCA parsing and token-level SNACS prediction, averaged over 5 random restarts, with standard deviation reported next to each average. The baseline system (BL) for UCCA is TUPA version 1.3.9 without any modifications, retrained on our data. The SNACS baseline system is the SVM classifier of Schneider et al. (2018).

tems which predict a terminal-level SNACS label (before it is mapped to a higher relation in post-processing), we compare SNACS disambiguation performance against (Schneider et al., 2018) in §5.3.

5.2 Integrated parsing results

Our MTL and joint systems outperform the baseline and a feature pipeline on refined UCCA units (figure 2 and table 4). The main benefit from considering UCCA and SNACS together in training is that the parser is better at recovering the (unlabeled) structure of units that should receive a SNACS relation in the integrated representation. This is illustrated in figure 3. This trend is confirmed in the precision and recall of UCCA units that have a gold SNACS token in their yield (unlabeled F-score: *BL* = 93.1, *dep-MTL/ter* = 95.2, *indep-MTL* = 96.0, see table 7 in the supplementary material). To the extent that these units are syntactic constituents (see table 2), this suggests that multitask learning with syntactic auxiliary tasks (Swayamdipta et al., 2018; Hershcovich et al., 2018) might be particularly beneficial for SNACS-augmented UCCA parsing. The feature pipeline is competitive, but noisy features from a previous classification step limit its performance on refined units. The upper bounds given by the oracle setting indicate that SNACS features are generally beneficial. *Indep-MTL* and systems that parse directly into the relation-refined representation struggle with predicting the correct SNACS refinements—and thus also exact UCCA+SNACS combinations—while the *joint/ter* model is consistently the most accurate.

However, there is little effect on overall labeled and unlabeled UCCA scores (table 5). Predicting SNACS simultaneously or interactively with UCCA (*joint/rel* and *dep-MTL*) apparently makes the parsing task harder. Note that particularly in

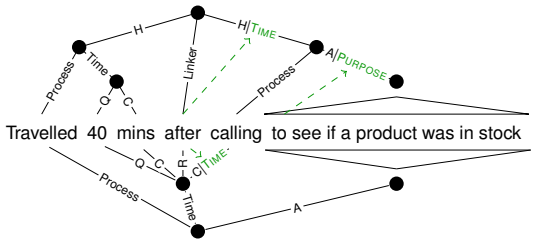

Figure 3: Simplified sample output. The *joint/ter* system (top) generates the intended scene structure and PURPOSE modifier attachment. The *BL* system (bottom) does not, and misses the PURPOSE role altogether.

setup	ref	# params

joint	ter	79.2M	
	rel	79.2M	

Table 6: Number of parameters of each model.

the *dep-MTL* setting, erroneous decisions in one task could negatively affect the other.

5.3 Token-based SNACS prediction results

Since some of our systems predict SNACS labels at the terminal level, they are directly comparable to previous work on SNACS classification. We compare against the auto-id/auto-syntax baseline from Schneider et al. (2018) in table 5.[14] Both the *dep MTL* and *joint* systems outperform the baseline in precision; and the *joint* system also in recall, leading to the overall best performance. The *indep-MTL* system does not reach baseline performance.

5.4 Model capacity

We examine whether the differences in performance can really be attributed to the linguistic in-

[14] Due to the diverging guidelines on multiword units in UCCA (§3.4), we ignore MWE boundaries.

formation in our data or merely to more powerful models by inspecting the number of each model's parameters (table 6). While we observe some variance in model capacity, we consider these to be minor differences. An exception is the *independent MTL* setup, which consists of two independent models, each dedicated to a specific task. However, this does not seem to give it an advantage in terms of final performance. The baseline has the fewest parameters, and the overall best condition, *joint/ter*, is neither the smallest nor the largest model, suggesting that the particular linguistic signals and the method of using them have a genuine effect on performance.

6 Related Work

The benefits of integrating lexical analysis and sentence semantic or syntactic structure have been pursued by a vast body of work over the years. Compositional approaches to the syntax-semantics interface, such as CCG (Steedman, 2000) and HPSG (Pollard and Sag, 1994), usually integrate the lexicon at the leaves of the syntactic parse, but propagate grammatically-relevant features up the tree. A different approach is taken by OntoNotes (Hovy et al., 2006), which consists of a number of separate, albeit linked tiers, including syntactic and argument structure, but also the lexical tiers of word senses and coreference.

Role semantics frequently features in structured semantic schemes. Some approaches, such as PropBank and AMR (Palmer et al., 2005; Banarescu et al., 2013), follow a lexical approach. The Prague Dependency Treebank tectogrammatical layer (Böhmová et al., 2003) uses a few lexicon-free roles, but their semantics is determined by virtue of their linkage to a lexicalized valency lexicon. Universal Decompositional Semantics (White et al., 2016) instead defines roles as a bundle of lexicon-free features, elicited by crowdsourcing.

The specific inventory for preposition/possessive relations that we use is SNACS, but there is a wider history of disambiguation of these items, especially in English: disambiguation systems have been described for possessives (Moldovan et al., 2004; Badulescu and Moldovan, 2009; Tratz and Hovy, 2013), prepositions with lexicalized sense definitions (e.g., Litkowski and Hargraves, 2007; Tratz and Hovy, 2011), and prepositions with coarse-grained classes (O'Hara and Wiebe, 2003, 2009; Srikumar and Roth, 2013; Gonen and Goldberg, 2016). Such disambiguation has also been investigated in tandem with semantic role labeling and parsing (Dahlmeier et al., 2009; Srikumar and Roth, 2011; Gong et al., 2018). Preliminary work suggests that SNACS may be applicable to subjects and objects, not just PPs, and thus in the future this framework could be extended to all UCCA participants (Shalev et al., 2019).

State-of-the-art results on UCCA parsing and SNACS disambiguation are described in contemporaneous work by Jiang et al. (2019); Liu et al. (2019), who achieve substantial gains using the ELMo and BERT contextualized word embeddings (Peters et al., 2018; Devlin et al., 2019). This is an orthogonal direction to the one we pursue here, and combining the two is left to future work.

7 Conclusion

We have introduced a new representation combining UCCA semantic structures and SNACS adpositional semantic roles; automatically merged existing annotations to create a gold standard; and experimented with several alternatives for parsing the integrated representation. Our results show that models profit from having access to both structural and lexical semantic information, confirming our hypothesis that UCCA and SNACS are complementary and compatible.

Based on preliminary results from a German corpus, we conjecture that this approach is applicable to other languages with no or only minimal changes—a direction we will explore further in future work. In addition, we plan to investigate the utility of the enhanced representation for downstream tasks involving meaning-preserving linguistic variation.

Generating Timelines by Modeling Semantic Change

Guy D. Rosin[1], Kira Radinsky[1,2]

Abstract

Though languages can evolve slowly, they can also react strongly to dramatic world events. By studying the connection between words and events, it is possible to identify which events change our vocabulary and in what way. In this work, we tackle the task of creating timelines—records of historical 'turning points', represented by either words or events, to understand the dynamics of a target word. Our approach identifies these points by leveraging both static and time-varying word embeddings to measure the influence of words and events. In addition to quantifying changes, we show how our technique can help isolate semantic changes. Our qualitative and quantitative evaluations show that we are able to capture this semantic change and event influence.

1 Introduction

Languages respond to world events in many ways. New words, phrases, and named entities are created, new senses may develop, and valences may change. Various approaches support the study of historical linguistics (e.g., comparative linguistics, etymology, etc.). In this work, we focus on a specific process for tracking the progression of meaning over time in sense, semantics, and in relation to other words and concepts. By leveraging changing relationships in temporal corpora, we demonstrate a way of 'embedding' words and world events. Observing changes in this embedding allows us to construct timelines that support the study of evolving languages.

The timeline of scientific and technical discoveries, for example, can drive the emergence of new word senses as these discoveries are 'named'. Take the word "cell" which evolved from its 12^{th} century meaning (a small room or chamber) to a new sense in the 17^{th} century (a basic unit of an organism) to the 19^{th} century meaning (an electric battery) and most recently to a shorthand for a mobile phone[1]. Critically, the *dominant senses* of a word vary over time as some meanings become less commonly used while others gain in popularity. This dynamic need not be driven only by the addition of certain senses. The prevalence of a hyponym, for example, may also drive a change in the ranking of senses. The word 'disaster' may call to mind very different things depending on the latest *type* of disaster. Thus, the word may evoke 'nuclear disaster' in a reader in 2011 (e.g., driven by the *Fukushima* incident). However, in 2012 the 'storm' sense may be more salient (e.g., driven by *Superstorm Sandy*).

Evolution of senses is but one way a language can evolve. Broader semantic changes can also occur. For example, the valence of the word may move or even flip (e.g., *terrific* or *bully*). Of particular interest to us are those changes that are more immediate and precipitated by key world events. For example, a war may lead certain terms to take on a negative connotation as a country or people become the 'enemy'. Large collections of text from a given period can capture all of these language changes as reflected by evolving context. By mining this text, our goal is to support the study of evolving languages.

Etymological studies allow us to understand the origin of words and changes in meaning (Alinei, 1995). This work produces not only an accounting of change but also an explanation of the social, scientific, or other world events that drive language shifts. Conventional production of etymological analysis often requires a detailed and laborious manual close-reading of historical texts (Geeraerts et al., 1997). By applying computational methods, our focus is on detecting semantic changes of words and events and producing possi-

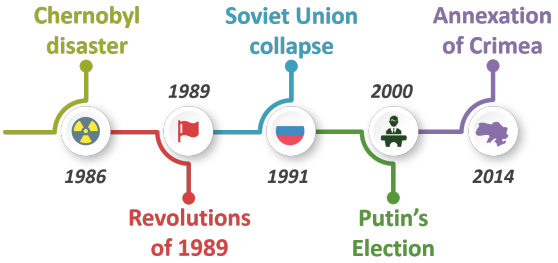

Figure 1: A timeline generated by our framework for *Russia*.

ble explanations from real-world drivers.

Problem Definition: In this work, we study the problem of timeline generation for a word or phrase. We use the term 'word' throughout the paper for convenience. Given a timeline of a word, a researcher should be able to understand the word's dynamics, i.e., the changes the word underwent over time. A timeline is defined as a sequence of time points and their descriptors (i.e., explanations of the changes the word underwent at that time point). A good timeline is such that enables the researcher to gain a better understanding of the word and its history (Althoff et al., 2015). It contains time points of significant changes, with relevant explanations of the changes, and with a minimal number of missing or redundant information.

We define several building blocks for constructing timelines. The first is the identification of time points during which the target word underwent significant semantic change (we refer to those as *Turning Points*, see Section 4). Second, we consider identifying associated descriptors of those changes. These descriptors are associated with a word's change at a particular time and can serve to explain its dynamics.

We experiment with two types of descriptors. The first involves *words* associated with the target word or affected by it (Section 5). The above 'cell' and 'disaster' examples can serve as examples of timelines with word descriptors. The second type is *events* (Section 6). One can explain changes the target word underwent based on significant world events. As an example, consider the timeline generated by our framework for the word "Russia" (Figure 1).

To identify events that are strongly associated with the change, we utilize time-varying language embeddings on both static snapshots (e.g., Wikipedia) and historical texts (35 years of the *New York Times*), allowing us to capture both syntactic and semantic variation of words (Section 3). We develop a mechanism for simultaneously embedding words and events in the same space (Section 6.1). We present several methods to leverage those embeddings for key historical events detection by evaluating the distance between words and events (Sections 6.2, 6.3).

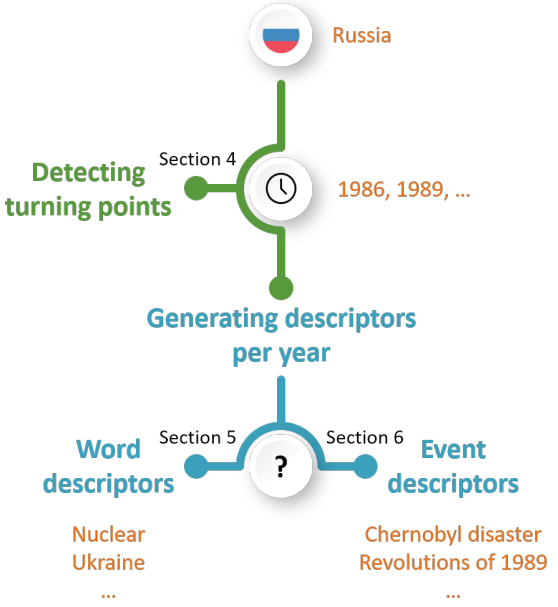

Figure 2: Flow diagram of timeline generation. The two basic building blocks are detecting turning points and generating descriptors, where the descriptors can be either words or events.

Figure 2 presents the flow of the paper through an example. Consider the word 'Russia'. First, we identify its turning points (Section 4), and then generate descriptors – either words (Section 5) or events (Section 6) – to construct its timeline. We contribute several algorithms for identifying significant events leveraging various types of embeddings, including a supervised learning approach.[2]

2 Related Work

Semantic Change: Most work on language evolution has focused on identifying semantic drifts and word meaning changes (see Kutuzov et al. (2018) for a recent survey). Various approaches have pursued the task of detecting changes in word meaning (Sagi et al., 2009; Mitra et al., 2014; Wijaya and Yeniterzi, 2011; Mihalcea and Nastase, 2012; Popescu and Strapparava, 2013; Jatowt and Duh, 2014; Kenter et al., 2015; Hamilton et al., 2016;

[2]Code and data available at https://github.com/guyrosin/generating_timelines

Azarbonyad et al., 2017). Specific approaches include: dynamic embedding models using a probabilistic Bayesian version of Word2Vec (Bamler and Mandt, 2017), pointwise mutual information (PMI) (Yao et al., 2018), and exponential family embeddings (Rudolph and Blei, 2018). Relatedness over time between words has also been studied. Radinsky et al. (2012) showed that words that co-occur in history have a stronger relation, Rosin et al. (2017) introduced the supervised task of temporal semantic relatedness, and Orlikowski et al. (2018) studied diachronic analogies. In our work, we focus on the world events behind the semantic changes—and isolate those events that co-occur with significant language change.

Change Detection for Semantic Shift Analysis: Detecting major changes involves detecting continuous peaks in time series. Kulkarni et al. (2015) and Basile et al. (2016) offered a mean shift model, and Rosin et al. (2017) used a threshold-based method for this task. We utilize the latter approach as it is simpler and more computationally effective.

Timeline Generation: Past work focused on generating timelines by leveraging information retrieval methods. Examples include the use of Facebook data (Graus et al., 2013), Twitter (Li and Cardie, 2014), and Wikipedia (Tuan et al., 2011) to generate context-aware timelines by ranking related entities by co-occurrence with the main timeline entity. Althoff et al. (2015) created timelines by mining a knowledge base, based on submodular optimization and web-co-occurrence statistics. Shahaf and Guestrin (2010) generated a chain of events connecting two news articles. Our work differs from the prior work in several ways. First, we consider the semantic changes a word undergoes and detect the events that influenced them. We study several word embeddings to measure change and relatedness between words and events over time and construct a timeline.

3 Event and Temporal Word Embedding

We consider several methods to represent events and words. These are used to identify semantic changes and generate timeline descriptors. To capture both words and events in the same space we consider *global embeddings*, which are created upon the English Wikipedia (see Section 7.1).

We also utilize the work of Rosin et al. (2017) for *temporal word embeddings*. Timeline construction requires modeling changes in words and events over time. When looking at a specific word, we wish to focus on its relevant meaning at a particular time. Thus, the *temporal word embeddings* are created using data from a large temporal corpus. Specifically, we leverage the New York Times (NYT) archive. The embeddings are generated for every time period (i.e., year) and enable us to investigate how words meanings and relatedness between words change over time (see Section 7.1).

Finally, in order to compare vectors of the same word in different, independently-trained, vector space models, we align every pair of models using Orthogonal Procrustes (Hamilton et al., 2016).

We use the following notations throughout the paper:

Notation 3.1. v_w is the vector representation of a word w.

Notation 3.2. v_w^t is the vector representation of a word w during time t.

Notation 3.3. $NN_k(w)$ is the set of k-nearest neighbors (kNN) of a word w.

Notation 3.4. $NN_k^t(w)$ is the set of k-nearest neighbors (kNN) of a word w during time t.

Notation 3.5. cos is cosine similarity, which we use as a similarity function between embeddings.

4 Timeline Turning Points

A timeline is composed of time points that identify the changes a word underwent. We refer to those as *Turning Points*, and experiment with several methods to identify them. Formally, let w be a target word, and t be a time point. Each method approximates the probability $d_t(w)$ of t to be a turning point of w. The turning points are then selected by performing peak detection (Rosin et al., 2017) on the series of $d_t(w)$ for every t. We experiment with two methodologies for turning point detection, leveraging the embeddings we introduce in Sections 3, 6.1:

(1) Neighborhood: Changes in the neighborhood of a word over time can be used to capture semantic changes of the word. This method measures the difference between the similar words sets of w between two consecutive years. Formally:

$$d_t(w) = 1 - \frac{\left|NN_k^t(w) \cap NN_k^{t-1}(w)\right|}{k} \quad (1)$$

where $NN_k^t(w)$ is the set of k-nearest neighbors (kNN) of w during time t.

(2) EmbeddingSimilarity: Employing word embeddings, we can also look at the change in the embedding vectors of w:

$$d_t(w) = 1 - cos\left(v_w^t, v_w^{t-1}\right) \quad (2)$$

5 Word Descriptors

The second building block of a timeline is *explaining* what triggered the semantic changes. We refer to such explanations as *descriptors*. One can explain semantic changes with words—significant associated words or terms that correlate to the target word's meaning drift. Letting w be the target word, and t be a time point, we are looking for words that became closer to w in vector space during t. Specifically, we look at the nearest neighbors of w at times t and $t-1$, and denote the set of descriptors by D_t:

$$D_t(w) = NN_k^t(w) \setminus NN_k^{t-1}(w) \quad (3)$$

For example, using this method for 'Russia' results in *Soviet Union* and *Soviet* for 1989, when the Soviet Union was dissolving, and *Ukraine*, *Kyrgyzstan*, and *Latvia* for 1990, when these countries attempted to gain independence from the Union.

6 Event Descriptors

As an alternative for word descriptors, we consider event descriptors. To generate these, given a target word w, our task is to identify its change in time t by a set of significant events E that likely affected w. In this section, we first describe the embeddings we use (Section 6.1) and then present several methods for detecting significant events (Sections 6.2, 6.3).

6.1 Projected Embedding for Events

Temporal word embeddings (Section 3) are created for every time period. They enable us to investigate how word meaning and relatedness between words change over time. However, as it may take some time until an event's name is determined and referred to in newspapers, the paper's text may not have meaningful embeddings for those events. For example, the name "World War I" was used only after WWII started. As a result, we are not able to compare events and words.

To address this problem, we leverage the global embeddings (Section 3). Since Wikipedia articles typically contain balanced descriptions of events, they can be a proper basis for event embeddings. Recall that the way these embeddings are created enables creating a common latent space for *both* words and concepts (and specifically, events), allowing us to compare both at the same time. Our solution involves projecting the global model on each temporal one. This way, we create a joint vector space for words and events, which represents a specific time period. We refer to these embeddings as "*Projected Embeddings*".

We assume that most words' meanings do not change over time and learn a transformation of one embedding space onto another, minimizing the distance between pairs of points. Let us define $W_{wiki} \in \mathbb{R}^{|V_{wiki}| \times d_{wiki}}$ as the matrix of embeddings learned from Wikipedia, where d_{wiki} is the embedding size and $|V_{wiki}|$ is the vocabulary size of Wikipedia. Similarly, $W_{nyt}^{(t)} \in \mathbb{R}^{|V_{nyt}^{(t)}| \times d_{nyt}^{(t)}}$ is the matrix of embeddings learned from the NYT at time t, where $d_{nyt}^{(t)}$ is the embedding size and $|V_{nyt}^{(t)}|$ is the vocabulary size of the NYT at time t. We seek a matrix $W^{(t)} \in \mathbb{R}^{|V_{wiki}| \times d_{nyt}^{(t)}}$ that will contain the transformation of W_{wiki} to $W_{nyt}^{(t)}$ for time t. By making an additional simplifying assumption that the vector spaces are equivalent under a linear transformation, we are able to find $W^{(t)}$ by optimizing the following linear regression model:

$$\arg\min_T \sum_{w_i \in V_{wiki} \cap V_{nyt}^{(t)}} \left\| W_{wiki}(w_i)T - W_{nyt}^{(t)}(w_i) \right\|_2^2 \quad (4)$$

where $T \in \mathbb{R}^{d_{wiki} \times d_{nyt}^{(t)}}$. We then obtain the projected matrix:

$$W^{(t)} = W_{wiki}\widehat{T}^{(t)} \quad (5)$$

where $\widehat{T}^{(t)}$ is the result of Equation 4. Similar methods were used in the field of temporal semantics to align embeddings of different time periods to a unified coordinate system (Szymanski, 2017; Kulkarni et al., 2015).

6.2 Similarity-Based Event Detection

We hypothesize that the events closest in vector space to a word should be the most significant to its timeline. We experiment with two score functions that are based on semantic similarity. The descriptors are chosen as the top-scoring events.

ByWord: Given a target word w, we look for its closest events in a specific time. We define a score function of an event e: $score(e) = cos(v_w, v_e)$ where cos is cosine similarity, and v_w and v_e are the respective embeddings of w and e.

ByKNN: We wish to extend the "impact circle" of the event, as events sometimes do not affect a word directly but through other words. We look for events that are closest not only to the target word but also to its neighbors. We calculate the following score for every possible event e:

$$score(e) = avg(\{cos(v_n, v_e) : n \in \{w\} \cup NN_k(w)\}) \quad (6)$$

6.3 Supervised Event Detection

The previous methods discuss only the semantic similarity of words and events, where we are actually interested in the probability of events to affect words. There are often multiple possible events that can act as explanations. Consider the following example. In 2010, several events related to Russia happened: New START (nuclear arms reduction treaty between the USA and Russia) was signed, there was a Winter Olympics, and the ROKS Cheonan (a South Korean warship) sunk. All relate to Russia, but only one appears to indicate a meaningful change to it—the New START event. Identifying the right events is a highly challenging task, as most usually all the candidate events are impactful events, related to the target word, and have an impact on various words due to their significance. As another example, Nelson Mandela's death is semantically the closest event to the word 'Clinton' during 2013, based on our projected embeddings. Though it is surely a powerful event and one that is related to many world leaders, it is hard to describe it as a turning point for either Bill or Hillary Clinton. Therefore, we attempt to *learn* which are the most relevant events for a given word. We present a classifier that receives an event and a word, and outputs the probability this event affected that word. This classifier functions as a predictor of the probability of an event e to cause a semantic change of a word w.

Training Data

To create training data for the classifier, we can use any embedding model that embeds both events and words, namely the global or the projected embeddings (Section 3 and 6.1). Given an event, we find terms affected by it and terms that are not.

Affected Terms: We limit the set of possible affected terms by an event and consider semantically similar terms to the event (we consider cosine similarity > 0.3). A term is considered to be affected by an event if the term's meaning changed during the time of the event, and did not change in the year before the event.

Unaffected Terms: Given an event, we sample terms from its semantically similar terms that were changed in the years *after* the event, and were not changed during the year it happened. This way, we try to capture terms that are related to the event but were changed due to other reasons.

Machine Learning Approach

We consider several supervised machine learning approaches, experimenting with random forest, SVM, neural networks, etc. We also devise several features leveraged by our classifiers:

- v_e and v_w, i.e., the embeddings of the event e and the word w. Any embedding model (Sections 3, 6.1) can be used.
- The semantic similarity between v_e and v_w.
- Categories of the event e, taken from DBpedia and represented using bag-of-words. Each event is associated with one or more categories in DBpedia (e.g., social event, sports, military conflict). The bag-of-words vector comprises the top 150 categories.
- Features that indicate the event's popularity: number of internal and external links in e's Wikipedia page, pageviews count of e's Wikipedia page[3]. Intuitively, a popular event might be impactful.

7 Experimental Setup

We briefly describe our dataset and embeddings before focusing on the evaluation.

7.1 Implementation Details

Embeddings: The global embeddings were created based on the Wikipedia dump of May 2016, using Word2Vec's skip-gram with negative sampling, with a window size of 10. Following Sherkat and Milios (2017), we perform a preprocessing step necessary for the embedding process to capture Wikipedia concepts and not just words: each inner link in the text (i.e., a link to a Wikipedia article) is replaced by an ID, so that every link to the same page is replaced by this page's ID. After filtering low-frequency words and concepts, we find 3.2M unique embeddings, of which 1.7M are concepts.

[3]We used Wikimedia Foundation's API to get pageviews of a single month (specifically October 2017).

For constructing temporal embeddings, we used the NYT archive[4], with articles from 1981 to 2016 (9GB of text in total). For each year of content, we created embeddings using Word2Vec's skip-gram with negative sampling, with a window size of 5 and a dimensionality of 140, using the Gensim library (Rehurek and Sojka, 2010). We filtered out words with less than 50 occurrences.

Events Data: We used DBpedia and Wikipedia as sources for events. First, we mined entities from DBpedia whose type is 'event' (i.e., `yago/Event100029378`, `Ontology/Event`), and that have an associated Wikipedia page and associated year of occurrence. Second, we mined 50K events from Wikipedia's monthly events pages[5] and retained the 30K events corresponding to our focus time period of 1981 to 2016. In this work, we focus on large, significant events, since these have the most potential to affect language (Chieu and Lee, 2004). Thus, we retained events with over 6000 monthly views (in October 2017) and over 15 external references. Our final dataset contains 1233 events, most related to armed conflicts, politics, disasters, and sports.

Classifier Dataset: To construct a "ground truth" dataset for our classifier, we find pairs of events (from the events dataset) and their affected and unaffected terms, as described in Section 6.3. For each event, we use either the global or projected embeddings to find 20 affected terms (there may be less, depending on the sensitivity of the change detection algorithm) and 20 unaffected terms. The dataset contains 21K pairs in total.

7.2 Experimental Methodology

We perform both qualitative and quantitative evaluations. First, we conduct user studies to capture the utility of our algorithms as they might be used in practice (e.g., in search engine results). Twenty evaluators participated using real events data (Section 7.1). We select a set of target words based on two criteria: popularity—so that most evaluators would know them and preferably parts of their history; and the number of significant related events—so that meaningful timelines would be produced. In practice, we selected 30 target words based on popularity (as expressed in the number of page views of the corresponding Wikipedia page).

[4] `http://spiderbites.nytimes.com/`

[5] For example, `https://en.wikipedia.org/wiki/Category:February_1992_events`

For a given target word, evaluators were presented with several timelines created by our algorithms and baseline methods (see below). While we evaluated both word and event descriptors for timelines, our evaluation is focused on events, as they proved to be more meaningful and interesting to the evaluators (see Section 8.2). Each timeline was accompanied by detailed descriptions and references. Our evaluators were asked to indicate whether an event was correct ('true') in its placement in the timeline and whether it was likely to have an impact on the target word. See Appendix A for a screenshot of the questionnaire used in the evaluation. Overall timeline quality was evaluated as described below.

Evaluation Metrics

Each timeline is evaluated using the following metrics (timelines with word descriptors are evaluated similarly—replacing 'event' with 'word'):

Accuracy: Fraction of events that are relevant to the target word (i.e., marked as true by the evaluators). $\frac{\#\text{true events}}{\#\text{true events}+\#\text{false events}}$

Relevance: How relevant the timeline is to the word. This is meant to approximate the precision metric. Relevance was indicated as a rank score on a scale from 1 to #timelines (#timelines being the number of timelines presented for the given word) and normalized as: $\frac{\text{relevance score}}{\#\text{timelines}}$

Missing Events: Evaluators were asked how many events they believed were missing from the timeline. We then normalize by the total number of events in the timeline. Intuitively, this measure is meant to approximate *1-recall*. $\frac{\#\text{missing events}}{\#\text{events in timeline}}$

Redundancy: Evaluators were asked how many events in the timeline are redundant (normalized by the total number of events in the timeline): $\frac{\#\text{redundant events}}{\#\text{events in timeline}}$

Ranking: Evaluators were asked to subjectively rank presented timelines from best to worst.

Effectiveness: Evaluators were asked to indicate their familiarity with the event history both before and after seeing the timeline. The difference between the two scores indicated the 'effectiveness' (as a soft measure of whether the timeline contained anything surprising or novel). The pre-evaluation score also served to measure the evaluator's familiarity with the topic.

Methods Compared

We perform experiments for the two building blocks of a timeline. First, we compare methods

of identifying turning points (Section 4). We approximate a gold standard for turning points by having evaluators mark years in which there is a turning point. This is determined by looking at all the events that took place during a specific year and approximating whether any of them is significant to the target word. We compare the identified years of our methods to this gold standard.

Second, we evaluated different ways to produce descriptors[6]:

WordDescriptors (Section 5): We use words as descriptors. For every year t, we select words that were added to the kNN of the target word during t (with $k = 20$, chosen empirically).

BaseEvents: A baseline method for event descriptors. We select events 'close' to the target word as descriptors—as measured by the frequency of the target word's appearance on the event's Wikipedia page.

WikiTimelines: Finally, we extract timelines from crowd-created Wikipedia timeline pages[7].

These baselines were compared to our algorithmic techniques:

ByWord and **ByKNN** are described in Section 6.2.

ByKNNGlobCls: We first use *ByKNN* to find 30 close events (determined empirically), and then use the events classifier (Section 6.3) to predict each event's influence. We rank the events by a combination of this prediction and the score of *ByKNN*. The classifier is trained on a dataset that was created using the global embeddings.

ByKNNCls: Similar to *ByKNNGlobCls*, with one difference: here the classifier's training set was created using the projected embeddings.

8 Results

8.1 Turning Point Evaluation

Comparing the two methods for turning point detection, we observed that 23% of the years detected by *Neighborhood* are false, compared to 15% by *EmbeddingSimilarity*. We believe this difference is due to the *Neighborhood* method capturing only the local neighborhood of the word, while an embedding can be more meaningful. For example, a word can change semantically not by altering its neighbors, but by moving in space towards other meanings, together with its neighbors.

8.2 Timeline Evaluation

We present the results of the timeline evaluation (Table 1), where the turning points are detected using the *EmbeddingSimilarity* method, as it reached the highest empirical performance (Section 8.1).

The *WordDescriptors* method achieves poor results, as expected. It is inaccurate and contains many redundant descriptors. For example, it generated the following descriptors for the word "Terror" during 2012-2014: Islamic terror, brutality, genocidal. They are all related to terror but do not help us deduce why the word 'Terror' was impacted, or what happened. Alternatively, the *ByWord* method performs much better. Looking at its generated timeline for 'Terror', we observe that it successfully identifies highly relevant events: the Benghazi attack (a terror attack against US government facilities in Libya), the mass shooting at Westgate Shopping Mall in Kenya, and the international military intervention against ISIL (the Islamic State organization). We find that *ByKNN* results and performance are similar to *ByWord*. As both methods consider the similarity between an event and a target word, we conjecture that the similarity function has a less impact on the timeline generation process. We empirically observe that in most cases a word close to an event would also be close to its neighbors.

The *WikiTimelines* method has the top accuracy. Given these timelines are manually created by domain experts, this is unsurprising. Nonetheless, the *ByKNNCls* method wins the three most important metrics: relevance, ranking, and effectiveness. Thus in the eyes of the evaluators, this method gives the most relevant timelines compared to all others, and maybe most importantly, provides novel information. As an example, the timeline created by *ByKNNCls* for 'Russia' contains several significant events that are missing from the same timeline created by *WikiTimelines*, such as Chernobyl disaster, the Revolutions of 1989 and the Dissolution of the Soviet Union.

The *ByKNNCls* method is more accurate than the other embedding-based methods, likely because it can filter out events that are identified by other methods but are in fact not impactful for the particular target word. However, it has a higher *Missing Events* score—suggesting true events are occasionally filtered out as well.

[7]For example, https://en.wikipedia.org/wiki/Timeline_of_Russian_history

Method	Accuracy	Relevance	Missing	Redundancy	Ranking	Effectiveness
WordDescriptors	0.43	0.32	0.65	0.3	0.28	0.03
BaseEvents	0.49	0.76	0.04	**0.03**	0.72	0.23
WikiTimelines	**0.81**	0.67	**0.03**	**0.03**	0.65	0.07
ByWord	0.60	0.86	0.09	0.06	0.78	**0.33**
ByKNN	0.61	0.81	0.12	0.08	0.80	0.31
ByKNNGlobCls	0.63	0.62	0.38	0.1	0.53	0.17
ByKNNCls	0.67	**0.89**	0.20	0.09	**0.86**	**0.33**

Table 1: Timelines evaluation results. Methods and metrics described in Section 7.2.

To measure the correspondence between evaluators' answers, we calculated Kendall's Tau, which resulted in an average value of 0.6.

8.3 Events Classifier Evaluation

We experiment with several supervised approaches for the events classifier (Section 6.3) and evaluate their performance using stratified 10-fold cross-validation. In this evaluation, the projected embeddings were used to create the training and test sets and for creating the classifier's features, since this configuration was found to result in the best performance (Section 8.4). Specifically, the parameters (optimized using grid search) and the AUC are as follows:

Logistic regression produced an AUC of 0.75. **SVM** with RBF kernel and C=1.0 produced 0.97. **Random Forest** classifier with 800 trees produced 0.97 as well. **Neural Network** with a single hidden layer of 100 neurons and Adam as the optimization algorithm achieved the best performance, with an AUC score of 0.98.

8.4 Projection Contribution

We measure the embeddings projection's contribution (Section 6.1) to the tasks of timeline generation and learning influence of events on words.

Timeline Generation Performance

We refer the reader to Table 1 to discuss the comparison between *ByKNNCls* and *ByKNNGlobCls*. These methods are almost identical—both use our classifier for detecting significant events. They differ in how the classifier is trained. *ByKNNGlobCls*'s training set is created using global embeddings, while *ByKNNCls*'s training set is created using projected embeddings. We observe a significant difference in the performance of these two methods. *ByKNNCls* achieves the best performance of all methods. It has far fewer false negatives than *ByKNNGlobCls* and higher accuracy. The other important metrics—relevance, ranking, and effectiveness—show improved performance as well. We conclude that representing events using the projected embedding brings high performance boosts for this task.

Embeddings	Acc.	Rec.	Prec.	F1	AUC
Glob/Glob	0.63	0.66	0.62	0.64	0.69
Glob/Proj	0.74	0.73	0.74	0.74	0.81
Proj/Glob	0.76	0.76	0.75	0.76	0.86
Proj/Proj	**0.94**	**0.94**	**0.94**	**0.94**	**0.98**

Table 2: Classifier performance using global and projected embeddings for creating its features/dataset.

Events Classifier Performance

To better understand the embedding features on the events classifier's performance (Section 6.3) we compared the impact of global and projected embeddings. Additionally, the training data of the classifier can be generated using any embedding. Thus, we perform an empirical evaluation comparing all combinations of embeddings for representing the *features* and the *training data* employed by the classifier (Table 2). Using global embeddings, we find an AUC of 0.69. Using global embeddings for the features and projected embeddings for the dataset, or vice versa, resulted in AUC of around 0.84. Using the projected embeddings for both yielded an AUC of 0.98—significantly better than any other combination—with $p < 0.05$ (using a Wilcoxon signed-rank test).

8.5 Events Classifier Contribution

Our main goal in developing the classifier (Section 6.3) was to enable us to identify the relevant events that affect a given word. As presented in Table 1, the main drawback of *ByWord* and *ByKNN* is a high false positive ratio given

this task. The *ByKNNCls* method is more accurate than the other embedding-based methods, probably due to the classifier filtering out many events that are identified by the other methods but are in fact not impactful for the particular target word. For example, we observe several false events that appear in the 'Israel' timeline that was generated by the *ByKNN* method and are all ignored by *ByKNNCls*. Each one of them is related to Israel, but not significant enough to make an impact on it, e.g., the *anthrax letters* (2001) had "death to Israel" written inside them. *Hurricane Katrina* (2005) brought Israel to send a humanitarian aid delegation to New Orleans. Furthermore, the decrease in the false positive ratio results in high ratings of the *ByKNNCls* timelines. Looking at the results in Table 1, we observe significant differences in multiple metrics: relevance, ranking, and effectiveness (tested using paired t-test with $p < 0.05$).

8.6 Discussion

Three main factors seem to affect the performance of our approach. First, ambiguity harms performance. For creating timelines for ambiguous words, a contextual embedding approach would be necessary. We leave that for future work. For example, ambiguous target words such as 'Oil' had worse scores than other similar words (e.g., 'Tsunami' and 'Disaster') and than expected. Second, a sufficient amount of significant events relevant to the target word is crucial, otherwise, the timelines would be too short in the eyes of the evaluators or the end users. For example, 'ISIS' which is a relatively new organization, has a few significant relevant events and therefore had weak results in our evaluation. Third, the available amount of data about the target word makes a difference. The more the better, as the temporal embeddings would then be rich and meaningful. We observed worse performance for relatively rare words, such as 'Bombing', compared more common ones (e.g., 'Attack' and 'Russia').

9 Conclusions

In this work, we develop methods to model the evolution of language in relation to world events. We introduced the task of timeline generation, which is composed of two components: identifying turning points when semantic changes occur, and representing descriptors (i.e., words or events in our case). We presented several embeddings for the task and studied their effect. We find that our proposed method of projecting embeddings from a large, static model to a temporal one (i.e., from *Wikipedia* to the *New York Times*) yielded the best performance. Given several baselines we determined that a supervised approach leveraging the projected embeddings yields the best results. Using our method, high quality timeline generation can be done automatically and at scale.

Abstract

Phenomenon-specific "adversarial" datasets have been recently designed to perform targeted stress-tests for particular inference types. Recent work (Liu et al., 2019a) proposed that such datasets can be utilized for training NLI and other types of models, often allowing to learn the phenomenon in focus and improve on the challenge dataset, indicating a "blind spot" in the original training data. Yet, although a model can improve in such a training process, it might still be vulnerable to other challenge datasets targeting the same phenomenon but drawn from a different distribution, such as having a different syntactic complexity level. In this work, we extend this method to drive conclusions about a model's ability to learn and *generalize* a target phenomenon rather than to "learn" a dataset, by controlling additional aspects in the adversarial datasets. We demonstrate our approach on two inference phenomena – dative alternation and numerical reasoning, elaborating, and in some cases contradicting, the results of Liu et al.. Our methodology enables building better challenge datasets for creating more robust models, and may yield better model understanding and subsequent overarching improvements.

1 Introduction

To successfully recognize textual entailment (RTE; Dagan et al., 2013), also known as natural language inference (NLI) (MacCartney and Manning, 2008; Bowman et al., 2015), a system needs to model a broad range of inference phenomena. Pre-neural systems often included explicit components, such as engineered features or syntax-based transformations (e.g. Stern and Dagan, 2012; Stern et al., 2012; Bar-Haim et al., 2015), to address particular inference types such as syntactic, lexical, and logical inferences. Today's neural models do not explicitly model such inferences, but instead attempt to learn them implicitly from the training data. Despite their success on common NLI dataset, recent challenge datasets designed for probing different linguistic phenomena showed that neural models often fail on particular inference types, like recognizing semantic relations and negation (Poliak et al., 2018; Naik et al., 2018; Glockner et al., 2018).

Recently, Liu et al. (2019a) showed that when probing reveals a model's failure on a specific linguistic phenomenon, it is often possible to amend this failure. They suggested to fine-tune the model on (a training section of) the challenge dataset itself, in order to teach it to address the specific target phenomenon, or in other words, to "inoculate" it against the adversarial data. Inoculation has two possible outcomes. The first - a success to address the phenomenon after fine-tuning - suggests the original training set did not cover this phenomenon sufficiently ("blind spot" of the dataset). A failure, on the other hand, indicates an inherent model weakness to handle the target phenomenon. This was presented as a general methodology, and was demonstrated on the NLI task, among others.

The inoculation approach seems an appealing way to teach NLI models to properly address a broad range of inference phenomena, by training on a targeted inoculation dataset for each phenomenon. However, the methodology as suggested in Liu et al. (2019a) is not conclusive as to whether inoculation succeeded thanks to the model learning the target phenomenon in a *general* manner or due to overfitting the particular distribution of the inoculation data, possibly leveraging superficial cues or artifacts. Accordingly, successful inoculation may not reliably predict whether the model would successfully address the same target phenomenon when facing it on datasets drawn from different distributions.

In this paper, we extend the inoculation method-

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 196–205
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

ology, analyzing the ability of models to generalize across different data distributions when addressing a specific inference phenomenon. In particular, we suggest varying both training and test distributions along several linguistic dimensions, like syntactic complexity or lexical diversity. In addition to indicating the model generalization ability, our methodology directs how to design the inoculation data in order to sufficiently cover the targeted phenomenon, when possible.

We demonstrate our methodology on two inference types, picked from the GLUE benchmark (Wang et al., 2019) diagnostic dataset: (1) dative alternation, a syntactic phenomenon, and (2) a specific type of numerical reasoning, pertaining to logical and arithmetic inference. To create our datasets, we introduce a templating method, by which we generated hundreds of synthetic examples from a single original sentence, while controlling the variance between the datasets.[1] We employ a recent NLI model, based on the pre-trained BERT masked language model (Devlin et al., 2019) fine-tuned on the MultiNLI dataset (Williams et al., 2018). For the dative alternation case, we find that the model struggles with generalizing over the syntactic dimension, requiring training over a relatively large variety of syntactically complex sentences. For the numerical reasoning case, we find that the model notably fails to generalize across diverse number ranges, a conclusion that might have been missed if we were to use only the original inoculation methodology. We hope our methodology will be adopted for additional NLP tasks, and specifically to a broader range of entailment inference types, as an avenue for developing robust NLI systems that can address specific inference phenomena.

2 Background

Neural NLI Models. Natural language inference is the task of identifying, given two text fragments, whether the second (*hypothesis*) can be inferred from the first (*premise*). While earlier models for these tasks relied on domain knowledge and lexical resources like WordNet (e.g MacCartney et al., 2008; Heilman and Smith, 2010), the release of the large-scale Stanford natural language inference dataset (SNLI; Bowman et al., 2015) shifted the focus to neural models which thrive given such large datasets. Typically, these models encode each of the premise and the hypothesis, combine them into a feature vector, and feed it into a classifier to make the entailment prediction. The encoding of the two sentences can be either independent of each other or dependent using an attention mechanism. These models typically do not rely on any external knowledge other than pre-trained word embeddings.

Contextualized Word Embeddings. Recently, the word embedding paradigm shifted from static token-based embeddings to dynamic context-sensitive ones. Notable contextual representations are ELMo (Peters et al., 2018b), BERT (Devlin et al., 2019), GPT (Radford et al., 2018) and XL-Net (Yang et al., 2019), which are pre-trained as language models on large corpora. Contextualized word embeddings have been used across a broad range of NLP tasks, outperforming the previous state-of-the-art models. Specifically, several works showed that they capture various types of linguistic knowledge, from syntactic to semantic and discourse relations (e.g. Peters et al., 2018a; Tenney et al., 2019; Shwartz and Dagan, 2019). Among many other tasks, NLI has also benefited from the use of contextualized word embeddings. The current state-of-the-art models use pre-trained contextualized word embeddings as their underlying representations, while fine-tuning on the NLI task (Liu et al., 2019b; Devlin et al., 2019). Despite their remarkable success on several datasets, it still remains unclear how these models represent the various linguistic phenomena required for solving the NLI tasks.

Existing Drawbacks and Challenge Datasets. Training an NLI model in this end-to-end manner assumes that any inference type involved in the sentence-level decision may be learned from the training data. However, recent work created challenge datasets which show that these models—when trained on the original NLI datasets—fail when they need to make inferences pertaining to certain linguistic phenomena, often ones which are not sufficiently represented in the training data. In these challenge datasets, a model is trained on the general NLI datasets, i.e. SNLI or the Multi-Genre Natural Language Inference datasets (MultiNLI; Williams et al., 2018). It is then used as a black box to evaluate on a given test set.

[1] All datasets and resources are available at https://github.com/ohadrozen/generalization.

Glockner et al. (2018) showed that substituting a single premise term with its hypernym (to create entailment examples) or a mutually exclusive term (for contradiction examples) challenges several pre-trained NLI models that performed well on the datasets on which they were trained. Naik et al. (2018) constructed a suite of "stress-tests", each pertaining to some linguistic phenomenon, and showed that NLI models fail on many of them (e.g. numerical reasoning, logical negations, etc.). Another line of work showed that NLI models may reach a surprising performance level on the NLI test sets just by exploiting artifacts in the generation of the hypotheses, rather than learning to model the complex entailment relationship (Gururangan et al., 2018; Tsuchiya, 2018; Poliak et al., 2018).

Fine-tuning on Challenge Datasets. Recently, Liu et al. (2019a) suggested that a model's failure to address a specific linguistic phenomenon may be attributed to one of the following cases: either the NLI training data does not sufficiently represent this phenomenon ("*dataset blind spot*") or the model is inherently incapable of learning to address this phenomenon. They suggested to fine-tune the NLI model on the specific challenge dataset in order to find out which case is currently observed. Specifically, in the case of a data blind spot, the performance on the challenge dataset is expected to improve after fine-tuning (i.e., the model is "inoculated" against the adversarial data). Otherwise, if the performance does not improve despite exposure to the phenomenon by fine-tuning, this may be an inherent weakness of the model. Finally, an additional possible outcome is that the performance on the original NLI test set is severely hurt after fine-tuning on the specific phenomenon, which may be due to overfitting.

3 Methodology

We extend the inoculation approach of Liu et al. (2019a) by additionally controlling for finer-grained dimensions of the training and test data. For a given inference type (Section 3.1), our methodology consists of the following steps. (1) First, we extract *premises* in the MultiNLI (Williams et al., 2018) training set that include the targeted linguistic phenomenon (Section 3.2). (2) For each found premise, we generate multiple diverse variations using our templating method (Section 3.3). (3) After generating diverse premises, we generate multiple matching *synthetic hypotheses* using a templating method (Section 3.4). As we generate synthetic hypotheses, we can make sure the premise-hypothesis pairs differ along our proposed diversity dimensions. (4) Finally, we define the train and test sets so that the variance between them is controlled with respect to the different dimensions (Section 3.5). This facilitates probing the success of the model to generalize a given inference type with respect to a specific dimension of the data.

3.1 Inference Types

We focus on the following two inference types from the diagnostic set of the GLUE benchmark (Wang et al., 2019) as test cases for our methodology.

Dative Alternation. This inference type refers to the alternation between a double-object construction ("*I baked him a cake*") and a prepositional indirect-object construction ("*I baked a cake for him*").

Numerical Reasoning. We focus on sentences relating to numbers by the relational phrases "*more than*" and "*less than*", normalizing all numbers to numerals. For example, "*There are **3** apples on the table*" entails "*There are **more than 2** apples on the table*"

3.2 Premise Extraction

For a given inference type, we start by finding premises in the MultiNLI train set that include the targeted linguistic phenomenon. We then construct templates based on these premises which are later used to generate synthetic premises and hypotheses. We do so in a semi-automatic way: we first use simple heuristics to track good candidates, and then manually select those that can be used as premises of NLI pairs that include the linguistic phenomenon in focus. For example, to track premises for the numerical reasoning inference type, we search for premises containing numbers and then choose the ones in which adding *more than* or *less than* before the number would keep the premise grammatical and coherent (e.g. "*the U.S. economy added **45** million jobs.*"), or ones which already include these terms before the number (e.g. "*The Citigroup deal, from beginning to end, took **less than 5** weeks.*"). We also make sure that we have enough diversity in the premise

	Dative Alternation

(14)	**Gen. Hypothesis (Neutral):**	*[My marriage], [despite much frustration], [lasted] 8 [years].*

Table 1: Examples for the premise-hypothesis generation process (notations are explained in Sections 3.3 and 3.4): (a) Premises are extracted from the MultiNLI train set (rows 1 and 8) (b) Premise templates are manually created (rows 2 and 9) (c) Hypothesis templates are automatically generated using the premise templates (rows 3 and 10) (d) New premises are automatically generated by instantiating them with the turkers' answers (rows 4 and 11) (e) new hypotheses with same instantiations are generated (rows 5-7 and 12-14).

length and syntactic complexity (see Section 3.5). Rows 1 and 8 in Table 1 exemplify such premises for the dative alternation and numerical reasoning inference types.

3.3 Premise Generation

To isolate the lexical dimension from the syntactic one, for each target phenomenon we synthesize multiple new premises, all sharing a similar syntactic structure by construction. To do so, we manually generate a *premise template* by replacing at least four spans in the premise with arguments ARG_i as placeholders. We do so while keeping the words related to the phenomenon in focus within the template. For example, from the premise "*Even our noble Saudi allies aren't willing to lend us their air bases.*", we generated the template "ARG_1 ARG_2 *lend* ARG_3 ARG_4." (see rows 2 and 9 in Table 1). We then let crowdsourcing workers instantiate each of the arguments to create new sentences. For the instantiations to later construct coherent sentences with high likelihood, we ask the workers to instantiate each argument separately, leaving the rest of the sentence unchanged, in a way that yields a new grammatical and coherent sentence that can make sense in some possible made up context (e.g. "*Even our noble Saudi allies ⟨* ***span to fill in*** *⟩ lend us their air bases.*"). To maintain similar sentence lengths and structures, we limit the instantiations to be at most one word longer or shorter than the original spans. For each argument we collected 6 instantiations which were manually validated for grammaticality and semantic coherence. We used all possible combinations of instantiations to generate hundreds of premises per template (rows 4 and 11 in Table 1). The annotation task was performed in Amazon Mechanical Turk, where to control the quality of the workers, we required that they have at least 98% acceptance rate for prior HITs. We paid $2.5 for two instantiations of all arguments in a given sentence (at most 14 instantiations per sentence).

3.4 Hypothesis Generation

For each *premise template* we automatically generate multiple *hypothesis templates* for each entailment label (entailment, neutral and contradiction), which differ from the premise only in the phenomenon in focus, as detailed for each inference type below.

Dative Alternation. We generate the entailed hypothesis templates by applying the inference type. Specifically, for entailing dative alternation, we either switch to the alternate constructions (row 5 in Table 1) or remove the first argument after the dative verb (row 6). For contradicting hypotheses templates, we remove the second argument, creating a grammatical yet contradictory hypothesis template (row 7). For each premise template we therefore generate 2 entailment hypotheses and 1 contradictory (no neutral).

Numerical Reasoning. For a premise consisting of a target numeric value NUM_p preceded by a relational expression REL_p $\in$

$\{less\ than, more\ than, \emptyset\}$, we generate multiple hypotheses by replacing the target number by a random number (from a given target range, see further below) and the relational expression by each of the expressions. The sentence-pair label is determined by the relation between the numeric expressions in the premise and the hypothesis, and may be any of entailment, neutral, or contradiction. For example, consider the premise template "[*The union*] [*has*] more than 4 [*thousand members*] [*in Canada*]". Replacing the numeric expression "*more than 4*" by "3" yields contradiction, while the substitute "*more than 3*" is entailing, and "*more than 5*" is neutral. This way, for each premise template we generate 22 different hypotheses: 4 entailment, 6 neutral and 12 contradiction. We used numeric values within the range 2-999.

3.5 Controlled Data Splits

The main motivation for our data splits is to control the variance between the train and test sets with respect to certain data dimensions. Specifically, for both inference types, we create a variance along the syntactic complexity dimension. Based on the premise template, we divided each dataset into 3 subsets with different syntactic complexity levels: *simple*, *medium* and *complex*, denoted by S, M and C respectively. We do so according to two criteria: sentence length and the depth in the constituency parsing tree in which the inference type occurs, using the Stanford Parser (Manning et al., 2014) (see Table 2).[2]

We also create a variance along different lexical dimensions. From the *simple* subset S we generate two additional subsets S_{Lex1} and S_{Lex2} in the following way. For each *simple* template, we first split its original instantiations into two groups, and then instantiate each such group separately into the template, creating two sets of instantiations of the same template $s_1 \in S_{Lex1}$ and $s_2 \in S_{Lex2}$, which are syntactically similar by construction, yet lexically different. We repeat this process for the *complex* subset as well to create C_{Lex1} and C_{Lex2}. We further split the dative alternation datasets lexically by the main verb, which allows testing how well the model generalizes this inference type for different dative verbs. This is done by changing the main dative verb in S_{Lex2} and C_{Lex2} creating new subsets S'_{Lex2} and C'_{Lex2}.[3] We split the numerical reasoning dataset similarly using different numerical ranges in the training and test sets.

In Section 4 we experiment with various splits of the training and test sets, which allow us to test the model's generalization over the various dimensions. For example, we test whether the model can learn an inference type on syntactically *simple* examples and generalize it to *complex* ones. See Table 2 for the statistics of each dataset.

	Simple	Medium	Complex	All
Number of Premise Templates				
Datives	10	9	9	28
Numbers	9	12	9	30
Number of Examples				
Datives	21K	36K	34K	91K
Numbers	181K	239K	182K	602K

Table 2: Statistics of the dative alternation and numerical reasoning datasets divided by syntactic complexity level.

4 Experiments

We use a standard model based on BERT (Devlin et al., 2019) as our NLI model. Specifically, we used the base-uncased pre-trained model from the pytorch-pretrained-bert library[4], and fine-tuned it for the NLI task on MultiNLI.[5] We conduct several experiments. First, we use our datasets for a typical probing task, i.e. testing how well the model performs on each inference type, *without being trained to address the specific inference type* (Section 4.1). Then, similarly to Liu et al. (2019a), we test the model's ability to learn each inference type by *further fine-tuning on specific examples for it* (Section 4.2). Finally, incorporating our innovation, we analyze the model's generalization ability by introducing variance in the proposed data dimensions between the train and test sets (Section 4.3).

4.1 Probing

We randomly selected 4,000 examples from each of the *simple*, *medium* and *complex* datasets, with

[2] For dative alternation we consider the depth of the dative verb, while for the numeric reasoning data we look at the depth of the number. We consider premise templates with less than 16 words and depth < 4 as *simple*, more than 25 words and depth > 6 as *complex*, and the rest as *medium*.

[3] For each template we choose a new dative verb that keeps the sentence coherent and grammatical.

[5] The MultiNLI dataset has domain-matched and mismatched development data. We use "matched" for our testing.

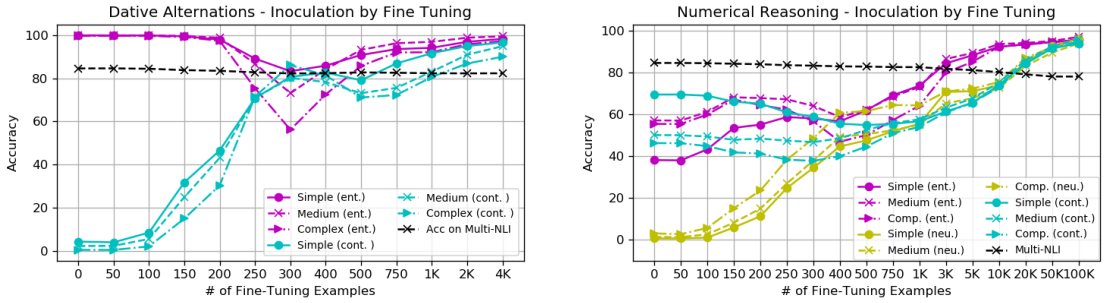

Figure 1: Average test accuracy on the dative alternation dataset (left) and the numerical reasoning dataset (right) as a function of number of training examples, divided by label. The black lines represent the average accuracy of the model on MultiNLI matched development set after fine-tuning. For numerical reasoning we use a larger range on the x-axis to capture the near-perfect performance for 100k examples.

Complexity	Ent.	Neutral	Cont.	All
MultiNLI Matched Dev Set				
All	83.56	84.12	86.37	**84.66**
Dative Alternation				
Simple	100	-	4.22	**52.63**
Medium	100	-	2.16	**49.27**
Complex	99.77	-	0.36	**50.45**
All	99.92	-	2.25	**50.78**
Numerical Reasoning				
Simple	38.14	0.66	69.53	**45.04**
Medium	57.14	1.36	50.14	**38.11**
Complex	55.48	3.04	46.26	**36.15**
All	50.25	1.69	55.31	**39.77**

Table 3: Accuracy of the model trained only on MultiNLI on our datasets, which are used as probing datasets. The Complexity column refers to the syntactic complexity of the sentences.

balanced labels, to serve as a test set. Table 3 shows the accuracy of the model on each test set.

On our dative alternation dataset, the accuracy on our test sets is substantially lower than on the MultiNLI development set (50.78% versus 84.66% respectively), suggesting that the model has not learned to address this inference type from the MultiNLI training data. The model has very high accuracy on the entailment examples, while close to zero on the contradiction ones. This is understandable considering that the sentence-pairs in this dataset by construction have high lexical overlap between the premise and hypothesis, leading the model to default to almost always predicting entailment.

On the numerical reasoning dataset, the model also seems to fail on this inference type with test set accuracy much lower than on the MultiNLI development set, suggesting that the model hasn't learned to address this inference type as well. The model has relatively low accuracy on the entailment and contradiction examples while close to zero accuracy on the neutral ones. This is due to the fact that the model classifies sentence-pairs with high lexical overlap but with a different numerical phrase as either entailment or contradiction, but almost never as neutral.

4.2 Fine Tuning

We follow Liu et al. (2019a) and fine-tune the model on the phenomenon-specific examples, testing how many training examples the model needs to observe before it performs reasonably well on this inference type.[6]

We split each dataset to training (77%) and test (23%) sets such that the same template is not used in both training and test. Each set consists of templates from all syntactic complexities, and a balanced number of examples from each label. We experiment with a different number of training examples ranging from 0 to 4,000 for the dative alternation sets and from 0 to 100,000 for numerical reasoning. We repeat this experiment five times with different training and test splits, while also testing the performance on the original MultiNLI matched development dataset. We report in Figure 1 the average accuracy across runs as a function of the number of training examples. In both datasets, fine-tuning greatly improves the performance.

On the dative alternation data, fine-tuning brings the performance on contradiction from 0 to 90%, suggesting the model can now distinguish well between the entailing and contradictory examples, reaching similar accuracy on both. The

[6]To fine-tune BERT, we use the Adam optimizer (Kingma and Ba, 2015) with a learning rate of $7 \cdot 10^{-7}$, $\beta_1 = 0.9$, $\beta_2 = 0.999$, and L_2 weight decay of 0.01.

good performance on this inference type indicates a blind spot in the MultiNLI dataset rather than a model weakness. As expected, the model reaches slightly better performance on examples with simpler syntactic structure than those with complex ones. Fine-tuning with 4,000 examples reduces the performance on the MultiNLI development set in about 2%. As Liu et al. suggested, this could result from the distribution of our dataset deviating from the distribution of the MultiNLI dataset, and possibly from having the original model overfitting to that distribution.

With respect to numerical reasoning, though only after a relatively large number of 10,000 training examples, the model seems to succeed in learning the phenomenon. According to Liu et al. (2019a), this result suggests that our challenge dataset did not reveal a weakness in the model, but instead a blind spot in the original dataset. Yet, this conclusion is challenged in the next subsection. In the numerical reasoning case we notice an even larger decrease in the performance on MultiNLI after fine-tuning - up to 6.5%. This may again result from different distributions across the datasets, influencing the performance more intensely due to the larger number of training examples.

4.3 Generalization

We now analyze the model's ability to generalize for each inference type across various data dimensions, using our proposed methodology. As we will see, this type of analysis yields additional, more elaborate and sometimes contradictory insights, which are not attainable by the prior methodologies that we applied in the previous two subsections.

Dative Alternation. First, we test the model's generalization ability at the syntactic complexity dimension, by training it on a dataset belonging to one category of syntactic complexity (among *simple*, *medium* and *complex*; see Section 3.5), and testing it on a dataset belonging to either *simple* or *complex*. We make sure examples in the training and test sets were generated by different templates.

The left side of Figure 2 displays the performance on the various experiments, revealing an interesting pattern: on the *simple* syntax test set, good performance is attainable regardless of the training set, while for the *complex* syntax test set, training on simple syntax performs inferiorly to training on complex syntax. This suggests that although the model is able to learn the dative alternation phenomenon and generalize to a certain extent, the model does not learn the phenomenon on its own, decoupled from learning argument positions, but rather it needs to be trained with dative alternation examples of high syntactic complexity to perform well.

The second data dimension we test is lexical diversity. We test the model's ability to generalize across syntactically-similar examples with a different main dative verb. To isolate the lexical aspect from other aspects, we fix the syntax by using the same templates for training and testing. For the *simple* category, we train the model on the S_{Lex1} subset and test it on both the S_{Lex2} subset with the same main dative verb, and on S'_{Lex2} with a different main verb that has not been seen in the training examples (see Section 3.5). We repeat the same process for the *complex* category.[7]

The right side of Figure 2 shows that when tested on the same syntactic complexity level as seen during training, the performance remains similar regardless of the similarity between the train and test dative verbs. This suggests that the model generalizes well on the lexical dimension and learns to recognize the dative alternation inference independently of the specific verb. We also observe that the model generalizes more easily from examples with simple syntax: on this category, the performance gap between the two test sets S_{Lex2} and S'_{Lex2} is smaller than the gap between the graphs of the complex category. This suggests the conclusion that unlike syntactic diversity, a large lexical diversity is not necessary when inoculating for dative alternation.

Numerical Reasoning. Again, we test the model's generalization ability with respect to syntactic complexity by splitting the train and test sets based on this dimension (left side of Figure 3). As opposed to dative alternation, here the gap between the performance when testing examples with more complex syntax than the training set and the performance when testing on simpler examples is rather small after enough training examples (up to 3.2% difference after 3,000 examples). We conjecture that the model learns to identify local patterns (e.g. "*more than* X") while the rela-

[7] For both S_{Lex1} and C_{Lex1} we sample 256 examples from each of 5 manually chosen templates from the related category.

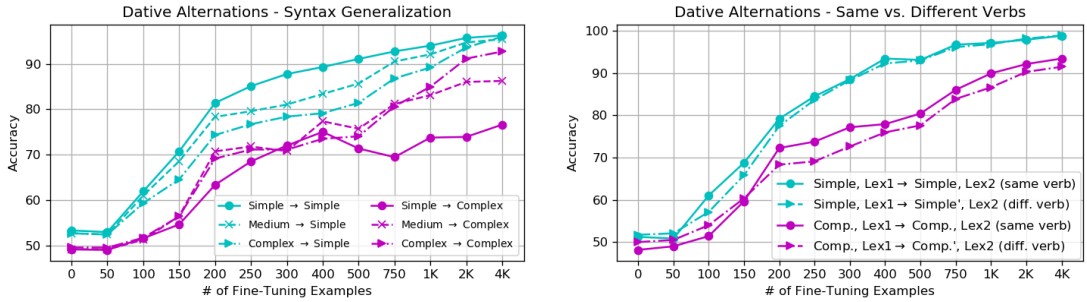

Figure 2: Test accuracy on the dative alternation dataset over the syntactic dimension (left) and average performance on the lexical dimension (right) as a function of number of training examples. The larger gaps on the left graph in comparison to the much smaller gaps on the right graph indicate a limited generalization ability over the syntactic dimension and a better one over different dative verbs

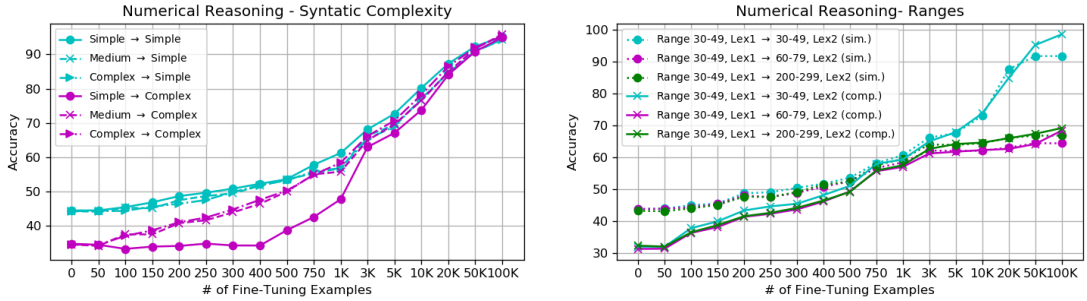

Figure 3: Test accuracy on the numerical reasoning dataset over the syntactic dimension (left) and on the range dimension (right) as a function of number of training examples. The gaps on the right graph comparing to the convergence on the left one suggest a good generalization ability over the syntactic dimension and a poor one over different number ranges.

tionships between them are less dependent on the global syntactic structure of the sentence. Moreover, the difference between the premise and the hypothesis is lexical and local (i.e. replacing the relational operator and the number), while their syntax remains otherwise identical, shifting the model's focus away from the syntax.

Regarding lexical diversity, we test whether the model can be trained on one range of numbers and perform well when tested on another. To that end, we populate the number placeholders in the templates with randomly sampled numbers from within a certain range, among 30-49, 60-79 and 200-299. We train on the first range and test on each of the ranges. To isolate the numeric aspect from the syntactic one, we fix the syntax by using the same templates for training and testing, while using different argument instantiations (as we did for the dative alternation when testing for lexical diversity of the dative verb).

The right side of Figure 3 shows the performance of each model as a function of training examples. Training and testing on the same range yields substantially better performance, while testing on a different range reaches accuracy of less than 70% even after 20,000 training examples, and seems to reach saturation. We also repeated the same experiment with number range of 1000-9999 in the test sets, resulting in a graph very similar to the 200-299 range. This indicates an inherent weakness of the model to learn the phenomenon and generalize it over different number ranges. Given that the number of training examples is limited, it might be challenging to inoculate the model to perform well on a wide variety of challenge datasets for this phenomenon. The success within the same (narrow) number range, when training gets large enough, might suggest that the model mostly memorizes specific number pairs and the arithmetic relation between them, rather than learning the arithmetic rules. These insights contradict the conclusion of the original inoculation analysis of a blind spot in the original dataset (in Section 4.2).

5 Conclusions

We presented a methodology to analyze the ability of NLI models to learn a specific inference

phenomenon and successfully generalize its modeling to datasets drawn from different distributions. By controlling the differences between the training and test sets along syntactic and lexical data dimensions, we were able to analyze how well the model generalizes with respect to each phenomenon over the different dimensions. We demonstrated our methodology on a standard model based on BERT, focusing on dative alternation and numerical reasoning. We found that high syntactic complexity is necessary for teaching dative alternations, while being less important for numerical reasoning. We also showed that the model is incapable of generalizing over different number ranges for numerical reasoning, indicating an inherent modeling weakness.

We suggest that our work opens promising as well as challenging research directions. A natural direction for future work would be to apply our methodology to a broader range of inference types and data dimensions. This would enable extensive analysis of NLI models' learning and generalization abilities, and may yield models that can truly address a range of inference phenomena in a fairly general manner. One question that still remains open at this point regards the models' ability to handle *multiple* inference phenomena within the same example, which is more representative of real-world scenarios.

Finally, we observed that fine-tuning the model on the phenomenon-specific data sometimes yields a decrease in the performance on the original dataset. One potential direction to avoid this in the future would be to perform multi-task learning rather than fine-tuning on the phenomenon-specific data. Better scheduling of multi-task training as presented by Kiperwasser and Ballesteros (2018) may also reduce the performance loss in such scenarios.

Acknowledgments

We would like to thank Ori Shapira for assisting in data analysis, and the anonymous reviewers for their constructive comments. Abstract

We present a fully unsupervised crosslingual semantic textual similarity (STS) metric, based on contextual embeddings extracted from BERT – Bidirectional Encoder Representations from Transformers (Devlin et al., 2019). The goal of *crosslingual STS* is to measure to what degree two segments of text in different languages express the same meaning. Not only is it a key task in crosslingual natural language understanding (XLU), it is also particularly useful for identifying parallel resources for training and evaluating downstream multilingual natural language processing (NLP) applications, such as machine translation. Most previous crosslingual STS methods relied heavily on existing parallel resources, thus leading to a circular dependency problem. With the advent of massively multilingual context representation models such as BERT, which are trained on the concatenation of non-parallel data from each language, we show that the deadlock around parallel resources can be broken. We perform intrinsic evaluations on crosslingual STS data sets and extrinsic evaluations on parallel corpus filtering and human translation equivalence assessment tasks. Our results show that the unsupervised crosslingual STS metric using BERT without fine-tuning achieves performance on par with supervised or weakly supervised approaches.

1 Introduction

Crosslingual semantic textual similarity (STS) (Agirre et al., 2016a; Cer et al., 2017) aims at measuring the degree of meaning overlap between two texts written in different languages. It is a key task in crosslingual natural language understanding (XLU), with applications in crosslingual information retrieval (Franco-Salvador et al., 2014; Vulić and Moens, 2015), crosslingual plagiarism detection (Franco-Salvador et al., 2016a,b), etc. It is also particularly useful for identifying parallel resources (Resnik and Smith, 2003; Aziz and Specia, 2011) for training and evaluating downstream multilingual NLP applications, such as machine translation systems.

Unlike in crosslingual textual entailment (Negri et al., 2013) or crosslingual natural language inference (XNLI) (Conneau et al., 2018), which are directional classification tasks, in crosslingual STS, continuous values are produced, to reflect a range of similarity that goes from complete semantic unrelatedness to complete semantic equivalence. Machine translation quality estimation (MTQE) (Specia et al., 2018) is perhaps the field of work that is the most related to crosslingual STS: in MTQE, one tries to estimate translation quality, by comparing an original source-language text with its machine translation. In contrast, in crosslingual STS, neither the direction nor the origin (human or machine) of the translation is taken into account. Furthermore, MTQE also typically considers the fluency and grammaticality of the target text; these aspects are usually not perceived as relevant for crosslingual STS.

Many previous crosslingual STS methods rely heavily on existing parallel resources to first build a machine translation (MT) system and translate one of the test sentences into the other language for applying monolingual STS methods (Brychcín and Svoboda, 2016). Methods that do not rely explicitly on MT, such as that in Lo et al. (2018), still require parallel resources to build bilingual word representations for evaluating crosslingual lexical semantic similarity. It is clear that there is a circular dependency problem on parallel resources.

Massively multilingual context representation models, such as MUSE (Conneau et al., 2017), BERT (Devlin et al., 2019), and XLM (Lample and Conneau, 2019), that are trained in an unsupervised manner with non-parallel data from each

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 206–215
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

language, have shown improved performance in XNLI classification tasks using task-specific fine-tuning.

In this paper, we propose a crosslingual STS metric based on fully unsupervised contextual embeddings extracted from BERT without fine-tuning. In an intrinsic crosslingual STS evaluation and extrinsic parallel corpus filtering and human translation error detection tasks, we show that our BERT-based metric achieves performance on par with similar metrics based on supervised or weakly supervised approaches. With the availability of the multilingual context representation models, we show that the deadlock around parallel resources for crosslingual textual similarity can be broken.

2 Crosslingual STS metric

Our crosslingual STS metric is based on YiSi (Lo, 2019). YiSi is a unified adequacy-oriented MT quality evaluation and estimation metric for languages with different levels of available resources. Lo et al. (2018) showed that YiSi-2, the crosslingual MT quality estimation metric, performed almost as well as the "MT + monolingual MT evaluation metric (YiSi-1)" pipeline for identifying parallel sentence pairs from a noisy web-crawled corpus in the *Parallel Corpus Filtering* task of WMT 2018 (Koehn et al., 2018b).

To measure semantic similarity between pairs of segments, YiSi-2 proceeds by finding alignments between the words of these segments that maximize semantic similarity at the lexical level. For evaluating crosslingual lexical semantic similarity, it relies on a crosslingual embedding model, using cosine similarity of the embeddings from the crosslingual lexical representation model. Following the approach of Corley and Mihalcea (2005), these lexical semantic similarities are weighed by *lexical specificity* using inverse document frequency (IDF) collected from each side of the tested corpus.

As an MTQE metric, YiSi-2 also takes into account fluency and grammatically of each side of the sentence pairs using bag-of-ngrams and the semantic parses of the tested sentence pairs. But since crosslingual STS focuses primarily on measuring the meaning similarity between the tested sentence pairs, here we set the size of ngrams to 1 and opt not to use semantic parses in YiSi-2. In addition, rather than compute IDF weights $w(e)$ and $w(f)$ for lexical units e and f in each language directly on the texts under consideration, we rely on precomputed weights from monolingual corpora $\mathbb{E}$ and $\mathbb{F}$ of the two tested languages.

The YiSi metrics are formulated as an F-score: by viewing the source text as a "query" and the target as an "answer", precision and recall can be computed. Depending on the intended application, precision and recall can be weighed differently. For example, in MT evaluation applications, we typically assign more weight to recall ("every word in the source should find an equivalent in the target"). For this application, we give equal weights to precision and recall.

Thus, the crosslingual STS of sentences **e** and **f** using YiSi-2 in this work can be expressed as follows:

$$
\begin{aligned}
v(u) &= \text{embedding of unit } u \\
s(e,f) &= cos(v(e), v(f)) \\
w(e) &= idf(e) = log(1 + \frac{|\mathbb{E}| + 1}{|\mathbb{E}_{\exists e}| + 1}) \\
w(f) &= idf(f) = log(1 + \frac{|\mathbb{F}| + 1}{|\mathbb{F}_{\exists f}| + 1}) \\
\text{precision} &= \frac{\sum_{e \in \mathbf{e}} \max_{f \in \mathbf{f}} w(e) \cdot s(e,f)}{\sum_{e \in \mathbf{e}} w(e)} \\
\text{recall} &= \frac{\sum_{f \in \mathbf{f}} \max_{e \in \mathbf{e}} w(f) \cdot s(e,f)}{\sum_{f \in \mathbf{f}} w(f)} \\
\text{YiSi-2} &= \frac{2 \cdot \text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}}
\end{aligned}
$$

where $s(e,f)$ is the cosine similarity of the vector representations $v(e)$ and $v(f)$ in the bilingual embeddings model.

In the following, we present the approaches we experimented with to obtain the crosslingual embedding space in supervised, weakly supervised and unsupervised manners.

2.1 Supervised crosslingual word embeddings with *BiSkip*

Luong et al. (2015) proposed *BiSkip* (with open source implementation `bivec`[1]) to jointly learn bilingual representations from the context cooccurrence information in the monolingual data and the meaning equivalent signals in the parallel data. It trains bilingual word embeddings with the objective to preserve the clustering structures of

[1] https://github.com/lmthang/bivec

words in each language. We train our crosslingual word embeddings using `bivec` on the parallel resources as described in each experiment.

2.2 Weakly supervised crosslingual word embeddings with *vecmap*

Artetxe et al. (2016) generalized a framework to learn the linear transformation between two monolingual word embedding spaces by minimizing the distances between equivalences listed in a collection of bilingual lexicons (with open source implementation `vecmap`[2]). We train our monolingual word embeddings using `word2vec`[3] (Mikolov et al., 2013) on the monolingual resources and then learn the linear transformation of the two monolingual embedding space using `vecmap` on the dictionary entries as described in each experiment.

2.3 Unsupervised crosslingual contextual embeddings with multilingual BERT

The above two mentioned embedding models produce static word embeddings that captures the semantic space to represent the training data. The shortcoming of these static embedding models is that they provide the same embedding representation for the same word without reflecting the context variation of them being used in different sentences. In contrast, BERT (Devlin et al., 2019) uses a bidirectional transformer encoder (Vaswani et al., 2017) to capture the sentence context in the output embeddings, such that the embedding for the same word unit in different sentences would be different and better represented in the embedding space. Multilingual BERT model is trained on the Wikipedia pages of 104 languages with a shared subword vocabulary. Pires et al. (2019) showed multilingual BERT works well on different monolingual NLP tasks across different languages.

Following the recommendation in Devlin et al. (2019), we use embeddings extracted from the ninth layer of the pretrained multilingual cased BERT-Base model[4] to represent subword units in the two sentences in assessment for the crosslingual lexical semantic similarity.

3 Experiment on crosslingual STS

We first evaluate the performance of YiSi-2 on the intrinsic crosslingual STS task, before testing its ability on the downstream task of identifying parallel data.

3.1 Setup

We use data from the SemEval-2016 Semantic Textual Similarity (STS) evaluation's crosslingual track (task1) (Agirre et al., 2016b), in which the goal was to estimate the degree of equivalence between pairs of Spanish-English bilingual fragments of text.[5] The test data is partitioned into two evaluation sets: the *News* data set has 301 pairs, manually harvested from comparable Spanish and English news sources; the *Multi-source* data set consists of 294 pairs, sampled from English pairs of snippets used in the SemEval-2016 monolingual STS task, translated into Spanish.

We apply YiSi-2 directly to these pairs of text fragments, using bilingual word embeddings trained under three different conditions (details of the training sets are given in Table 1):

bivec : BWE's are produced with *bivec*, trained on WMT 2013 ES-EN parallel training data.

vecmap : BWE's are produced with *vecmap*, trained on all WMT 2013 ES and WMT 2019 EN monolingual data, using *Wikititles* as bilingual lexicon.[6]

BERT : BWE's are obtained from pre-trained multilingual BERT models.

We compare the YiSi-2 approach to direct cosine computations on sums of bilingual word embeddings (*bivec_sum*, *vecmap_sum* and *bert_sum*). We also compare our approach to an MT-based approach, in which each Spanish fragment is first machine-translated into English, then compared to the original English fragment, using English word embeddings, produced with *word2vec* trained on WMT 2019 news translation task monolingual data. Similarity is measured either as the cosine of the sums of word vectors from each fragment (*w2v_sum*), or with YiSi using monolingual embeddings as if they were bilingual (YiSi-1_{w2v}).

[5] In this task, the order of languages in pairs was randomized, so that it was first necessary to detect which fragment was in which language. Here, we work from properly ordered pairs.

YiSi-2_{bert}	0.8723	**0.7190**

Table 2: Pearson's correlation of the system scores with the gold standard on the two test sets from the SemEval-16 crosslingual STS task.

The MT system used is a phrase-based SMT system, trained using standard resources – Europarl, Common Crawl (CC) and News & Commentary (NC) – totaling approximately 110M words in each language. We bias the SMT decoder to produce a translation that is as close as possible on the surface to the English sentence. This is done by means of log-linear model features that aim at maximizing n-gram precision between the MT output and the English sentence. More details on this method can be found in Lo et al. (2016).

3.2 Results

The results of these experiments are presented in Table 2, where performance is measured in terms of Pearson's correlation with the test sets' gold standard annotations. For reference, we also include results obtained by the UWB system (Brychcín and Svoboda, 2016), which was the best performing system in the SemEval 2016 crosslingual STS shared task. The UWB system is an MT-based system with a STS system trained on assorted lexical, syntactic and semantic features. Globally, using the YiSi metric to measure semantic similarity performs much better than sentence-level cosine ("*_sum" systems). On the *News* dataset, the best results are obtained by combining an MT-based approach with YiSi-1 using monolingual word embeddings (MT+YiSi-1_{w2v}), reflecting the in-domain nature of the text for the MT system. However, this is followed very closely by both the supervised BWE's (YiSi-2_{bivec}) and BERT (YiSi-2_{bert}), which yield very similar results, and clearly outperform semi-supervised BWE's (YiSi-2_{vecmap}). The nature of the *Multisource* translations appears to be quite different from what supervised BWE's and the MT system have been exposed to in training (YiSi-2_{bivec} and MT+YiSi-1_{w2v}), which possibly explains their much poorer performance on this dataset. In contrast, weakly supervised BWE's and BERT behave much more reliably on this data.

Overall, while MT and supervised BWE's seem to work best with YiSi when large quantities of in-domain training data is available, the fully unsupervised alternative of using a pretrained BERT model comes very close, and behaves much better in the face of out-of-domain data.

4 Experiment on Parallel Corpus Filtering

Next, we evaluate YiSi on the task of *Parallel Corpus Filtering* (PCF). Quality – or "cleanliness" – of parallel training data for MT has been shown to affect MT quality at different degrees, and various characteristics of the data – parallelism of the sentence pairs and the grammaticality of target-language data – impact MT systems in different ways (Goutte et al., 2012; Simard, 2014; Khayrallah and Koehn, 2018).

Here, we use data from the WMT19 shared task on PCF. In this shared task, participants were challenged to find good quality translations from noisy sentence-aligned parallel corpora, for the purpose of training MT systems for translating from two low-resource languages, Nepali and Sin-

hala, into English.[7] Both corpora were crawled from the web, using ParaCrawl (Koehn et al., 2018a). Specifically, the task is to produce a score for each sentence pair in these noisy corpora, reflecting the quality of that pair. The scoring schemes are evaluated by extracting the top-scoring sentence pairs from each corpus, then using them to train MT systems; these systems are run on test sets of Wikipedia articles (Guzmán et al., 2019), and the results are evaluated using BLEU (Papineni et al., 2002). In addition to the noisy corpora, participants are allowed to use a few small sets of parallel data, covering different domains, for each of the two low-resource languages, as well as a third, related language, Hindi (which uses the same script as Nepali). The provided data also included much larger monolingual corpora for each of English, Hindi, Nepali and Sinhala.

4.1 Setup

In these experiments, we focus on the Nepali-English corpus, and perform PCF in three steps:

1. **pre-filtering**: apply *ad hoc* filters to remove sentences that are exact duplicates (masking numbers, emails and web addresses), that contain mismatching numbers, that are in the wrong language according to the `pyCLD2` language detector[8] or that are excessively long (either side has more than 150 tokens). We also filter out all pairs where over 50% of the Nepali text is comprised of English, numbers or punctuation.

2. **scoring**: we score sentence pairs using YiSi-2.

3. **re-ranking**: to optimize vocabulary coverage in the resulting MT system, we apply a form of re-ranking: going down the ranked list of scored sentence pairs, we apply a 20% penalty to the pair's score if it does not contain at least one "new" source-language word bigram, i.e., a pair of consecutive source-language tokens not observed in previous (higher-scoring) sentence pairs. This has the effect of down-ranking sentences that are too similar to previously selected sentences.

[8] https://github.com/aboSamoor/pycld2

WMT19 parallel corpus filtering		
system	1M-word	5M-word
random	1.30	3.01
Zipporah	**4.14**	**4.42**
YiSi-2$_{bivec}$	3.86	3.76
YiSi-2$_{vecmap}$	4.00	3.76
YiSi-2$_{bert}$	3.77	3.77

Table 4: Uncased BLEU scores on the official WMT19 PCF dev ("dev-test") sets achieved by the SMT systems trained on the 1M- and 5M-word corpora subselected by the scoring systems.

The scoring step is performed with YiSi-2, using bilingual word embeddings obtained under three different conditions (details of the various training sets used can be found in Table 3):

bivec : supervised BWE's produced using *bivec*, trained on the WMT19 PCF (clean) parallel data.

vecmap : weakly supervised BWE's are produced with *vecmap*, trained on all monolingual WMT19 PCF data, using *Wikititles* and the provided dictionary entries as bilingual lexicon.

BERT : BWE's obtained from pretrained multilingual BERT models.

As in the WMT19 PCF shared task, we evaluate the quality of our scoring by training MT systems and measuring their performance on the official test set. We used the provided software to

extract the 1M-word and 5M-word samples from the original test corpora, using the scores of each of our systems in turn. We then trained MT systems using the extracted data: our MT systems are standard phrase-based SMT systems, with components and parameters similar to the German-English SMT system in Williams et al. (2016).

4.2 Results

BLEU scores of the resulting MT systems are shown in Table 4. For comparison, we present the results of random scoring, as well as results obtained by the Zipporah PCF method (Xu and Koehn, 2017). Zipporah combines fluency and adequacy features to score sentence pairs; adequacy features are derived from existing parallel corpora, and the feature combination (logistic regression) is optimized on in-domain parallel data. Therefore, Zipporah can be seen as a fully supervised method. The Zipporah-based MT systems were trained similarly to other systems in the results reported here.

All systems produced with YiSi-2 produce similar results. Interestingly, the MT systems produced with YiSi-2 in the 5M-word condition are not better than those of the 1M-word condition. This is possibly explained by the large quantity of noisy data in the WMT19 Nepalese-English corpus: it is not even clear that there are 5M words of proper translations in that corpus. In such harsh conditions, pre- and post-processing steps become crucially important, and deduplicating the data may even turn out to be harmful, if that means allowing more space for noise. The MT systems produced with Zipporah all achieve higher BLEU scores than YiSi-2, which may be explained by Zipporah's explicit modeling of target-language fluency. This is especially apparent in the 5M-word condition, but it may explain Zipporah's slightly better performance in the 1M-word condition as well. Overall, the benefits of supervised and weakly supervised approaches over using a pre-trained BERT model for PCF appear to be minimal, even in very low-resource conditions such as this.

5 Experiments on Translation Equivalence Error Detection

Given a text and its translation, *Translation Equivalence Error Detection* (TEED) is the task of identifying pairs of corresponding text segments whose meanings are not strictly equivalent. Note that, while in practice "translation errors" can take many forms, here, we are strictly focusing on meaning errors. In this formulation of the problem, we are also assuming that the source and target texts have been properly segmented into sentences and aligned.

The TEED problem is essentially the same as that of Parallel Corpus Filtering (PCF), discussed in the previous section. However, the usage scenario is quite different: in PCF, one is typically dealing with a very large collection of segment pairs, only a fraction of which are true translations; the PCF task is then to filter out pairs which are not proper translations, possibly with some tolerance for pairs of segments that do share partial meaning. In TEED, the data is mostly expected to be high-quality translations; the task is then to identify those pairs that deviate from this norm, even on small details.

5.1 Setup

We experiment the TEED task using a data set obtained from the Canadian government's Public Service Commission (PSC). As part of its mandate, the PSC periodically audits Canadian government job ads, to ensure that they conform with Canada's *Official Languages Act*: as such, job ads must be posted in both of Canada's official languages, English and French, and both versions must be equivalent in meaning.

Our *PSC* data set consists of 175 000 "Statement of merit criteria" paragraphs, identifying any skill, ability, academic specialization, relevant experience or any other essential or asset criteria required for a position to be filled. Of these, 3521 have been manually annotated for equivalence errors by PSC auditors. Out of the 3521 pairs, 164 (4.6%) were reported to contain equivalence errors. The majority of these errors result from missing information in one language or the other (45%). In a slightly smaller proportion (43%), we find pairs of segments that don't express exactly the same meaning – a surprisingly large proportion of this last group consists in cases where the word *and* is translated as *or* or vice-versa. The rest consist in terminology issues and untranslated segments.

We experimented applying the YiSi-2 metric to this task, using bilingual word embeddings obtained under four different conditions:

PSC.vecmap : BWE's are produced with *vecmap*, trained on all unannotated PSC data, using *wikititles* as bilingual lexicon.

WMT.bivec : BWE's are produced with *bivec*, trained on all bilingual French-English data provided for the WMT 2015 News translation shared task.

BERT : BWE's obtained from pretrained multilingual BERT models.

Details about the training data can be found in Table 5.

5.2 Results

For these experiments, we considered an application scenario in which a text and its translation, in the form of pairs of matching segments, are scored using YiSi-2, and presented to a user, ranked in increasing order of score, so that pairs most likely to contain a translation error are presented first. The performance of the system can then be measured in terms of true and false positive rates, precision and recall, over subsets of increasing sizes of the test set. In Table 6, we report results in terms of mean F-score, with $\beta = 1$ and $\beta = 2$, and in terms

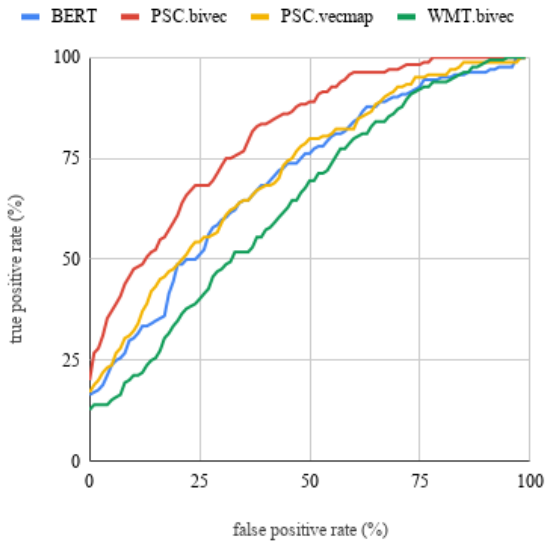

Figure 1: ROC curves of Sentence-level translation error detection results on PSC test data.

of the *Area under the ROC curve* (ROC AUC), which can be interpreted as the probability that a system will score a randomly chosen faulty translation lower than a randomly chosen good translation. The ROC curves themselves can be seen in Figure 1.

Globally, YiSi-2 clearly performs best at this task when using BWE's trained on domain-specific parallel data (PSC.bivec), even when there is very limited quantities of such data, as is the case here. However, BERT models perform comparably to vector-mapped BWE's trained with in-domain data (PSC.vecmap), and substantially better than BWE's trained on large quantities of generic, out-of-domain parallel data (WMT). We conclude that, in the absence of in-domain parallel data, for TEED applications, an unsupervised YiSi-2 method will perform at least as well as supervised methods trained on out-of-domain data.

6 Conclusion

We presented a fully unsupervised crosslingual semantic textual similarity (STS) metric, based on contextual embeddings extracted from BERT without fine-tuning. We perform intrinsic evaluations on crosslingual STS data sets and extrinsic evaluations on parallel corpus filtering and human translation equivalence assessment tasks. Our results show that the unsupervised metric we propose achieves performance on par with supervised or weakly supervised approaches. We show that the circular dependency on the existence of parallel resources for using crosslingual STS to identify parallel data can be broken.

In this paper, we have only experimented with the contextual embeddings extracted from pre-trained multilingual BERT model. For domain-specific applications, such as the job advertisement domain in the PSC translation equivalence error detection task, the performance of YiSi-2 could potentially be improved by fine-tuning BERT with in-domain data, something we plan to examine in the near future. We will also want to explore the use of other multilingual context representation models, such as MUSE (Conneau et al., 2017), XLM (Lample and Conneau, 2019), etc.

Acknowledgement

We would like to thank Dominic Demers and his colleagues at the Canadian governments Public Service Commission (PSC) for providing the PSC data set and managing the human annotation in the experiments.

Abstract

Recent work has validated the importance of subword information for word representation learning. Since subwords increase parameter sharing ability in neural models, their value should be even more pronounced in low-data regimes. In this work, we therefore provide a comprehensive analysis focused on the usefulness of subwords for word representation learning in truly low-resource scenarios and for three representative morphological tasks: fine-grained entity typing, morphological tagging, and named entity recognition. We conduct a systematic study that spans several dimensions of comparison: **1)** *type of data scarcity* which can stem from the lack of task-specific training data, or even from the lack of unannotated data required to train word embeddings, or both; **2)** *language type* by working with a sample of 16 typologically diverse languages including some truly low-resource ones (e.g. Rusyn, Buryat, and Zulu); **3)** the choice of the *subword-informed word representation method*. Our main results show that subword-informed models are universally useful across all language types, with large gains over subword-agnostic embeddings. They also suggest that the effective use of subwords largely depends on the language (type) and the task at hand, as well as on the amount of available data for training the embeddings and task-based models, where having sufficient in-task data is a more critical requirement.

1 Introduction and Motivation

Recent studies have confirmed the usefulness of leveraging subword-level information in learning word representations (Peters et al., 2018; Heinzerling and Strube, 2018; Grave et al., 2018; Zhu et al., 2019, *inter alia*), and in a range of tasks such as sequence tagging (Lample et al., 2016; Akbik et al., 2018; Devlin et al., 2019), fine-grained entity typing (Zhu et al., 2019), neural machine translation (Sennrich et al., 2016; Luong and Manning, 2016; Lample et al., 2018; Durrani et al., 2019), or general and rare word similarity (Pilehvar et al., 2018; Zhu et al., 2019). The subword-informed word representation architectures leverage the internal structure of words and assume that a word's meaning can be inferred from the meaning of its constituent (i.e., subword) parts. Instead of treating each word as an atomic unit, subword-informed neural architectures reduce data sparsity by relying on parameterization at the level of subwords (Bojanowski et al., 2017; Pinter et al., 2017; Chaudhary et al., 2018; Kudo, 2018).

An increasing body of work focuses on various aspects of subword-informed representation learning such as segmentation of words into subwords and composing subword embeddings into word representations (Lazaridou et al., 2013; Cotterell and Schütze, 2015, 2018; Avraham and Goldberg, 2017; Vania and Lopez, 2017; Kim et al., 2018; Zhang et al., 2018; Zhao et al., 2018, *inter alia*).[1] The increased parameter sharing ability of such models is especially relevant for learning embeddings of rare and unseen words. Therefore, the importance of subword-level knowledge should be even more pronounced in *low-data regimes* for *truly low-resource languages*. Yet, a systematic study focusing exactly on the usefulness of subword information in such settings is currently missing in the literature. In this work, we fill this gap by providing a comprehensive analysis of subword-informed representation learning focused on low-resource setups.

Our study centers on the following axes of comparison, focusing on three representative tasks where subword-level information can guide learn-

*Equal contribution, work partly done while at HITS.

[1]An overview of a variety of subword-informed word representation architectures and different segmentation and composition strategies is provided by Zhu et al. (2019).

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 216–226

ing, namely fine-grained entity typing (FGET), morphological tagging (MTAG), and named entity recognition (NER): **1)** Since data scarcity can stem from unavailability of (i) task-specific training data or (ii) unannotated corpora to train the embeddings in the first place, or (iii) both, we analyse how different data regimes affect the final task performance. **2)** We experiment with 16 languages representing 4 diverse morphological types, with a focus on truly low-resource languages such as Zulu, Rusyn, Buryat, or Bambara. **3)** We experiment with a variety of subword-informed representation architectures, where the focus is on unsupervised, widely portable language-agnostic methods such as the ones based on character n-grams (Luong and Manning, 2016; Bojanowski et al., 2017), Byte Pair Encodings (BPE) (Sennrich et al., 2016; Heinzerling and Strube, 2018), Morfessor (Smit et al., 2014), or BERT-style pretraining and fine-tuning (Devlin et al., 2019) which relies on WordPieces (Wu et al., 2016). We demonstrate that by tuning subword-informed models in low-resource settings we can obtain substantial gains over subword-agnostic models such as skip-gram with negative sampling (Mikolov et al., 2013) across the board.

The main goal of this study is to identify viable and effective subword-informed approaches for truly low-resource languages and offer modeling guidance in relation to the target task, the language at hand, and the (un)availability of general and/or task-specific training data. As expected, our key results indicate that there is no straightforward *"one-size-fits-all"* solution, although certain approaches (e.g., BPE-based or character n-grams) emerge as more robust in general. The optimal subword-informed configurations are largely task-, language-, and resource-dependent: their performance hinges on a complex interplay of the multiple factors mentioned above. For instance, we show that fine-tuning pretrained multilingual BERT (Devlin et al., 2019; Wu and Dredze, 2019) is a viable strategy for "double" low-resource settings in the NER and MTAG tasks, but it fails for the FGET task in the same setting; furthermore, its performance can be matched or surpassed by other subword-informed methods in NER and MTAG as soon as they obtain sufficient embedding training data.

2 Methodology

In what follows, we further motivate our work by analyzing two different sources of data scarcity: embedding training data (termed *WE data*) and task-specific training data (termed *task data*). Following that, we motivate our selection of test languages and outline the subword-informed representation methods compared in our evaluation.

Types of Data Scarcity. The majority of languages in the world still lack basic language technology, and progress in natural language processing is largely hindered by the lack of annotated *task data* that can guide machine learning models (Agić et al., 2016; Ponti et al., 2018). However, many languages face another challenge: the lack of *large unannotated text corpora* that can be used to induce useful general features such as word embeddings (Adams et al., 2017; Fang and Cohn, 2017; Ponti et al., 2018):[2] i.e. WE data.

The absence of data has over the recent years materialized the *proxy fallacy*. That is, methods tailored for low-resource languages are typically tested only by proxy, simulating low-data regimes exclusively on resource-rich languages (Agić et al., 2017). While this type of evaluation is useful for analyzing the main properties of the intended low-resource methods in controlled *in vitro* conditions, a complete evaluation should also provide results on true low-resource languages *in vivo*. In this paper we therefore conduct both types of evaluation. Note that in this work we still focus on low-resource languages that have at least some digital footprint (see the statistics later in Table 1), while handling zero-resource languages without any available data (Kornai, 2013; Ponti et al., 2018) is a challenge left for future work.

(Selection of) Languages. Both *sources of data scarcity* potentially manifest in degraded task performance for low-resource languages: our goal is to analyze the extent to which these factors affect downstream tasks across morphologically diverse language types that naturally come with varying data sizes to train their respective embeddings and task-based models. Our selection of test languages is therefore guided by the following goals: **a)** following recent initiatives (e.g. in language modeling) (Cotterell et al., 2018; Gerz et al., 2018), we aim to ensure coverage of different genealogical and typological properties; **b)** we aim to cover low-resource languages with varying amounts of available WE data and task-specific data.

We select 16 languages in total spanning 4 broad

[2]For instance, as of April 2019, Wikipedia is available only in 304 out of the estimated 7,000 existing languages.

	Agglutinative						Fusional						Introflexive		Isolating	
	BM	BXR	MYV	TE	TR	ZU	EN	FO	GA	GOT	MT	RUE	AM	HE	YO	ZH
EMB	40K	372K	207K	5M	5M	69K	5M	1.6M	4.4M	18K	1.5M	282K	659K	5M	542K	5M

BERT				✓	✓		✓		✓					✓	✓	✓

Table 1: Overview of test languages and data availability. EMB denotes the maximum number of tokens in corresponding Wikipedias used for training embeddings. Actual Wikipedia sizes are larger than 5M for (TE, TR, EN, HE, ZH), but were limited to 5M tokens in order to ensure comparable evaluation settings for data scarcity simulation experiments across different languages. FGET, NER, and MTAG rows show the number of instances for the three evaluation tasks (see §3): number of entity mentions for FGET, number of sentences for NER and MTAG. In MTAG, we omit languages for which UDv2.3 provides only a test set, but no training set. The BERT row shows the languages supported by multilingual BERT. Languages are identified by their ISO 639-1 code.

morphological types, listed in Table 1. Among these, we chose one (relatively) high-resource language for each type: Turkish (agglutinative), English (fusional), Hebrew (introflexive), and Chinese (isolating). We use these four languages to *simulate* data scarcity scenarios and run experiments where we *control* the degree of data scarcity related to both embedding training data and task-related data. The remaining 12 languages are treated as test languages with varying amounts of available data (see Table 1. For instance, relying on the Wikipedia data for embedding training, Gothic (GOT) is the language from our set that contains the fewest number of word tokens in its respective Wikipedia (18K, in terms of Wikipedia size this ranks it as 273th out of 304 Wikipedia languages); Irish Gaelic (GA) with 4.4M tokens is ranked $87/304$.

Subword-Informed Word Representations. We mainly follow the framework of Zhu et al. (2019) for the construction of subword-informed word representations; the reader is encouraged to refer to the original paper for more details. In short, to compute the representation for a given word $w \in V$, where V is the word vocabulary, the framework is based on three main components: 1) *segmentation* of words into subwords, 2) *interaction* between subword and position embeddings, and 3) a *composition function* that yields the final word embedding from the constituent subwords. Zhu et al. (2019) explored a large space of possible subword-informed configurations. Based on their findings, we select a representative subset of model configurations. They can be obtained by varying the components listed in Table 2.

Concretely, w is first segmented into an ordered subword sequence from the subword vocabulary S by a deterministic subword segmentation method. To enable automatic language-agnostic segmentation across multiple languages, we focus on unsupervised segmentation methods: we work with Morfessor (Smit et al., 2014), character n-grams (Bojanowski et al., 2017) and BPE (Gage, 1994). We use the default parameters for Morfessor, and the same 3 to 6 character n-gram range as Bojanowski et al. (2017). For BPE, the number of merge operations is a tunable hyper-parameter. It controls the segmentation "aggressiveness": the larger the number the more conservative the BPE segmentation is. Following Heinzerling and Strube (2018), we investigate the values $\{1e3, 1e4, 1e5\}$: this allows us to test varying segmentation granularity in relation to different language types.

After segmentation into subwords, each subword is represented by a vector $\mathbf{s}$ from the subword embedding matrix $\mathbf{S} \in \mathbb{R}^{|S| \times d}$, where d is the dimensionality of subword embeddings. Optionally, the word itself can be appended to the subword sequence and embedded into the subword space in order to incorporate word-level information (Bojanowski et al., 2017). To encode subword order, $\mathbf{s}$ can be further enriched by a trainable position embedding $\mathbf{p}$. We use addition to combine subword and position embeddings, namely $\mathbf{s} := \mathbf{s} + \mathbf{p}$, which has become the de-facto standard method to encode positional information (Gehring et al., 2017; Vaswani et al., 2017; Devlin et al., 2019).

Finally, the subword embedding sequence is passed to a composition function, which computes the final word representation. Li et al. (2018) and Zhu et al. (2019) have empirically verified that composition by simple addition, among other more complex composition functions, is a robust choice. Therefore, we use addition in all our experiments.

Similar to Bojanowski et al. (2017); Zhu et al. (2019), we adopt skip-gram with negative sampling

Component	Option	Label
Segmentation	Morfessor	`morf`
	BPE	`bpeX`
	char n-gram	`charn`
Word token	exclusion	*w-*
	inclusion	*w+*
Position embedding	exclusion	*p-*
	additive	*p+*
Composition function	addition	*add*

Table 2: Components for constructing subword-informed word representations. In the `bpeX` label $X \in \{1e3, 1e4, 1e5\}$ denotes the BPE vocabulary size.

(Mikolov et al., 2013) as our word-level distributional model: the target word embedding is computed by our subword-informed model, and the context word is parameterized by the (word-level) context embedding matrix $\mathbf{W}_c \in \mathbb{R}^{|V| \times d_c}$.

We compare subword-informed architectures to two well-known word representation models, also captured by the general framework of Zhu et al. (2019): 1) the subword-agnostic skip-gram model from the `word2vec` package (Mikolov et al., 2013) (W2V), and 2) `fastText` (FT) (Bojanowski et al., 2017). The comparison to W2V aims to validate the potential benefit of subword-informed word representations for truly low-resource languages, while the comparison to FT measures the gains that can be achieved by more sophisticated and fine-tuned subword-informed architectures. We also compare with pretrained multilingual $BERT_{base}$ (Devlin et al., 2019) on the languages supported by this model.

3 Evaluation Tasks

Fine-Grained Entity Typing. FGET is cast as a sequence classification problem, where an entity mention consisting of one or more tokens (e.g. *Lincolnshire*, *Bill Clinton*), is mapped to one of the 112 fine-grained entity types from the FIGER inventory (Ling and Weld, 2012; Yaghoobzadeh and Schütze, 2015; Heinzerling and Strube, 2018). Since entity mentions are short token sequences and not full sentences, this semi-morphological/semantic task requires a model to rely on the subword information of individual tokens in the absence of sentence context. That is, subwords can provide evidence useful for entity type classification in the absence of context. For instance, *Lincolnshire* is assigned the type `/location/county` as *-shire* is a suffix that strongly indicates a location. Hence, FGET is well-suited for evaluating subword-informed representations, and can benefit from the information.

Morphological Tagging. MTAG is the task of annotating each word in a sentence with features such as part-of-speech, gender, number, tense, and case. These features are represented as a set of key-value pairs. For example, *classified* is a finite (Fin) verb (V) in indicative (Ind) mood, third person, past tense, which is annotated with the morphological tag {POS=V, Mood=Ind, Person=3, Tense=Past, VerbForm=Fin}, and the female singular third-person possessive personal pronoun *her* with the morphological tag {Gender=Fem, Number=Sing, Person=3, Poss=Yes, PronType=Prs}.

Named Entity Recognition. NER is the task of annotating textual mentions of real-world entities with their semantic type, such as person, location, and organization: e.g., *Barack Obama (person) was born in Hawaii (location).*

4 Experimental Setup

Embedding Training: WE Data. For training word and subword embeddings, we rely on Wikipedia text for all 16 languages, with corresponding Wikipedia sizes listed in Table 1. For training embeddings in controlled low-resource settings with our 4 "simulation" languages, we sample nine data points to simulate low-resource scenarios with WE data. Specifically, we sample 10K, 20K, 50K, 100K, 200K, 500K, 1M, 2M, and 5M tokens of article text for each of the 4 languages. For the other 12 languages we report results obtained by training embedding on the full Wikipedia edition.

Task-Specific Data: Task Data. The maximum number of training instances for all languages is again provided in Table 1. As before, for 4 languages we simulate low-resource settings by taking only a sample of the available task data: for FGET we work with 200, 2K or 20K training instances which roughly correspond to training regimes of different data availability, while we select 300,[3] 1K, and 10K sentences for NER and MGET. Again, for the remaining 12 languages, we use all the available data to run the experiments. We adopt existing data splits into training, development, and test portions for MTAG (Cotterell and Heigold, 2017), and random splits for FGET (Heinzerling and Strube, 2018; Zhu et al., 2019) and NER (Pan et al., 2017).

[3] With a smaller number of instances (e.g., 100), NER and MGET model training was unstable and resulted in near-zero performance across multiple runs.

A large number of data points for scarcity simulations allow us to trace how performance on the three tasks varies in relation to the availability of WE data versus task data, and what data source is more important for the final performance.

Embedding Training Setup. When training our subword-informed representations, we argue that keeping hyper-parameters fixed across different data points will possibly result in underfitting for larger data sizes or overfitting for smaller data sizes. Therefore, we split data points into three groups: $[10K, 50K]$ (G1), $(50K, 500K]$ (G2) and $(500K, 5M]$ (G3), and use the same hyper-parameters for word embedding training within the same group. For G1, we train with batch size 32 for 60 epochs and set the minimum word frequency threshold to 2. For G2 the values are: $128/30/3$, and $512/15/5$ for G3. This way, we ensure that 1) the difference of the absolute data sizes can be compared within the same data group, and 2) for the corresponding data points in different groups ($10K$, $100K$, $1M$) the sample efficiency can be compared, as the models trained on these data points undergo roughly the same number of updates.[4]

Task-Specific Training Setup. For FGET, we use the dataset of Heinzerling and Strube (2018) obtained by mapping entity mentions from Wikidata (Vrandečić and Krötzsch, 2014) to their associated FIGER-based most notable entity type (Ling and Weld, 2012). For each language, we randomly sample up to 100k pairs of entity mentions with corresponding entity type and create random 60/20/20 train/dev/test splits. Our FGET model is designed after the hierarchical architecture by Zhu et al. (2019). For each entity token, we first use our subword-informed model to obtain word representations, and then feed the token embedding sequence into a bidirectional LSTM with 2 hidden layers of size 512, followed by a projection layer which predicts the entity type. We initialize our FGET model with the pretrained subword model, and fine-tune it during training. With BERT, we input the entire entity mention and then use the representation of the special `[CLS]` token for classification. We train with early stopping, using Adam (Kingma and Ba, 2015) with default parameters across all languages. As suggested by Wu and Dredze (2019), BERT hyper-parameters are more sensitive to smaller data sizes, so we tune them on the smallest data point with 200 training instances. We follow Wu and Dredze (2019) to select hyper-parameter candidates, i.e., $2e{-}5/3e{-}5/5e{-}5$ for learning rate, $16/32$ for batch size and triangular learning rate scheduler with first 10% of batches as warm-up. We do an exhaustive search on four high resource languages: EN, TR, HE, ZH and select the hyper-parameter combination with the best average score on the development sets.

For MTAG, we evaluate on the multilingual morphological annotations provided by the Universal Dependencies project (Nivre et al., 2016) and adopt the experimental protocol of Cotterell and Heigold (2017). Specifically, we cast MTAG as a sequence labeling task by treating the concatenation of all key-value pairs for a given word as the word's label. As sequence labeling model, we train a bidirectional LSTM (Hochreiter and Schmidhuber, 1997; Plank et al., 2016), with two layers of size 1024 and dropout 0.4, using early stopping on the development set. For experiments involving multilingual BERT, we fine-tune all of BERT's layers and feed the final layer into an LSTM before classification. The evaluation metric is per-label accuracy, i.e., a word's morphological tag is either predicted correctly or not, and there is no partial credit for the correct prediction of only a subset of features.

We evaluate NER performance on WikiAnn (Pan et al., 2017), a multilingual dataset which provides three-class entity type annotations which were automatically extracted from Wikipedia. We train sequence labeling models using exactly the same architectures and hyper-parameters as in MTAG, and report F1 scores. As WikiAnn does not come with predefined train/dev/test sets, we create random 60/20/20 splits.

5 Results and Discussion

Results for data scarcity simulation experiments are summarized in Figures 1-3, while the results on the remaining 12 languages for all three tasks are provided in Tables 3-4, with the best results among different configurations of subword-informed methods reported. As the first main finding, the results show that subword-informed architectures substantially outperform the subword-agnostic skip-gram W2V baseline, and the gaps are in some cases very large: e.g., see the results in Figures 1-3 for the settings with extremely scarce WE data. These scores verify the importance of subword-level knowledge

[4] We train `fastText` and skip-gram from `word2vec` with the same number of epochs that is used to train our subword-informed models on the corresponding data points.

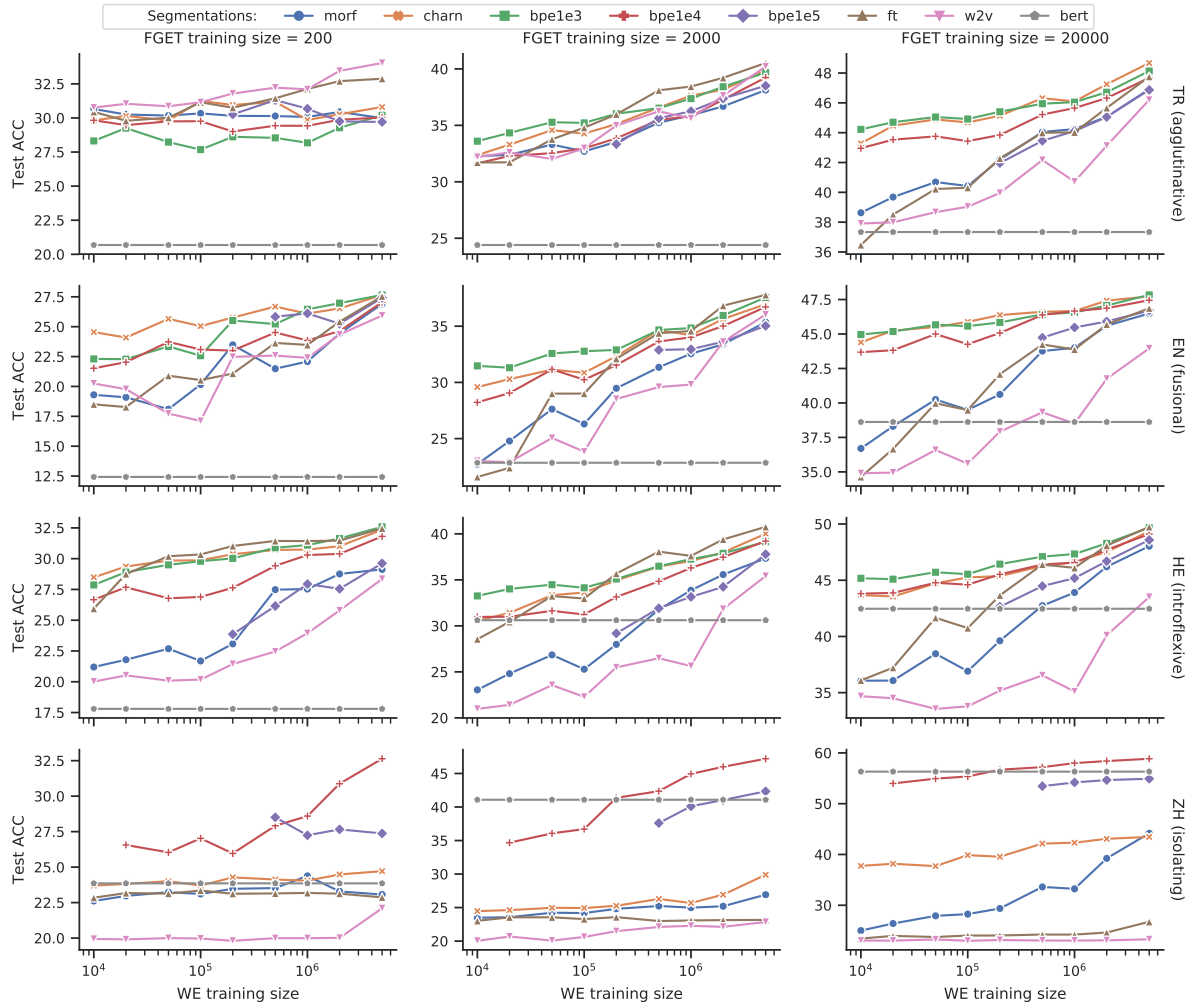

Figure 1: Test performance (accuracy) in the FGET task for different segmentation methods in data scarcity simulation experiments across 4 languages representing 4 broad morphological types, averaged over 5 runs. Some data points with Chinese (ZH) are not shown as in those cases the subword model is reduced to single characters only.

for low-resource setups.

Simulating Data Scarcity. Another general finding concerns the importance of WE data versus task data. The simulation results in Figure 1-3 suggest that both types of data are instrumental to improved task performance: This finding is universal as we observe similar behaviors across tasks and across different languages. While WE data is important, considerably larger gains are achieved by collecting more task data: e.g., see the large gains in FGET when training on 200 versus 2K entity mentions. In summary, both types of data scarcity decrease performance, but the impact of scarce task data seems more pronounced. Collecting more WE data when dealing with scarce task data leads to larger gains in the FGET task compared to MTAG or NER.

While subword models are generally better than the baselines across different data points, less aggressive segmentation models and token-based models close the gap very quickly when increasing WE data, which is in line with the findings of Zhu et al. (2019), where `morf` eventually prevails in this task with abundant WE data. This again verifies the usefulness of subword-level knowledge for low-(WE) data regimes. Similar trends emerge in terms of task data, but the advantage of subword models seems more salient with more task data. The underlying task architectures start making use of subword features more effectively: this shows that subword-level knowledge is particularly useful for the three chosen morphological tasks.

Performance of BERT. An interesting analysis regarding the (relative) performance of pretrained multilingual BERT model emerges from Figures 1-3. Fine-tuned BERT displays much stronger performance in low-resources settings for the MTAG and NER tasks than for the FGET task (e.g., compare the sub-figures in the first columns of the

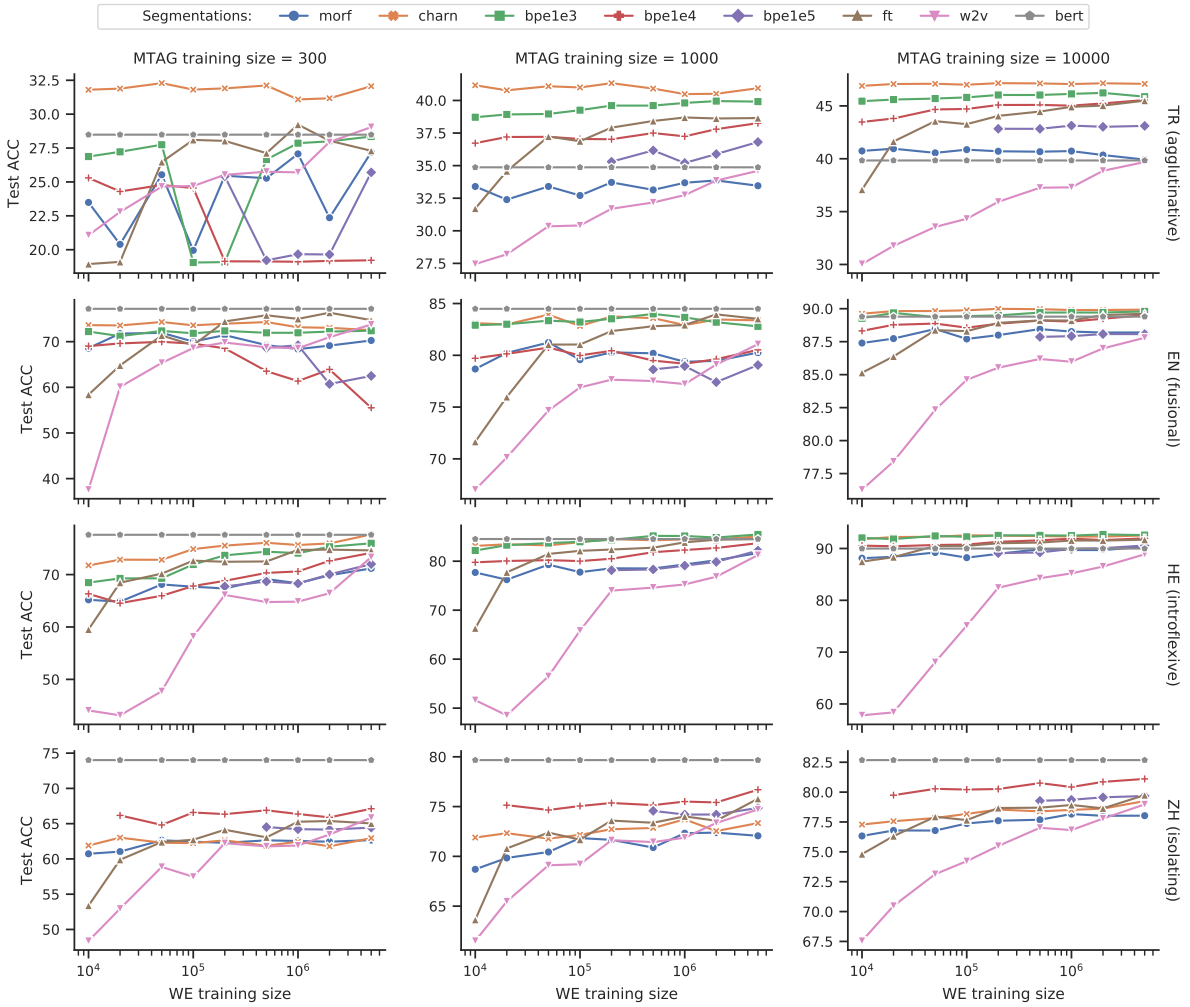

Figure 2: Test performance in the MTAG task in data scarcity simulation experiments.

corresponding figures). The explanation of MTAG and NER performance is intuitive. A pretrained BERT model encodes a massive amount of background knowledge available during its (multilingual) pretraining. However, as we supplement other subword-informed representation learning methods with more data for training the embeddings, the gap gets smaller until it almost completely vanishes: other methods now also get to see some of the distributional information which BERT already consumed in its pretraining.

BERT performance on FGET versus MTAG and NER concerns the very nature of the tasks at hand. The input data for FGET consist mostly of 2-4 word tokens (i.e., entity mentions), while MTAG and NER operate on full sentences as input. Since BERT has been pretrained on sentences, this setting is a natural fit and makes fine-tuning to these tasks easier: BERT already provides a sort of "contextual subword composition function". This stands in contrast with the other subword-informed approaches. There, we might have good non-contextual subword embeddings and a pretrained "non-contextual" composition function, but we have to learn how to effectively leverage the context for the task at hand (i.e., by running an LSTM over the subword-informed token representations) from scratch.[5]

Truly Low-Resource Languages. The results on the 12 test languages in Table 3-4 suggest that subword-informed models are better than the baselines in most cases: this validates the initial findings from the simulation experiments. That is, leveraging subword information is important for WE induction as well as for task-specific training. The

[5]Another factor at play is multilingual BERT's limited vocabulary size (100K WordPiece symbols), leaving on average a bit under 1K symbols per language. Due to the different sizes of Wikipedias used for pretraining BERT, some languages might even be represented with far fewer than 1K vocabulary entries, thereby limiting the effective language-specific model capacity. Therefore, it is not that surprising that monolingual subword-informed representations gradually surpass BERT as more language-specific WE data becomes available. This finding is also supported by the results reported in Table 3.

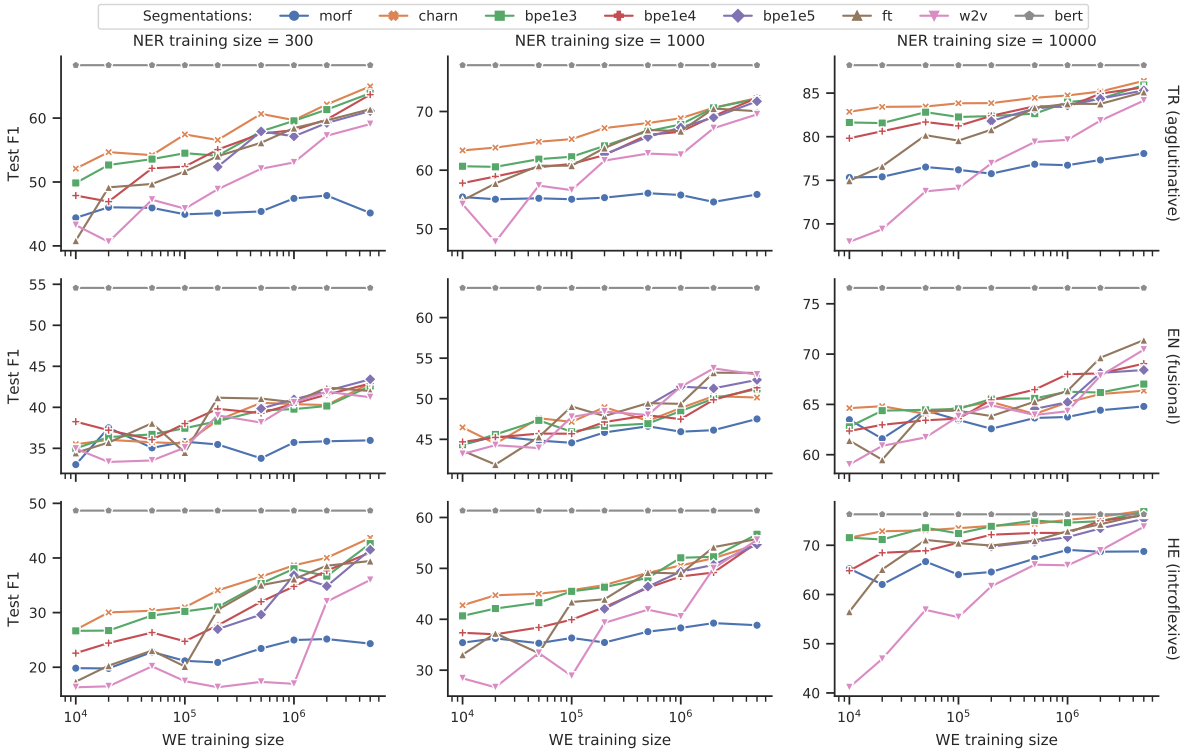

Figure 3: Test performance (F1 score) in the NER task in data scarcity simulation experiments. We do not show results for Chinese as the annotations of the Chinese NER are provided only on the character-level and thus impede experimentation with most of the subword-informed methods used in our evaluation.

gains with subword methods become larger for languages with fewer WE data (e.g., ZU, BM, GOT); this is again consistent with the previously reported simulation experiments.

Tasks, Language Types, Subword Configurations. The results further suggest that the optimal configuration indeed varies across different tasks and language types, and therefore it is required to carefully tune the configuration to reach improved performance. For instance, as agglutinative languages have different granularities of morphological complexity, it is not even possible to isolate a single optimal segmentation method within this language type. Overall, the segmentation based `charn` followed by BPE emerge as most robust choices across all languages and tasks. However, `charn` has the largest number of parameters and is slower to train compared to other segmentations, and in case of BPE its number of merge operations must be tuned to yield competitive scores.

While we do not see extremely clear patterns from the results in relation to particular language types, the scores suggest that for agglutinative and fusional languages a hybrid segmentation such as `charn` or a moderate one (`bpe1e4`, `bpe1e5`) is a good choice. For introflexive and isolating languages, more aggressive segmentations seem to be also competitive in FGET and MTAG, while `bpe1e4` being very effective for ZH, and `charn` (again) and `bpe1e5` seems to be preferred in NER.

Apart from segmentation methods, we also analyzed the effect of word token embeddings ($w+$) and position embeddings ($p+$) in the subword-informed learning framework (Zhu et al., 2019) (see before Table 2 in §2), shown in Figure 4. NER can clearly benefit from both $w+$ and $p+$ and $w+$ is also useful for MTAG. However, for other tasks, the fluctuations between configurations are minimal once the segmentation has been fixed, which suggests that the most critical component is indeed the chosen segmentation method: this is why we have mostly focused on the analyses of the segmentation method and its impact on task performance in this work. Regarding the composition functions, as demonstrated in Zhu et al. (2019), more complex composition functions do not necessarily yield superior results in a range of downstream tasks. We therefore leave the exploration of more sophisticated composition functions for future work.

6 Conclusions and Future Work

We have presented an empirical study focused on the importance of subword-informed word repre-

sentation architectures for truly low-resource languages. Our experiments on three diverse morphological tasks with 16 typologically diverse languages of varying degrees of data scarcity have validated that subword-level knowledge is indeed crucial for improved task performance in such low-data setups. The large amount of results reported in this work has enabled comparisons of different subword-informed methods in relation to multiple aspects such as the degree of data scarcity (both in terms of embedding training data and task-specific annotated data), the task at hand, the actual language, as well as the methods' internal design (e.g. the choice of the segmentation method). Our results have demonstrated that all these aspects must be considered in order to identify an optimal subword-informed representation architecture for a particular use case, that is, for a particular language (type), task, and data availability. However, similar paterns emerge: e.g., resorting to a segmentation method based on character n-grams seems most robust across the three tasks and across languages, although there are clear outliers. In future work, we will extend our focus to other target languages, including the ones with very limited (Adams et al., 2017) or non-existent digital footprint.

Abstract

Recurrent neural network grammars (RNNGs) generate sentences using phrase-structure syntax and perform very well in terms of both language modeling and parsing performance. However, since dependency annotations are much more readily available than phrase structure annotations, we propose two new generative models of projective dependency syntax, so as to explore whether generative dependency models are similarly effective. Both models use RNNs to represent the derivation history with making any explicit independence assumptions, but they differ in how they construct the trees: one builds the tree bottom up and the other top down, which profoundly changes the estimation problem faced by the learner. We evaluate the two models on three typologically different languages: English, Arabic, and Japanese. We find that both generative models improve parsing performance over a discriminative baseline, but, in contrast to RNNGs, they are significantly less effective than non-syntactic LSTM language models. Little difference between the tree construction orders is observed for either parsing or language modeling.

1 Introduction

Recurrent neural network grammars (Dyer et al., 2016, RNNGs) are syntactic language models that use predicted syntactic structures to determine the topology of the recurrent networks they use to predict subsequent words. Not only can they learn to model language better than non-syntactic language models, but the conditional distributions over parse trees given sentences produce excellent parsers (Fried et al., 2017).

In this paper, we introduce and evaluate two new dependency syntax language models which are based on a recurrent neural network (RNN) backbone (§2).[1] Dependency syntax is particularly appealing as many more languages have dependency treebanks (e.g. the Universal Dependencies Project (Nivre et al., 2017)) than have large numbers of phrase structure annotations.

Like RNNGs, our proposed models predict structure and words jointly, and the predicted syntactic structure is used to determine the structure of the neural network that is used to represent the history of actions taken by the model and to make a better estimate of the distribution over subsequent structure-building and word-generating actions. Because we use RNNs to encode the derivation history, our models do not make any explicit independence assumptions, but instead condition on the complete history of actions. The two proposed models do, however, differ in the order that they construct the trees. The first model operates top down (§2.1), starting at the root and recursively generating dependents until the last modifier has been generated. The second operates bottom up (§2.2), generating words from left to right and interleaving decisions about how they fit together to form tree fragments and finally a fully formed dependency tree.[2]

Because neither model makes explicit independence assumptions, given enough capacity, infinite data, and a perfect learner, both models would converge to the same estimate. However, in our limited, finite, and imperfect world, these two models will impose different biases on the learner: in one order, relevant conditioning information may be more local (which could mean the neural networks have an easier time learning to exploit the relevant information rather than becom-

[1] We release code for these two models, which can be found at https://github.com/armatthews/dependency-lm.

[2] In this work, we limit ourselves to models that are capable only of generating projective dependency trees.

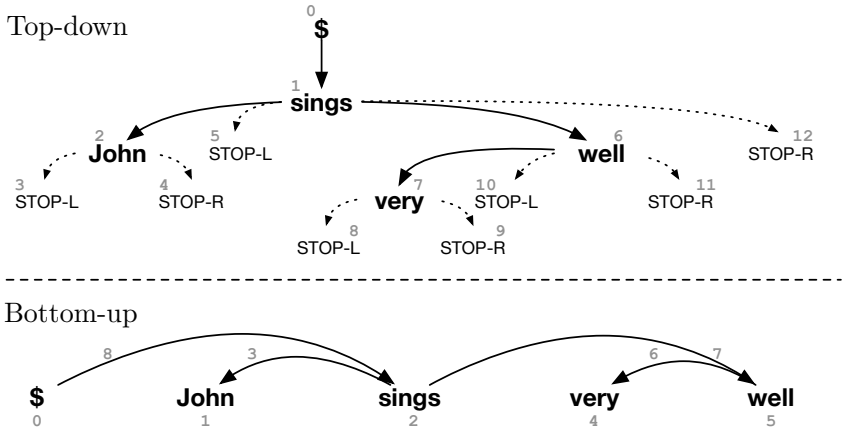

Figure 1: Generation process for the same dependency tree under the top-down and bottom-up models. As the indices of the generation events show, the top-down model generates recursively from the root, whereas the bottom-up model generates from left to right.

ing distracted by accidental correlations), while in the other it may be more distant. These differences thus imply that the two models will have different structural biases, but it is not at all clear whether one should out perform the other. We therefore explore to what extent this choice of construction order affects performance, and we evaluate the proposed models on language modeling and parsing tasks across three typologically different languages (§3).

Our findings (§4) show that, like RNNGs, generative dependency models make good parsers. Given the small scale of the Universal Dependency corpora, this result is also in line with previous work which shows that joint generative models offer very sample-efficient estimates of conditional distributions (Yogatama et al., 2017). Second, we find that both dependency models are *less effective* as language models than phrase structure RNNGs or than standard LSTM language models. This negative result is not entirely surprising. Although information about syntactic dependencies seems intuitively that it would be helpful for defining good conditioning contexts for language models, since its earliest days (Tesnière, 1959), work on dependency syntax has largely focused on discriminative models of *existing* sentences. In contrast, the phrase structure annotations found in, e.g., the Penn Treebank that were used to demonstrate improved language modeling performance with RNNGs are indebted to linguistic theories (e.g., government and binding theory, X-bar theory) which are broadly concerned with determining which sentences are grammatical and which are not—a crucial aspect of language modeling (Marcus et al., 1993). Finally, we observe only minimal differences in language modeling performance for top-down and bottom-up models. This result is surprising in light of how different the estimation problems are, but it is a clear demonstration of the ability of RNNs to learn to extract relevant features from data presented in any different but consistent orders.

2 Models

We present two models for jointly generating projective dependency trees and sentences. The processes are illustrated in Fig. 1. The first is a top-down model (§2.1), which starts by generating the root of the sentence, and then recursively generating its left and right modifiers. The second is a bottom-up model (§2.2), which generates terminals in a left to right order. In both cases, there is a deterministic mapping from well-formed sequences of generation actions into dependency trees. Following convention in parsing literature, we refer to such action sequences as oracles.

Both models both are parameterized with recursively structured neural networks that have access to the complete history of generation events. Thus, the factorization of the tree probability is justified by the chain rule. However, because of the difference in build orders, the conditional probabilities being estimated are quite different, and we thus expect these models might be more or less effective at either language modeling or (when used in conjunction with Bayes' rule) parsing.

To illustrate the different estimation problems posed by the two models, consider the first generation event in both cases. In the top-down model,

the root word (usually the main verb of the sentence) is generated first; whereas in the bottom-up model, the first probability modeled is the probability of the first word in the sentence. Also, in the top-down model a verb always generates its dependentents (which has implications for how agreement is modeled), whereas in the bottom-up model, it the left dependents (whatever their function) will be generated first, and then the verb generation will be conditional on them. Again, we emphasize that these differences potentially result in differences in the difficulty of the estimation problem (or how much capacity the model needs to represent accurate conditionals), but do not impact the expressivity or correctness of the models.

2.1 Top-Down

Our first model is a top-down model. The model begins with an empty root node.[3] Starting from the root the model recursively generates child nodes using its GEN action. When the model chooses the GEN action it then selects a new head word from its vocabulary and creates a new node descended from the most recent open constituent. Each node created in this way is pushed onto a stack of open constituents, and begins creating its left children.

To indicate that the current node (i.e. the top node in the stack) is done generating left children the model takes its STOP-L ("stop left") action, after which the current node begins generating its right children. Analogously, to indicate that the current node is done generating right children the model selects its STOP-R ("stop right") action. With this the current constituent is complete and thus popped off the stack and attached as a child of the new top-most constituent. See Figure 2 for examples of the effects of each of these three actions on a partially built tree structure and Algorithm 1 for a sketch of their implementation.

At each decision point the model conditions on the output of an LSTM over the partially completed constituents on the stack, beginning with the root and ending with the top-most constituent. The result is passed through an MLP and then a softmax that decides which action to take next (Figure 3). If the model chooses the GEN action, the hidden vector from the MLP is used to separately choose a terminal.

[3]The root node may never have left children. In this way it is though the root node has already generated its STOP-L, though this step is not explicitly modelled

Algorithm 1 Top-Down Tree Generation

```
1:  procedure EMBEDTREE(node)
2:      state = lstm_initial_state
3:      for child in node do
4:          if child is terminal then
5:              state.add(WordEmbs[child])
6:          else
7:              state.add(EMBEDTREE(child))
8:      return state
9:  procedure PICKNEXTACTION(stack)
10:     h = MLP_action(EmbedTree(stack))
11:     action ~ softmax(h)
12:     return action
13: procedure PICKWORD(stack)
14:     h = MLP_word(EmbedTree(stack))
15:     word ~ softmax(h)
16:     return word
17: procedure GENERATENODE(stack)
18:     action = PICKNEXTACTION(stack)
19:     if action == GEN then
20:         word = PICKWORD(STACK)
21:         stack.push(new Node(word))
22:     else if action == STOP-L then
23:         stack.back().add_child(STOP-L)
24:     else if action == STOP-R then
25:         stack.back().add_child(STOP-R)
26:         child_emb = stack.pop()
27:         stack.back().add_child(child_emb)
```

To embed each subtree on the stack we use another LSTM. First we feed in the head word of the constituent, followed by the embeddings of each of the constituent's children, including the special STOP-L and STOP-R symbols. We then additionally add a gated residual connection from the head word to final subtree representation to allow salient information of the head word to be captured without needing to pass through an arbitrary number of LSTM steps (Figure 4).

2.2 Bottom-Up

Our second model generates sentences bottom-up, in the same manner as a shift-reduce parser. A sentence is modeled as a series of actions (related to the arc-standard transitions used in parsing (Nivre, 2013)) that manipulate a stack of embedded tree fragments. There are three types of actions: SHIFT(x), which pushes a new terminal x onto the stack, REDUCE-L, which combines the two top elements on the stack into one single sub-

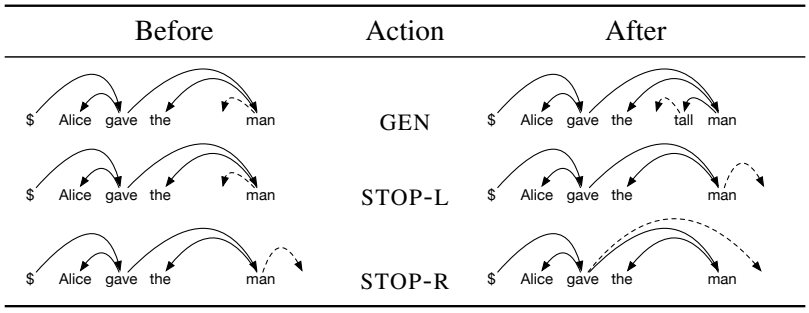

Figure 2: Examples of the three actions of our top-down model. The dotted arrow indicates where the new word will go if the GEN action is chosen next. GEN creates a new terminal node and moves the dotted arrow to point to the left of the new token. STOP-L moves the dotted arrow from the left of the current token to the right thereof. STOP-R moves the dotted arrow from the right of the current token back up to its parent node.

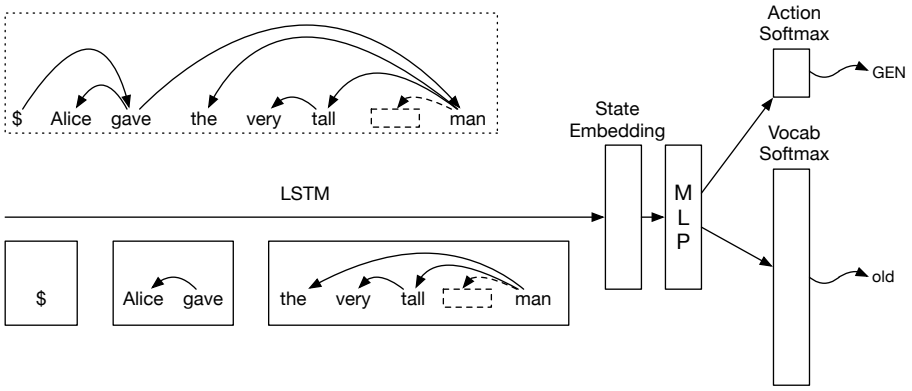

Figure 3: To encode the history of generation events in the top-down process, we use an LSTM over *subtree embeddings* (See Figure 4). The LSTM proceeds from the root of the tree down to the most recent open node. Each item in the LSTM is an embedding of a word and its already generated descendants. STOP symbols have been suppressed for clarity.

tree with the left of the two as the head (i.e. with a leftward arrow), and REDUCE-R which again combines the top two elements of the stack, this time making the right one the head. See Figure 5 for examples of how these three actions affect the stack of partially built tree structures during the parsing of an example sentence.

At each time step the model conditions on the state of the stack using an LSTM running over entries from oldest to newest. The resulting vector $\boldsymbol{h}$ is then passed through an MLP, and then a softmax over the three possible action types. If the SHIFT action is taken, the vector $\boldsymbol{h}$ is re-used and passed through a separate MLP and softmax over the vocabulary to choose an individual word to generate. If one of the two REDUCE actions is chosen, the top two elements from the stack are popped, concatenated (with the head-to-be first, followed by the child), and passed through an MLP. The result is a vector representing a new subtree that is then pushed onto the stack. Kuncoro et al. (2017) showed that this type of stack-based representation alone is sufficient for language modeling and parsing, and indeed that more involved models actually damage model performance. See Figure 6 for an example of how this bottom-up model chooses an action.

2.3 Marginalization

Traditionally a language model takes a sentence $\boldsymbol{x}$ and assigns it a probability $p(\boldsymbol{x})$. Since our syntax-based language models jointly predicts the probability $p(\boldsymbol{x}, \boldsymbol{y})$ of a sequence of terminals $\boldsymbol{x}$ and a tree $\boldsymbol{y}$, we must marginalize over trees to get the total probability assigned to a sentence $\boldsymbol{x}$, $p(\boldsymbol{x}) = \sum_{\boldsymbol{y} \in \mathcal{T}(\boldsymbol{x})} p(\boldsymbol{x}, \boldsymbol{y})$, where $\mathcal{T}(\boldsymbol{x})$ represents the set of all possible dependency trees over a sentence $\boldsymbol{x}$. Unfortunately the size of $\mathcal{T}(\boldsymbol{x})$ grows exponentially in the length of $\boldsymbol{x}$, making explicit marginalization infeasible.

Instead we use importance sampling to approximate the marginal (Dyer et al., 2016). We use the

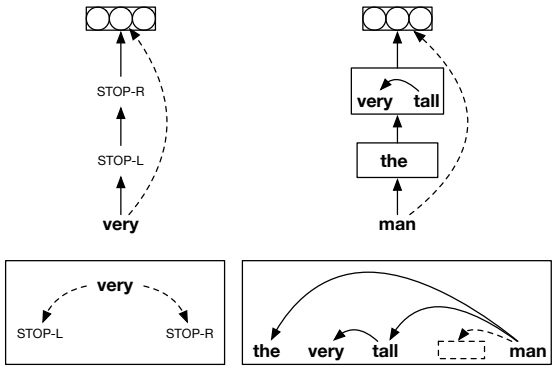

Figure 4: Examples of embedding two subtrees in the top-down model. A subtree is embedded using an LSTM over its child subtrees (solid lines) with a gated residual connection from the root word to the final embedding (dotted lines).

parser of Dyer et al. (2015), a discriminative neural stack-LSTM-based bottom-up parser, as our proposal distribution $q(\boldsymbol{x}, \boldsymbol{y})$ and compute the approximate marginal using $N = 1000$ samples per sentence: $p(\boldsymbol{x}) \approx \frac{1}{N} \sum_{i=1}^{N} \frac{p(\boldsymbol{x},\boldsymbol{y})}{q(\boldsymbol{x},\boldsymbol{y})}$.

2.4 Parsing Evaluation through Reranking

In order to evaluate our model as a parser we would ideally like to efficiently find the MAP parse tree given an input sentence. Unfortunately, due to the unbounded dependencies across the sequences of actions used by our models this inference is infeasible. As such, we instead rerank a list of 1000 samples produced by the baseline discriminative parser, a combination process that has been shown to improve performance by combining the different knowledge learned by the discriminative and generative models (Fried et al., 2017).

For each hypothesis parse in the sample list we query the discriminative parser, our top-down model, and our bottom-up model to obtain a score for the parse from each. We combine these scores using weights learned to optimize performance on the development set (Och, 2003).

3 Experimental Setup

Our primary goal is to discover whether dependency-based generative neural models are able to improve the performance of their discriminative brethren, as measured on parsing and language modeling tasks. We also seek to determine the effect construction order and the biases implicit therein has on performance on these two tasks. To this end, we test a baseline discriminative parser, our two models, and all combinations of these three models on a parsing task in several languages, and we test a baseline and our two models' performance on a language modeling task on the same set of languages.

3.1 Data Sets

We use the Universal Dependency corpora (Nivre et al., 2017) for three languages with very different structures: English, Japanese, and Arabic, as provided for the 2017 CoNLL shared task on universal dependency parsing. In all languages we convert all singleton terminal symbols to a special UNK token. See Table 1 for details regarding the size of these data sets.

For language modeling we evaluate using the gold sentence segmentations, word tokenizations, and part of speech tags given in the data. For parsing, we evaluate in two scenarios. In the first, we train and test on the same gold-standard data using in our language modeling experiments. In the second, we again train on gold data, but use UDPipe (Straka and Straková, 2017) to segment, tokenize, and POS tag the dev and test sets starting from raw text, following the default scenario and most participants in the CoNLL 2017 shared task.

3.2 Baseline Models

On the language modeling task we compare against a standard LSTM-based language model baseline (Mikolov et al., 2010), using 1024-dimensional 2-layer LSTM cells, and optimized using Adam (Kingma and Ba, 2014).

For the parsing task we compare against the discriminative parser of Dyer et al. (2015), a bottom-up transition-based parser that uses stack-LSTMs, as well as the overall top system (Dozat et al., 2017) from the 2017 CoNLL shared task on multilingual dependency parsing (Zeman et al., 2017). That work uses a discriminative graph-based parser that uses a biaffine scoring function to score each potential arc. Moreover, it uses character-level representations to deal with morphology and a PoS tagger more sophisticated than UDPipe – two major changes from the shared task's default pipeline. These two differences afford them a substantial advantage over our approach which only modifies the parsing step of the pipeline.

Finally, we show the results of an oracle system looking at the 1000-best lists used for our reranking experiments. Note that since this oracle system

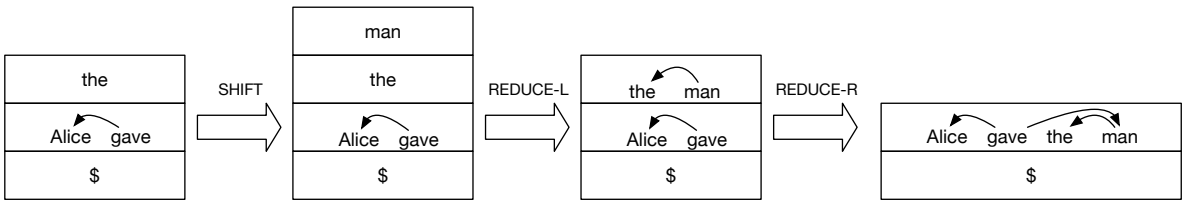

Figure 5: Examples of the three actions of our bottom-up model and their effects on the internal stack. SHIFT adds a new terminal to the top of the stack. REDUCE-L combines the top two elements of the stack with a left arc from the head of the top-most element to the head of the second element. REDUCE-R combines the top two elements with a right arc from the head of the second element to the head of the top-most element.

is constrained to using only this list of samples it is not able to achieve 100% parsing accuracy.

3.3 Hyperparameters

All models use two-layer 1024-unit LSTMs and 1024-dimensional word/action embeddings. All other MLPs have a single hidden layer, again with 1024 hidden units. We implement all models using DyNet (Neubig et al., 2017), and train using Adam (Kingma and Ba, 2014) with a learning rate of 0.001, dropout with $p = 0.5$, and minibatches of 32 sentences. We evaluate the model on a held out dev set after 150 updates, and save the model to disk whenever the score is a new best. All other settings use DyNet defaults.

4 Results

Parsing results Results on the parsing task can be found in Table 2. We observe that in English with the gold-standard preprocessing our models perform particularly well, showing an improvement of 1.16% UAS F1 for the top-down and 0.82% UAS F1 for the bottom-up model when individually combined with our discriminative parser. Combining all three models together gives a total of 1.46% absolute improvement over the baseline, indicating that the models capture knowledge lacking in the baseline model, and knowledge that is complementary to each other.

The story is similar in Japanese and Arabic, though the gains are smaller in Japanese. We hypothesize that this is due to the fact that parsing Japanese is relatively easy because of its strict head-final and left-branching nature, and thus our baseline is already a remarkably strong parser. This hypothesis is backed up by the fact that the baseline parser alone is only 3-4% UAS away from the oracle by itself, compared to about 10% away on English and Arabic. Thus our relative improvement, measured in terms of the percentage of possible improvement achieved, is quite consistent across the three languages, at roughly 13%.

Results on the test set using UDPipe's noisy preprocessing also saw encouraging results from

the three-model ensemble gaining 1.99%, 0.40%, and 1.61% on English, Japanese, and Arabic respectively, solidly outperforming the 2017 CoNLL shared task baselines across the board, and beating Dozat et al. (2017), the overall shared task winner's, submission on Japanese.

Of particular note is that on both the gold and non-gold data, and across all three languages, the performance of the top-down and bottom-up models is quite similar; neither model consistently outperforms the other. In Japanese we do find the bottom-up parser beats the top-down one when used alone, but when combined with the discriminative model the lead evaporates, and in both of the other languages there is no clear trend.

These results are consistent with Fried et al. (2017) that has shown that generative models are particularly good at improving discriminative models through reranking, as they have an effect similar to ensembling dissimilar models.

Language modeling results We find that despite successes on parsing, our dependency models are not empirically suitable for language modeling. Table 3 shows the performance of our models on the language modeling task. Across all three languages, both of our models underperform a baseline RNNLM by a consistent margin of about 0.5 nats per word.

Again we note that the two models perform remarkably similarly, despite their completely different construction orders, and thus the completely different sets of information they condition on at each time step. Again neither model is a clear overall victor, and in each individual language the models are extremely close in performance.

5 Analysis

One of our most intriguing findings is that our two proposed models perform remarkably similarly in spite of their differing construction orders. One would naturally assume that the differing orders, as well as the wildly different history information available at each decision point, would lead to performance differences. We seek to hone in on *why* the two models' performances are so similar.

Unfortunately the fact that the models use different conditioning contexts makes direct comparison of sub-sentential scores impossible. The top-down model, which generates the verb before its subject noun, may have large entropy when choosing the verb, but an easier time choosing the subject since it can condition on the verb limiting its choices to appropriate semantic classes, person,

	Structure	Terminals
Top-Down	4.97	67.9
Bottom-Up	7.42	63.3

Table 4: Our models' average negative log likelihoods on the English dev set broken down into structure and terminal components

number, et cetera. The bottom-up model, on the other hand, will generate the subject noun from the entire list of possible nouns first, and then will focus its probability on relevant and agreeing verb forms when generating the verb.

To this end we plot the scores (i.e. the negative log probabilities) the models assign to each gold tree in the English dev set. The raw scores between the top-down and bottom-up models are highly correlated (Pearson's $r = 0.995$), largely due to the fact that longer sentences naturally have lower probabilities than shorter sentences. As such, we examine length-normalized scores, dividing each sentence's score by its length. The results are still largely correlated ($r = 0.88$), with a few outliers, all of which are very short (<3 tokens) sentences.

We hypothesize that much of this correlation stems from the fact that for a given sentence both models must generate the same sequence of terminal symbols. Some sentences will have rare sequences of terminals while others have more common words, leading to an obvious, but perhaps uninformative, correlation. To examine this possibility we factor our models' scores into a *terminal* component and a *structure* component so that the overall negative log likelihood of a sentence is decomposed as $\text{NLL} = \text{NLL}_{\text{terminals}} + \text{NLL}_{\text{structure}}$. We then examine the correlation between the two models' scores' terminal components and their structure components separately. We find that the terminal components are still strongly correlated ($r = 0.91$), while the structure components are largely uncorrelated ($r = 0.09$), hinting that information the two models learned about the correct structure of English sentences differs. See Appendix Figure 7 for a visual representation of these data. Overall the top-down model also assigns much higher probabilities to correct structures, but lower probabilities to the correct terminal sequences (Table 4).

6 Related Work

Most work on discriminative dependency parsing follows the bottom-up paradigm (Nivre, 2003; Nivre et al., 2007; Dyer et al., 2015; Kiperwasser and Goldberg, 2016), but top-down models have also shown some promise (Zhang et al., 2015).

Generative dependency models go back to Hays (1964), but most existing such models (Buys and Blunsom, 2015; Jiang et al., 2016) have relied on independence assumptions whether used for parsing, unsupervised dependency induction, or language modeling. Buys and Blunsom (2015) also describe a generative bottom-up neural parser, but use hand-crafted input features and limit the model to third-order features. Titov and Henderson (2010) explore a generative parsing model with no independence assumptions based on sigmoid belief networks (Neal, 1992) instead of RNNs.

The CoNLL 2017 shared task saw many different models succeed at parsing Universal Dependencies. Most of the top contenders, including the best scoring systems on the languages discussed in this work, use discriminative models.

Kanayama et al. (2017) had tremendous success on Japanese using a wildly different approach. They train a model to identify likely syntactic heads, then assume that all other words simply attach in a left-branching structure, which works due to the strictly head-final nature of Japanese.

Dozat et al. (2017) train a discriminative neural parser which uses a BiLSTM to generate hidden representations of each word (Kiperwasser and Goldberg, 2016). These representations are used to score arcs, which are greedily added to the tree.

Björkelund et al. (2017) perform best on Arabic, using an ensemble of many different types of bottom-up discriminative parsers. They have each of twelve parsers score potential arcs, learn a weighting function to combine them, and use the Chu-Liu-Edmonds algorithm (Chu, 1965; Edmonds, 1967) to output final parses.

All three of these discriminative models are very effective for analysis of a sentence, none of them are able to be converted into a similar generative model. At best, the biaffine model of Dozat et al. (2017) could generate a bag of dependencies without order information, which makes it impractical as the basis for a generative model.

There has been past work on building recurrent neural models that condition on the buffer to make parsing decisions in a shift-reduce parser. Hender-

son (2004) was among the first to introduce such a model. They introduce both a generative and discriminative model based on Simple Synchrony Networks (Lane and Henderson, 1998), and use a pre-cursor to attention mechanisms to choose which previous states are most relevant at the current timestep. More recently Dyer et al. (2015) created a similar model based on stack LSTMs.

There has also been past work on language modelling with generation orders other than the typical left-to-right. Ford et al. (2018) examine a variety of possibilities, but stop short of syntax-aware oderings. Buys and Blunsom (2018) investigate neural language models with latent dependency structure, also concluding that while dependencies perform well on parsing they underperform for language modelling.

7 Conclusion

In this paper we test our hypothesis that dependency structures can improve performance on language modeling and machine translation tasks, in the same way that constituency parsers have been shown to help. We conclude that generative dependency models do indeed make very good parsing models, and, as has been observed in phrase structure parsing, combining a generative dependency parser with a traditional discriminative one does indeed improve parsing performance. We however also find using dependency models information to structure the intermediate representations in language modeling does not easily lead to better outcomes.

This pattern of results suggests that while dependencies may be a useful tool for text analysis, but are less suited to characterizing a generation process of sentences than phrase structure grammars area. Finally, we find that the choice of top-down or bottom-up construction order affects performance minimally on both the parsing and language modeling tasks despite the large differences in the local conditioning contexts of each action choice.

Abstract

We present a new method for transition-based parsing where a solution is a pair made of a dependency tree and a derivation graph describing the construction of the former. From this representation we are able to derive an efficient parsing algorithm and design a neural network that learns vertex representations and arc scores. Experimentally, although we only train via local classifiers, our approach improves over previous arc-hybrid systems and reach state-of-the-art parsing accuracy.

1 Introduction

While transition-based dependency parsing is usually implemented as a beam-search procedure, *e.g.* (Kiperwasser and Goldberg, 2016), some recent work such as (Shi et al., 2017) showed that global inference can be performed efficiently with dynamic programming. To this end, the stack representing pending subparses and the buffer representing the unconsumed input must both be abstracted into equivalence classes, while remaining rich enough to help with accurate predictions.

In this paper we first explicitly consider that a solution in transition-based parsing is represented as a pair made of a derivation graph and a derived dependency tree allowing the scoring function to be expressed naturally as a sum over these 2 structures. While we restrict our presentation to arc-hybrid systems, our method can be applied quite directly to other transition rule systems.

Secondly we show that this representation leads to an exact $O(n^4)$ parsing algorithm using dynamic programming. This algorithm can be seen as an extension of the minimal feature set arc-hybrid parsing algorithm presented in (Shi et al., 2017) where the contribution of the dependency arcs can be explicitly added to the scoring function as in the Eisner parsing algorithm (Eisner, 1996).

We then propose an alternative approach to global inference where derivation steps are represented as dense vectors based on the number and type of steps in a derivation. With this abstraction we design a neural architecture based on non-local networks (Wang et al., 2017) related to self-attention mechanism (Vaswani et al., 2017; Gu et al., 2018) to learn these representations while maintaining the possibility for exact decoding.

Our contribution can be summarized as follows: *(i)* a representation of arc-hybrid parsing as maximum subgraphs selection where a solution contains dependencies and derivation information; *(ii)* a polynomial dynamic programming algorithm to solve this problem exactly; *(iii)* a neural architecture able to learn representations for the subgraph vertices and compute arc scores without explicit stack and buffer representations.

These contributions are validated empirically by experimental results on the Penn Treebank where our system reaches state-of-the-art accuracy (94.8% UAS) for arc-hybrid parsing with networks of comparable size.

We first review arc-hybrid dependency parsing (§2) then present a deductive scheme to solve it (§3). The neural architecture is presented in §4 and experiments reported in §5. Finally we discuss some related work in §6.

2 Arc-Hybrid Dependency Parsing

2.1 Arc-Hybrid Derivations

Intuitively, the arc-hybrid parsing strategy (Gómez-Rodríguez et al., 2008; Kuhlmann et al., 2011) builds dependency parses incrementally by reading the sentence from left to right. The pending words are words which have been given all their left modifiers but may have not been given all their right dependents yet. The pending words are stored in the stack which

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 238–248
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

initially contains a dummy root word. The words which have not been read yet are stored in order in the buffer. The first word in the buffer is called the frontier word.

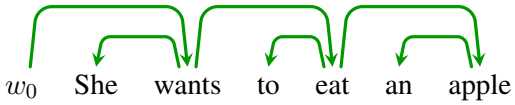
The algorithm proceeds by reducing the most recent pending word (the top of the stack) which means assigning it a governor. This governor is either the current frontier word, creating a left arc, or the previously most recent pending word (below in the stack), creating a right arc. Once given a governor, the most recent pending word is popped out. When the frontier word has been given all his left dependents, it is shifted which means it is pushed in the stack, becomes the most recent pending word and the next word in the sentence becomes the frontier word.

More formally, the arc-hybrid parsing algorithm is defined using configurations. Following standard definition, a configuration is a triplet $[\sigma, \beta, A]$ where σ is a stack of indexes of words which have not been given a governor yet, β a list (buffer) of indexes of words still to be read[1], and A the set of dependency arcs that have been constructed so far.

Given sentence $w = w_1, ..., w_n$ and dummy root token w_0, there are one initial configuration $c_1 = [0, 1..., \emptyset]$ and many goal configurations of the form $[0, \emptyset, A]$. There exist 3 transition rules to pass from one configuration to another[2]:

shift $[\sigma, b|\beta, A] \rightarrow^S [\sigma|b, \beta, A]$

left $[\sigma|d, h|\beta, A] \rightarrow^L [\sigma, h|\beta, A \cup \{(h, d)\}]$



right $[\sigma|h|d, \beta, A] \rightarrow^R [\sigma|h, \beta, A \cup \{(h, d)\}]$

A derivation for w is a sequence $\gamma = c_1, t_1, c_2, t_2, \ldots, t_{2n}, c_{2n+1}$ of $2n$ transitions from c_1 leading to a goal configuration c_{2n+1}.

The set of derivations for a sentence w is noted D_w. It can be shown that derivations all generate projective dependency trees and that, for a sentence with n words, they each contain n shift operations and n left or right reductions[3].

Shifts and reductions can be seen as forming a well-parenthesized expression. Each word is associated with a kind of parenthesis and shifting and reducing this word correspond to opening and closing parentheses of this kind.

For instance, in *She wants to eat an apple*, the derivation $(_{\text{She}})^L(_{\text{wants}}(_{\text{to}})^L(_{\text{eat}}(_{\text{an}})^L(_{\text{apple}})^R)^R)^R$, where shifting a word is represented by a subscripted opening parenthesis and reductions are closing parentheses typed either L or R, will generate the following dependency tree:

Arc-hybrid parsing amounts to finding the highest-scoring derivation for a sentence:

$$\hat{\gamma} = \arg\max_{\gamma \in D_w} s(\gamma)$$

If we assume s decomposes over transition scores $s_\ell(c_\ell, t_\ell)$, we retrieve the well-studied cumulative sum of its transition scores.

$$s(\gamma) = \sum_{1 \leq \ell \leq 2n} s_\ell(c_\ell, t_\ell) \quad (1)$$

2.2 General Formulation for Dynamic Programming

We present a dynamic programming (DP) algorithm for arc-hybrid parsing with cumulative transition scores as in Eq. 1. This algorithm cannot be used as such since states references complete stack contents, of which there is an exponential number, leading to an intractable complexity. To use this algorithm in practice we would need to resort to beam search in order to approximate solutions, see for instance (Dyer et al., 2015).

However, this constitutes a general framework from which efficient algorithms can be derived by considering various equivalence classes over states and independence assumptions in the scoring function. For instance we can retrieve the *Minimal Feature Set* algorithm of Shi et al. (2017), or the new algorithm presented in Section 3.

In our algorithm, an item ${}^{\sigma,A}\langle \boldsymbol{i}, \boldsymbol{j} \rangle^B$ represents the following set of subsequences of a derivation:

$${}^{\sigma,A}\langle \boldsymbol{i}, \boldsymbol{j} \rangle^B : [\sigma, i..., A] \xrightarrow{*} [\sigma|i, j..., B]$$

i.e. subsequences which start with *shifting* w_i and end with w_i on top of the stack and w_j on top of the buffer[4]. As a special case, we will note ${}^{\emptyset,\emptyset}\langle \mathbf{0}, \boldsymbol{j} \rangle^B$ the set of subderivations starting from the initial configuration $[0, 1..., \emptyset]$ and leading to $[0, j..., B]$.

[1] A buffer containing $(i, ..., n)$ will be denoted by "i...".

[2] Shift and left transitions require a non-empty buffer and the stack has to be of length at least 2 for left and right transitions since w_0 cannot be the governor of a left arc.

[3] Note that derivation is not unique for a dependency tree.

[4] such a subderivation is only possible if $i < j \leq n+1$ and $A \subset B$.

Goal: Goal items have the form: ${}^{\emptyset,\emptyset}\langle \boldsymbol{0}, \boldsymbol{n{+}1}\rangle^{A} : [\emptyset, 0..., \emptyset] \xrightarrow{*} [0, \emptyset, A]$.

Axioms: The algorithm starts with the set of items corresponding to possible shifts[5]: ${}^{\sigma,A}\langle \boldsymbol{i}, \boldsymbol{i{+}1}\rangle^{A} : [\sigma, i..., A] \rightarrow [\sigma|i, i{+}1..., A]$. The first axiom[6] ${}^{\emptyset,\emptyset}\langle \boldsymbol{0}, \boldsymbol{1}\rangle^{\emptyset}$ pictures a dummy sub-derivation that would put w_0 on top of the stack and lead to the initial configuration $[0, 1..., \emptyset]$.

DP Steps: A DP step consists in building an item ${}^{\sigma,A}\langle \boldsymbol{i}, \boldsymbol{j}\rangle^{B}$ by composing ${}^{\sigma,A}\langle \boldsymbol{i}, \boldsymbol{k}\rangle^{C}$, ${}^{\sigma|i,C}\langle \boldsymbol{k}, \boldsymbol{j}\rangle^{D}$, and a *reduce* operation on word w_k:

$$\begin{array}{rrcl} {}^{\sigma,A}\langle \boldsymbol{i}, \boldsymbol{k}\rangle^{C} : & [\sigma, i..., A] & \xrightarrow{*} & [\sigma|i, k..., C] \\ {}^{\sigma|i,C}\langle \boldsymbol{k}, \boldsymbol{j}\rangle^{D} : & [\sigma|i, k..., C] & \xrightarrow{*} & [\sigma|i|k, j..., D] \\ \textit{reduce} : & [\sigma|i|k, j..., D] & \rightarrow & [\sigma|i, j..., B] \end{array}$$

We thus have a *right reduction* rule:

$$\frac{{}^{\sigma,A}\langle \boldsymbol{i}, \boldsymbol{k}\rangle^{C} \quad {}^{\sigma|i,C}\langle \boldsymbol{k}, \boldsymbol{j}\rangle^{D}}{{}^{\sigma,A}\langle \boldsymbol{i}, \boldsymbol{j}\rangle^{D\cup\{(i,k)\}}} \quad [(i \rightarrow k)]$$

and a *left reduction* rule:

$$\frac{{}^{\sigma,A}\langle \boldsymbol{i}, \boldsymbol{k}\rangle^{C} \quad {}^{\sigma|i,C}\langle \boldsymbol{k}, \boldsymbol{j}\rangle^{D}}{{}^{\sigma,A}\langle \boldsymbol{i}, \boldsymbol{j}\rangle^{D\cup\{(k,j)\}}} \quad [(k \leftarrow j)]$$

Scoring Items: We trivially score an axiom ${}^{\sigma,A}\langle \boldsymbol{i}, \boldsymbol{i{+}1}\rangle^{A}$ with the score of a *shift* transition occurring in configuration $[\sigma, i..., A]$.

We compute the score of a DP step as the sum of the scores of the combined items and the score of *reducing* w_k from configuration $[\sigma|i|k, j..., D]$. When several DP steps produce the same item, it is assigned the highest score.

2.3 Minimal Feature Set Algorithm

For this algorithm (Shi et al., 2017), the score of a transition t_ℓ does not depend on the whole configuration but only on the index on top of the stack and the first index of the buffer. In other words, local scores s_ℓ only depend on word indexes (i,j,k). This assumption is crude but it allows for quite large items equivalence classes. We can retrieve this algorithm from the one above by removing unnecessary information in the items. Items of the form ${}^{\sigma,A}\langle \boldsymbol{i}, \boldsymbol{j}\rangle^{B}$ will simply reduce to $\langle \boldsymbol{i}, \boldsymbol{j}\rangle$, there will be $O(n^2)$ such items, and the DP complexity will be $O(n^3)$. More concretely, we have the following schemata:

Goal: $\langle \boldsymbol{0}, \boldsymbol{n{+}1}\rangle$.

Axioms: $\langle \boldsymbol{i}, \boldsymbol{i{+}1}\rangle$.

DP Steps:

$$\frac{\langle \boldsymbol{i}, \boldsymbol{k}\rangle \quad \langle \boldsymbol{k}, \boldsymbol{j}\rangle}{\langle \boldsymbol{i}, \boldsymbol{j}\rangle} \quad [(i \rightarrow k)]$$

and

$$\frac{\langle \boldsymbol{i}, \boldsymbol{k}\rangle \quad \langle \boldsymbol{k}, \boldsymbol{j}\rangle}{\langle \boldsymbol{i}, \boldsymbol{j}\rangle} \quad [(k \leftarrow j)]$$

One of the issues with this parsing scheme is the difficulty to interpret item scores consistently. In the case of a left reduction (producing $k \leftarrow j$ above) the score of $\langle \boldsymbol{k}, \boldsymbol{j}\rangle$ can be interpreted as the score of word j being the governor of word k and the score of $\langle \boldsymbol{i}, \boldsymbol{k}\rangle$ as the score of shifting word k in the context of i being the most recent pending word.

On the contrary, in the case of a right reduction (producing $i \rightarrow k$ above) if the score of $\langle \boldsymbol{i}, \boldsymbol{k}\rangle$ may well be interpreted analogously as the score of having i as a governor of k, we cannot interpret $\langle \boldsymbol{k}, \boldsymbol{j}\rangle$ as the score of shifting k, and it may be difficult to interpret this item score in terms of a transition operation.

3 Parsing with Derivations and Dependencies

3.1 A New Score for Derivations

We depart form previous work and make the dependency arc contribution explicit in the score function:

$$\hat{\gamma}, \hat{\tau} = \underset{\gamma,\tau \in S_w}{\arg\max}\, s(\gamma) + s(\tau) \qquad (2)$$

where S_w is the set of pairs (γ, τ) with $\gamma \in D_w$ and τ the dependency tree corresponding to γ. We use an arc-factored model for τ from now on and discuss scores for γ.

We define an equivalence class (i, q) containing all configurations c_ℓ such that the first index i_ℓ of β_ℓ equals i and the size of stack $|\sigma_\ell|$ equals q. Thus, we rewrite cumulative transition scores as:

$$s^{(u)}(\gamma) = \sum_{1 \leq \ell \leq 2n} s_u(i_\ell, |\sigma_\ell|, t_\ell). \qquad (3)$$

We also consider a score function based on the nestedness property of shift/reduce derivations. A score is given to each pair consisting of a shift and its corresponding (left or right) reduction. In other

[5] There is one axiom for each possible configuration $[\sigma, i..., A]$ with $0 \leq i < n$, σ a valid stack and A the set of corresponding arcs.

[6] Other axioms can be generated lazily from stack and arcs set pairs of items created by DP steps.

words, we exploit the perfect matching induced by a derivation between shift and reduce transitions: if t_ℓ is a shift transition and $t_{\ell'}$ its matching reduction, we consider a score depending on the equivalence classes of c_ℓ and $c_{\ell'+1}$. Note that the nestedness property implies that the stacks σ_ℓ and $\sigma_{\ell'+1}$ are equal. Moreover, $i_{\ell'+1} = i_{\ell'}$ as $t_{\ell'}$ is a reduction, an operation which does not modify the buffer. Denoting by M the set of matching shift/reduce pairs $(t_\ell, t_{\ell'})$ in γ, this gives:

$$s^{(m)}(\gamma) = \sum_{(t_\ell, t_{\ell'}) \in M} s_m(i_\ell, |\sigma_\ell|, i_{\ell'}). \quad (4)$$

Note that $s_m(i_\ell, |\sigma_\ell|, i_{\ell'})$ can be seen as the score of performing a reduction when i_ℓ is on the top of the stack of size $|\sigma_\ell|$ and $i_{\ell'}$ is the first word position of the buffer. Hence, this gives a score similar to the reduction score used in the minimal feature set algorithm. The difference is that the score takes into account the size of the stack but not the type (left or right) of reduction that is performed. The direction information will be given by the dependency arc score.

Finally, the derivation score is:

$$s(\gamma) = s^{(u)}(\gamma) + s^{(m)}(\gamma) \quad (5)$$

3.2 Graph Representation of a Derivation

In this section we represent the derivation of the arc-hybrid parsing using graphs.

A derivation is a sequence of n shifts and n reductions such that no more reductions than shifts are performed at each step. Such a sequence is a Dyck word and can then be represented as a path in an $(n+1) \times (n+1)$ grid starting at the lower left corner, ending at the lower right corner, using only up-right diagonal arcs and downward arcs (Roman, 2015). Such representation is the starting point of our derivation graph.

Define the *derivation graph* $G = (V, A)$ as follows. $V = \{v_i^q | 1 \leq q \leq i \leq n+1\}$ represents the set of equivalence classes. A vertex v_i^q corresponds to the class (i, q) of configurations, where w_i is the first word in the buffer[7] and the stack is of size q. The arc set A is given by $A = T \cup E$ where T represents transitions between states and E matches between shifts and reductions. We note $T = T^S \cup T^L \cup T^R$:

- $T^S = \{(v_i^q, v_{i+1}^{q+1}) | 1 \leq q \leq i \leq n\}$,
- $T^L = \{(v_i^q, v_i^{q-1})^L | 2 \leq q \leq i \leq n\}$,
- $T^R = \{(v_i^q, v_i^{q-1})^R | 2 \leq q \leq i \leq n+1\}$.

T^S, T^L and T^R represent shifts and tagged reductions respectively. We set $E = \{(v_i^q, v_j^q) | 1 \leq q \leq i < j \leq n+1\}$ because a shift can be matched to a reduction only if the size of the stack is the same before the shift and after the reduce. Note that for a sentence with n words, G will have $O(n^2)$ vertices and $O(n^3)$ arcs.

A derivation γ obtained by the arc-hybrid parsing will be represented by a pair (P, M) where $P \subseteq T$ is a path representing the derivation γ and $M \subseteq E$ is the set of arcs matching the shifts with their associated reductions in the derivation.

More formally, (P, M) is a solution if and only if we have the following. P is a path from v_1^1 to v_{n+1}^1 in G using only arcs of T. By construction, it contains n arcs of T^S and n arcs of $T^L \cup T^R$. It then corresponds to the sequence of transitions $t_1, \ldots, t_{2n}$. Note that any arc (v_i^q, v_{i+1}^{q+1}) in P consists in pushing word w_i on the top of the stack and any arc (v_i^q, v_i^{q-1}) in P consists in popping the top of the stack. One can retrieve the sequence of configurations $c_1, \ldots, c_{2n+1}$ thanks to the transitions.

Remark that each vertex v_i^q covered by P corresponds to configuration c_{2i-q} since $i-1$ shifts and $i-q$ reduces have been performed. An arc (v_i^q, v_j^q) of E belongs to M if the transition t_{2i-q} is a shift, transition t_{2j-q-1} is a reduction and these shift and reduce operations are matched together. Hence, $(v_i^q, v_j^q) \in M$ implies that (v_i^q, v_{i+1}^{q+1}) and (v_j^{q+1}, v_j^q) belong to P.

One can associate a score s_u from Eq. (3) with each arc of T and a score s_m from Eq. (4) with each arc of E. In this case, $s(\gamma)$ corresponds to

$$s(\gamma) = \sum_{a \in P} s_u(a) + \sum_{a \in M} s_m(a) \quad (6)$$

As an illustration, the derivation presented in the introduction can be represented by the set of black arcs P and red arcs M in Figure 1.

3.3 Dynamic Programming Algorithm

From the graph representation above we can derive a DP algorithm which computes the score of the optimal solution subgraph. This algorithm can be seen as a specialization of the general framework presented in Section 2.2 for our scoring functions.

[7] The value $n+1$ for i indicates that the buffer is empty.

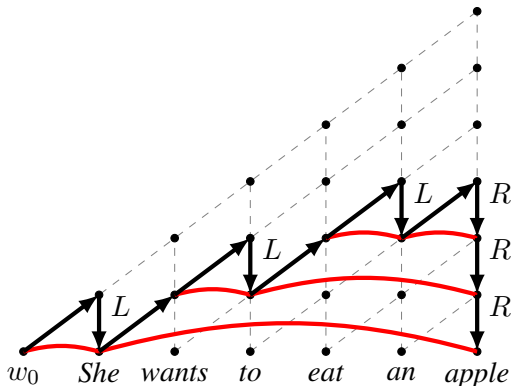


Figure 1: A Derivation for *She wants to eat an apple*. Shifts (resp. reductions) are represented in black diagonal (resp. vertical) arcs. Red curved edges represent matchings. Vertices are configuration classes v_i^q.

Since score functions s_u and s_m take the size of the stack into account, items with different (initial) stack sizes cannot be equivalent. Hence, items of the form ${}^q\langle \boldsymbol{i}, \boldsymbol{j} \rangle$ are needed, where $q = |\sigma|$ represents the size of the stack before shifting w_i. Leaving out the resulting dependency arcs, both *reduction* rules can be written with these equivalent items:

$$\frac{{}^q\langle \boldsymbol{i}, \boldsymbol{k} \rangle \quad {}^{q+1}\langle \boldsymbol{k}, \boldsymbol{j} \rangle}{{}^q\langle \boldsymbol{i}, \boldsymbol{j} \rangle}$$

There are $O(n^3)$ equivalent items and the DP complexity will be $O(n^4)$. Such items will be scored in the following way :

- the score of an axiom ${}^q\langle \boldsymbol{i}, \boldsymbol{i+1} \rangle$ is $s_u(i, q, \textit{shift})$. Axioms appear as black diagonal arcs (v_i^q, v_{i+1}^{q+1}) in Figure 1.
- In a DP step, the score of the *reduce* transition is $s_u(j, q+2, \textit{reduce})$. The transition is represented as a black vertical arc (v_j^{q+2}, v_j^{q+1}) in Figure 1.
- Finally the *matching* score in a DP step is $s_m(k, q+1, j)$. This score corresponds to red curved arcs (v_k^{q+1}, v_j^{q+1}) in Figure 1.

Figure 2 depicts both reduction rules. An item is represented as an arrow for the initial shift, and a triangle for the well-nested part of the subderivation. A reduction builds a new item by extending the well-nested part of the left antecedent with a new matching arc obtained from the right antecedent and the new reduction arc.

A dependency arc is added to assign a head to k, the midpoint of the reduction rule, depending on the direction of the reduction.

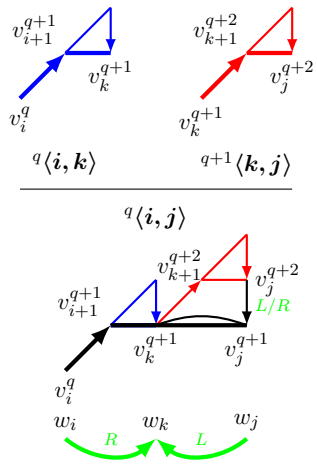

Figure 2: *Illustration of reduction rules.* Items are represented by a diagonal arc (first shift) and an horizontal edge (well-nested part). When combining two items in a reduction rule, a (curved) matching edge and a (vertical) reduction arc are added. The type of the reduction leads to a new dependency arc for the modifier w_k.

4 Learning Derivation Scores

We first present our network architecture inspired by recent work on self attention (Vaswani et al., 2017; Wang et al., 2017) which is able to learn representations of arc-hybrid configuration classes, that we call step representations. These representations are then used to compute derivation scores.

Our network is an encoder/decoder. The encoder computes word and step representations in the specific context of the sentence to be parsed, while the decoder computes arc scores.

We borrow from the transformer layer (Vaswani et al., 2017) the idea of global attention but extend it to the case where the size of the output is different from the size of the input. This has already been explored in (Gu et al., 2018) in the context of Machine Translation. However our problem is simpler because the size of the output is always twice the size of the input, in other words we do not have to estimate the size of the output.

4.1 Notation

A feed-forward layer is a sequence of an affine transformation, a ReLU filter and a linear transformation, *i.e.* $\text{FF}(\mathbf{x}) = V(\max(0, (W\mathbf{x} + b)))$, with V, W, b trainable parameters.

We call interpolation layers functions like $I(\mathbf{x}, \mathbf{y}) = C(\mathbf{x}) \cdot \mathbf{x} + (1 - C(\mathbf{x})) \cdot \mathbf{y}$ where C is a linear transformation followed by a sigmoid squashing, and $\cdot$ denotes the component-wise product.

Combining the previous two, we define highway layers (Greff et al., 2017) as functions $H(\mathbf{x}) = I(\mathbf{x}, FF(\mathbf{x}))$, i.e. an interpolation of input $\mathbf{x}$ and a feed-forward transformation of $\mathbf{x}$.

We also make use of biaffine functions following (Dozat and Manning, 2017) that we define as functions of the form $B(\mathbf{e}, \mathbf{f}) = \mathbf{e}^\top M \mathbf{f} + V\mathbf{e}$, with matrix M and vector V learnable parameters.

4.2 Layer Structure

Each layer L_i is the composition of two sublayers A_i, computing a generalized attention, and B_i, performing a feed-forward transformation. As is the case in previous approaches, each sublayer is followed by a layer normalization (Ba et al., 2016) and a residual connection to prevent underflows.

In more details, each layer takes as input a sequence of size n of dense vectors of size d packed as a matrix $\mathbf{X}$ in $\mathbb{R}^{n \times d}$ and a query vector sequence of size o, either equal to n or $2n$ depending on the layer (see infra) packed as a matrix $\mathbf{Y}$ in $\mathbb{R}^{o \times d}$. When $\mathbf{X}$ and $\mathbf{Y}$ are the same, we recover the self-attention mechanism of the transformer layer. The layer forward value is given by the following equations, where LN is a layer normalization:

$$\begin{aligned} a_i(\mathbf{X}, \mathbf{Y}) &= \mathbf{X} + A_i(\mathbf{X}, \mathbf{Y}) \\ b_i(\mathbf{X}) &= \mathbf{X} + B_i(\mathbf{X}) \\ L_i(\mathbf{X}, \mathbf{Y}) &= LN(b_i(LN(a_i(\mathbf{X}, \mathbf{Y})))). \end{aligned}$$

The first sublayer A_i computes for each output position in Y a multi-head scaled dot-product attention over input query Y and key/value X, with m attention heads.

$$A_i(\mathbf{X}, \mathbf{Y}) = \sum_{h=1}^{m} (A(Q_i^h \mathbf{Y}, K_i^h \mathbf{X}, V_i^h \mathbf{X}))$$

Each attention head A takes a query as input queries, keys and values, and computes for each query vector a convex combination of value vectors, the coefficients of which are given by an operation between the query and the key vectors:

$$A(\mathbf{Q}, \mathbf{V}, \mathbf{K}) = \text{softmax}(\mu \mathbf{Q}\mathbf{K}^\top)\mathbf{V}$$

where softmax is applied row-wise and μ is a smoothing factor between 0 and 1, which is set to $d^{-0.5}$, where d is the size of a query vector, following previous implementations of dot-product attention (Luong et al., 2015).

The second sublayer B_i applies the same feed-forward transformation to each element of the sequence of vectors returned by A_i.

4.3 Word and Position Embeddings

Each word in the train set is associated with a real vector stored in a lookup table E. In order to cope with unseen words, we follow (Kiperwasser and Goldberg, 2016) and at training time words are randomly `UNK`-ed with a probability inversely proportional to their frequency in the train set.

Contrarily to recurrent networks such as LSTMs, attention networks do not have a built-in notion of position so it must be provided externally. In our systems, we have two types of positions, namely word positions and step positions. We use position embeddings stored in lookup tables called respectively T and S.

4.4 Word Encoder and Dependency Scores

Our encoder is the composition of e self-attention layers starting from word and position vectors.

$$\begin{aligned} X_0 &= [E(w_1) + T(1); \ldots; E(w_n) + T(n)] \\ X_i &= L_i(X_{i-1}, X_{i-1}), 1 \leq i \leq e \end{aligned}$$

After encoding, we get X_e that we interpret as a sequence of contextualized word vectors. We can use these vectors to predict arc scores. In the following, we use a biaffine function B_{dep} to define the raw score between head at position i and modifier at position j: $s_{w_i \to w_j} = B_{\text{dep}}(X_e[i], X_e[j])$.

These raw scores are used in two ways.First and most obviously they score dependency arcs of the derived tree in this model. Second, for each modifier we use incoming arc scores to weigh potential heads and compute an expected head vector. We use normalized scores via softmax to interpolate head vectors. As a result for each vector word $X_e[i]$ we obtain an expected head vector $Y_e[i]$, which will be used hereafter.

4.5 Step Encoder

For steps, we distinguish the first layer from the others. For the first layer, input is the sequence returned by the last word encoder noted X_e and expected heads Y_e, and the query is initialized with

the increasing sequence of valid step position embeddings called $P = [S(1); \ldots; S(2n)]$.

$$D_0 = X_e + Y_e,\ P_1 = P,\ D_1 = L_{e+1}(D_0, P_1)$$

For $k > 1$, we set $D_k = L_{e+k}(D_{k-1}, D_{k-1})$.

Given sentence w, we note $h(w)$ the sequence of vectors returned by the last decoder layer.

4.6 Decoders as Local Classifiers

In this section we present how the score function can be decomposed as local probabilities. Given a sentence w, we assume the probability of a derivation γ is conditioned upon its corresponding derived tree τ. This condition prevents inconsistencies between τ and γ but plays no other role in the scoring function. The probability of a derived tree decomposes as independent head predictions computed by a logistic regression over head scores.

$$\begin{aligned} p(\gamma, \tau|w) =& p(\gamma|w, \tau) \times p(\tau|w) \\ =& p(\gamma|w, \tau) \times \prod_{h \to m \in \tau} p(h|m, w) \end{aligned}$$

The probability of a derivation in D_w is the probability at each independent step ℓ of 2 events: the transition t_ℓ and the step position r_ℓ of the corresponding reduction for a shift, or a dummy position for a reduction. We consider these two events to be independent but requiring the knowledge of the difference q_ℓ between the number of shifts and reductions already performed before the current step. This difference can also be interpreted in the context of the arc-hybrid algorithm as the depth of the stack. The difference is then used as a parameter for the potentials. This gives:

$$\begin{aligned} p(\gamma|w) &= \prod_{\ell=1}^{2|w|} p(t_\ell, r_\ell, q_\ell|w, \ell) \\ &= \prod_{\ell=1}^{2|w|} p_d(q_\ell|w, \ell) \times p(t_\ell, r_\ell|w, \ell, q_\ell) \\ &= \prod_{\ell=1}^{2|w|} p_d(q_\ell|w, \ell) \\ &\qquad \times p_u(t_\ell|w, \ell, q_\ell) \times p_m(r_\ell|w, \ell, q_\ell) \end{aligned}$$

The condition on sentence and step index w, ℓ is implemented via functions taking the ℓ^{th} step representation of w computed as described in the previous section, denoted $h(w)_\ell$ or simply h_ℓ if the sentence is clear from the context.

In practice we restrict the set of values for q_ℓ as the set of natural numbers between one and nine, and a special value for differences greater or equal to ten[8]. We use a lookup table F to convert discrete difference values to dense representations.

Note that although the 3 distributions are conditioned on the same step representations introduced in the previous section, these representations are first passed through highway layers, $\{H_i\}_{i=d,u,m}$, parameterized for each distribution. This helps with the specialization of step representations while keeping the possibility to share information between tasks.

The first two distributions are categorical distributions of the exponential family. They are computed as normalized potentials given by feedforward transformations of steps and differences.

$$\begin{aligned} p_d(q|h_\ell) &\propto \exp \mathrm{FF}_d(F(q) + H_d(h_\ell)), \\ p_u(t|q, h_\ell) &\propto \exp \mathrm{FF}_t(F(q) + H_u(h_\ell)). \end{aligned}$$

The third distribution is computed with a biaffine function B_m followed by a softmax, as in (Dozat and Manning, 2017). We reserve an extra value for the result random variable which encodes the absence of corresponding reduction.This is used when s is not a shift step. Note the difference embedding is only used on the left side of M.

$$p_m(r|h_\ell, q) \propto \exp B_m(F(q) + H_m(h_\ell), h_{\ell+r})$$

Learning is performed by simply maximizing the conditional log-likelihood of the 4 distributions over the correct derivations given a set of sentences. Once parameterized, it is straightforward to see how these distributions can fit the score model of Equation 5.

Conditional log-likelihood minimization requires to compute values for each distribution along gold solutions, which means it is a $O(n^2)$ procedure, because of distributions on dependency arcs and matching transitions, which both require 2 position parameters in order to be computed.

5 Experiments

Data We ran experiments on the Wall Street sections of the English Penn Treebank (Marcus

[8] We found almost all train sentences could be parsed with stack size below 10.

POS embedding size	28
Other embedding size	100
Encoder input/output size	256
Decoder input/output size	256
Hidden layer size in B subnetworks	512
attention heads	8
Maximum step numbers	200
Maximum difference D (stack height)	10
Number of word encoder layers	4
Number of step encode layers	4

Table 1: Network hyperparameters

Setting	UAS
Ours	$\mathbf{94.82} \pm 0.10$
Ours, joint training, but decoding with	
dependency scores only	94.80 ± 0.09

Table 2: Comparisons on PTB test set

et al., 1994) converted to Stanford Dependencies (de Marneffe and Manning, 2008). Transition sequences were obtained from dependencies and in case of ambiguity right reductions were always performed before shift if possible. We followed the standard split (02-21 for training, 23 for testing and 22 for development purposes) and used POS tags predicted by the Stanford MaxEnt tagger trained using 10-way jackknifing (Toutanova et al., 2003). We evaluate on unlabeled attachment without punctuation, with CoNLL evaluation script.

Implementation Hyperparameters are given in Table 1. In addition to word embeddings parameterized on the PTB, we use pretrained Glove vectors (Pennington et al., 2014). Our prototype is written in C++ with DYNET[9] for neural computations (Adam optimizer and default values) and UDPIPE[10] for reading and writing data files. Minibatches contain around 1,000 tokens. We train each model for 100 epochs and select our best model according to its development UAS. We follow previous works with transformers to set the learning rate (Vaswani et al., 2017). For the first $8,000$ updates the learning increases linearly with the number of steps, then it decreases proportionally to the squared root of the number of steps. We use the formula of Strubell et al. (2018).

Results Results on the PTB test set are presented in Table 2 and comparisons with previous work on arc-hybrid parsing with comparable network sizes. Parsing results are obtained by averaging 5 models initialized with different random seeds and standard deviation is also provided. Our system reaches 94.8% UAS and parses the whole section 23 in 1.13 seconds (DP only) on an Intel Xeon 2.10 GHz. Although our system is trained via local classifiers, we can see that it improves over global systems trained without step encodings.

Ablations indicate that the major part of scoring comes from dependencies. We may also conclude that (i) derivation information is useful per se but most importantly as an auxiliary task to improve dependencies and (ii) the stack size is paramount in this model since otherwise the network has no indication of the stack content. If not considered, accuracy drop considerably: step indexes alone are too vague as they can correspond to many different stack and buffer contents.

6 Discussion and Related Work

Derivation Parsing Maximum subgraph selection has played a central role in dependency parsing since the MST reduction by McDonald et al. (2005) and can also be traced back to the parsing-as-intersection tradition in phrase-based parsing – see for instance (Billot and Lang, 1989) – where the goal is to find, starting from a generic grammar, a graph-structure (a shared forest) that recognizes the input presented as a string or an automaton. In dependency parsing, this approach has since been extended to more complex dependencies such as non-crossing and 1-endpoint-crossing dependencies (Kuhlmann and Jonsson, 2015; Cao et al., 2017).

There is a long line of research which solve the different variants of transition-based dependency parsing algorithms with dynamic programming. Recent work showed that this can be performed efficiently, in $O(n^3)$, for arc-hybrid parsers (Gómez-Rodríguez et al., 2008) and have since been extended with non-linear classifiers (Kiperwasser and Goldberg, 2016; Shi et al., 2017) to reach state-of-the-art parsing accuracy.

We depart from both in the following way. In most works on maximum subgraph selection, the class of valid subgraph is a class defined only by

[9] https://github.com/clab/dynet
[10] http://ufal.mff.cuni.cz/udpipe

properties on dependencies. Here we represent *derivations* instead of derived structures. In that respect, we are closer to approaches developed for mildly-context sensitive formalisms such as Tree Adjoining Grammars which work primarily on the derivation tree (Corro et al., 2017) and consider the derived tree, i.e. the parse structure, as a by-product. Compared to other dynamic programming approaches to arc-hybrid parsing, we therefore work on a richer model, and have more expressive power to take a representation of states into account in the scoring scheme. This comes at a cost since the time complexity of our parsing algorithm is $O(n^4)$, an order of magnitude higher. The stack information (size) is minimal and is used to parameterize access to information available from step embeddings.

Compared to joint parsing systems working on both constituents and dependencies, our approach doesn't require external linguistic knowledge such as head percolation rules. On the other hand, since derivations don't add new information, but merely offer a new vision of the problem, the potential accuracy gain is lower.

Machine Learning Aspects Self-attention networks have been used in parsing, see for instance (Kitaev and Klein, 2018), whether based on dependencies or syntagms. Curiously we found few models of transition-based parsing based on these networks, and bidirectional recurrent network are still preferred in most architectures, where they are believed to capture some information about the sequential nature of transition-based algorithms. Instead we present a non-sequential model of transition-based parsing where representation vectors are obtained via unrolled iterative estimation (Greff et al., 2017).

Our encoder-decoder architecture together with independence assumptions made in the probabilistic model which decomposes a derivation score in several subtasks can be seen as auxiliary tasks as in (Coavoux et al., 2018).

The use of expected head vectors as input of the step encoder is related to the syntactic head attention of the SRL neural architecture in (Strubell et al., 2018).

7 Conclusion

We presented the arc-hybrid parsing transition rule system as a subgraph selection problem and showed how this can be solved exactly by a dynamic programming algorithm. This theoretical result is backed up by state-of-the-art results on the PTB.

This new representation of the problem is the basis of a novel neural architecture which learns vertex representations (for derivation steps) and edge scores (for derivation features).

From a parsing perspective, understanding why derivation prediction is a good auxiliary task to learn syntactic dependencies could prove insightful to explain how transitions and dependencies are related.

The derivation/derived pair is a very powerful concept that remains to be fully exploited. In particular, there are two promising avenues for future improvements. First, the learning framework could be enriched in a setting where the derivation graph is modeled as a latent variable and marginalized over. It remains to be seen if this can be done exactly or if sampling is required for efficiency. Second, since the score of a solution is the sum of the scores of elements in a pair, it should be possible to design an approximate solver based on lagrangian decomposition more efficient in practice.

Abstract

Debate *motions* (proposals) tabled in the UK Parliament contain information about the stated policy preferences of the Members of Parliament who propose them, and are key to the analysis of all subsequent speeches given in response to them. We attempt to automatically label debate motions with codes from a pre-existing coding scheme developed by political scientists for the annotation and analysis of political parties' manifestos. We develop annotation guidelines for the task of applying these codes to debate motions at two levels of granularity and produce a dataset of manually labelled examples. We evaluate the annotation process and the reliability and utility of the labelling scheme, finding that inter-annotator agreement is comparable with that of other studies conducted on manifesto data. Moreover, we test a variety of ways of automatically labelling motions with the codes, ranging from similarity matching to neural classification methods, and evaluate them against the gold standard labels. From these experiments, we note that established supervised baselines are not always able to improve over simple lexical heuristics. At the same time, we detect a clear and evident benefit when employing BERT, a state-of-the-art deep language representation model, even in classification scenarios with over 30 different labels and limited amounts of training data.

1 Introduction

Commonly known as the *Hansard* record, transcripts of debates that take place in the House of Commons of the United Kingdom (UK) Parliament are of interest to scholars of political science as well as the media and members of the public who wish to monitor the actions of their elected representatives. Debate *motions* (the proposals tabled for debate) are expressions of the policy positions taken by the governments, political parties, and individual Members of Parliament (MPs) who propose them. As all speeches given and all votes cast in the House are responses to one of these proposals, the motions are key to any understanding and analysis of the opinions and positions expressed in the subsequent speeches given in parliamentary debates.

By definition, debate motions convey the stated policy preferences of the MPs or parties who propose them. They therefore express polarity—*positive* or *negative*—towards some target, such as a piece of legislation, policy, or state of affairs. As noted by Thomas et al. (2006), the polarity of a debate proposal can strongly affect the language used by debate participants to either support or oppose it, effectively acting as a polarity shifter on the ensuing speeches. Analysis of debate motions is therefore a key first step in automatically determining the positions presented and opinions expressed by all speakers in the wider debates.

Additionally, there are further challenges associated with this task that differentiate it from the forms of sentiment analysis typically performed in other domains. Under Parliament's *Rules of Behaviour*,[1] debate participants use an esoteric speaking style that is not only laden with opaque procedural language and parliamentary jargon, but is also indirect, containing few explicitly negative words or phrases, even where negative positions are being expressed (Abercrombie and Batista-Navarro, 2018a).

The topics discussed in these debates revolve

[1] https://www.parliament.uk/documents/rules-of-behaviour.pdf

Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

around policies and policy domains. Topic modelling or detection methods, which tend to produce coarse overviews and output neutral topics such as 'education' or 'transport' (as in Menini et al. (2017), for instance), are therefore not suitable for our purposes. Rather, we seek to find the proposer of a motion's position or *policy preference* towards each topic—in other words, an *opinion-topic*. Topic labels do exist for the Hansard transcripts, such as those produced by the House of Commons Library or parliamentary monitoring organsitions such as Public Whip.[2] However, these are unsuitable due to, in the former case, the fact that they incorporate no opinion or policy preference information, and for the latter, being unsystematic, insufficient in both quantity and coverage of the topics that appear in Hansard, and not future-proof (that is, they do not cover unseen topics that may arise (Abercrombie and Batista-Navarro, 2018b)).

In this paper, we use the coding scheme devised by the Manifesto Project,[3] because: *(a)* it is systematic, having been developed by political scientists over a 40 year period, *(b)* it is comprehensive and designed to cover any policy preference that may be expressed by any political party in the world, *(c)* it has been devised to cover any policies that may arise in the future, and (d) there exist many expert-coded examples of manifestos, which we can use as reference documents and/or for validation purposes.

We approach automatic policy preference labelling at both the motion and (quasi-)sentence levels (see Section 2). We envisage that the output could therefore be used for downstream tasks, such as sentiment and stance analysis and agreement assessment of debate speeches, which may be performed at different levels of granularity.

Our contributions This paper makes the following contributions to the literature surrounding natural language processing of political documents and civic technology applications:

1. We develop a corpus of English language debate motions from the UK Parliament, annotated with policy position labels at two levels of granularity. We also produce annotation guidelines for this task, analysis of inter-annotator agreement rates, and further evaluation of the difficulty of the task on data from both parliamentary debates and the manifestos. We make these resources publicly available for the research community.

2. We test and evaluate two different ways of automatically labelling debate motions with Manifesto Project codes: lexical similarity matching and supervised classification. For the former, we compare a baseline of unigram overlap with cosine similarity measurement of vector representations of the texts. For the latter, we test a range of established baselines and state-of-the-art deep learning methods.

2 Background

Rather than being forums in which speakers attempt to persuade one another of their points of view, as the word 'debate' may imply, parliamentary speeches are displays of position-taking that MPs use to communicate their policy preferences to 'other members within their own party, to members of other parties, and, most important, to their voters' (Proksch and Slapin, 2015). Debate *motions* are proposals put forward in Parliament, and as such are the objects of all votes and decisions made by MPs, and, in theory at least, of all speeches and utterances made in the House.[4] Each parliamentary debate begins with such a motion, and may include further *amendment* motions (usually designed to alter or reverse the meaning of the original) as it progresses. Motions routinely begin with the words '*I beg to move That this House ...*', and may include multiple parts, as in *Example 1*,[5] which consists of two clauses, and appears to take a positive position towards international peace:

> *I beg to move*
> *That this House notes the worsening humanitarian crisis in Yemen;*
> *and calls upon the Government to take a lead in passing a resolution at the UN Security Council that would give effect to an immediate ceasefire in Yemen.* (1)

The concept of *policy preferences* is widely used in the political science literature (e.g. Budge

et al., 2001; Lowe et al., 2011; Volkens et al., 2013) to represent the positions of political actors expressed in text or speech. The Manifesto Project is an ongoing venture that spans four decades of work in this area and consists of a collection of party political documents annotated by trained experts with codes (labels) representing such preferences. Organised under seven 'domains', the coding scheme comprises 57 policy preference codes, all but one of which (*408: Economic goals*) are 'positional', encoding a positive or negative position towards a policy issue (Mikhaylov et al., 2008). Indeed, many of these codes exist in polar opposite pairs, such as *504: Welfare State Expansion* and *505: Welfare State Limitation*. The included manifestos are coded at the *quasi-sentence* level—that is, units of text that span a sentence or part of a sentence, and which have been judged by the annotators to contain 'exactly one statement or "message"' (Werner et al., 2011), as in *Example 2*, in which a single sentence has been annotated as four quasi-sentences:[6]

> *To secure your first job we will create 3 million new apprenticeships;*
> 411: Technology and Infrastructure
>
> *take everyone earning less than 12,500 out of Income Tax altogether*
> 404: Economic Planning
>
> *and pass a law to ensure we have a Tax-Free Minimum Wage in this country;*
> 412: Controlled Economy
>
> *and continue to create a fairer welfare system where benefits are capped to the level that makes work pay so you are rewarded for working hard and doing the right thing.*
> 505: Welfare State Limitation

(2)

3 Related work

There exists a large body of work concerning the analysis of opinions and policy positions in the related domains of legislative debate transcripts (for a survey, see Abercrombie and Batista-Navarro, 2019) and party political manifestos (see Volkens et al., 2015). Inspired by work on analysis of text from other domains, such as product reviews and social media, much of the computer science research in this area has concentrated on classifying the sentiment polarity of individual speeches (e.g. Burford et al., 2015; Thomas et al., 2006; Yogatama et al., 2015). Political scientists meanwhile, have tended to focus on position scaling—the task of placing the combined contributions of a political actor on a (usually) one-dimensional scale, such as *Left–Right* (e.g. Glavaš et al., 2017b; Laver et al., 2003; Nanni et al., 2019a; Proksch and Slapin, 2010). In either case, the majority of this work does not take into consideration the topics or policy areas addressed in the speeches.

Supervised classification approaches to opinion-topic identification have been explored in a number of papers. Abercrombie and Batista-Navarro (2018b) obtain good performance in classifying debate motions as belonging to one of 13 'policies' or opinion-topics. However, this approach is somewhat limited in that they use a set of pre-existing labelled examples which does not extend to cover the whole Hansard corpus or any new policies that may arise in the future. A similar setting to ours is that of Herzog et al. (2018), who use labels from the Comparative Agendas Project (CAP).[7] However, while they seek to discover latent topics present in the corpus, we wish to determine the policy-topic of each individual debate/motion. Rather than employ labelled manifesto data, as we do, they use the descriptions of the CAP codes.

Concerning policy identification in party political manifestos, previous studies have focused on topical segmentation (Glavaš et al., 2016) and classification of sentences into the seven coarse-grained policy domains (Glavaš et al., 2017a; Zirn et al., 2016). Meanwhile, Subramanian et al. (2018) recently presented a deep learning model that classifies manifesto sentences with the finer-grained code-level scheme of the Manifesto Project, as well as placing them on a Left-Right scale. In order to contribute to these research efforts and following recent advancements in deep language representation models (Devlin et al., 2018; Peters et al., 2018), we test the potential of BERT (Bidirectional Encoder Representations from Transformers) for policy-topic classification on both debate motions and manifestos.

[6] Conservative Party manifesto 2015.

[7] https://www.comparativeagendas.net

There is also a growing body of research on the evaluation of annotations for this domain. While the Manifesto Project relies on trained individual annotators to label manifestos, Mikhaylov et al. (2008) report the results of experiments which show that agreement between annotators is difficult to achieve, casting doubts on the reliability of the Project's codes. However, in similar experiments, Lacewell and Werner (2013) report greater inter-annotator agreement, and claim that with ongoing training, annotators can produce reliable labels. An extended analysis of the validity and reproducibility of the coding scheme is offered by Gemenis (2013), who remarks on the fact that 'the problem of unreliability does not lie with the coders but with the complex nature of the CMP (Comparative Manifesto Project) coding scheme'. Aware of such challenges, and in order to offer an additional comparison to these previous studies, in this work we provide a detailed analysis of the agreement rates of our annotators on both manifestos and debate motions.

4 Data

In the experimental section we report on the use of codes from the Manifesto Project as policy preference labels, with the goal of applying them to debate motions. These labels are convenient because: *(a)* like debate transcripts, they have been collected over time; and *(b)* the Project is ongoing, meaning that new example manifestos will continue to be added to it, mitigating potential concept drift problems (in which the language used to refer to aspects of different policy areas may change diachronically).

To construct our corpus, we made use of the data sources described below:

The Manifesto Project

We used annotated manifestos *(1)* as reference texts for labelling of debate motions by similarity matching, and *(2)* training a neural network for cross-domain classification of the motions. We downloaded all fifteen of the annotated United Kingdom (including Northern Ireland) manifestos from the Manifesto Corpus Version 2018-1 (Krause et al., 2018)—that is those that have been coded under version 4 of the coding scheme.[8]

Domain	Manifestos	Debates	
	QSs	Motions	QSs
1: External Relations	1,436	50	186
2: Freedom & Democracy	767	30	106
3: Political System	1,627	47	220
4: Economy	4,296	87	380
5: Welfare & Quality of Life	2,235	118	528
6: Fabric of Society	1,574	33	153
7: Social Groups	1,180	21	110
0: No meaningful category	166	0	0

Table 1: The number of quasi-sentences (QSs) coded under each domain in the UK manifestos that we use as reference texts and training data and the number of debate motions and quasi-sentences that we label under each domain in the motion policy preference corpus.

Party	Year(s)	QSs
Conservative	2015	1589
DUP	2015	229
Green Party	2015	2235
Labour	2001, 2015	2503
Liberal Democrats	1997, 2015	2759
Plaid Cymru	2015	776
SDLP	2015	407
Sinn Féin	2015	272
SNP	1997, 2001, 2015	2309
UKIP	2015	1349
UUP	2015	417

Table 2: The parties and years of publication of the manifestos that we use as reference texts and training data, and the number of labelled quasi-sentences (QSs) by party in this subset of the manifesto data.

In this subset, the number of UK manifesto quasi-sentences labelled with codes in each domain varies considerably (see Table 1). These manifestos were written by a variety of political parties for elections over an 18 year period (Table 2). The most prevalent code in these manifestos is *504: Welfare State Expansion* (2,691 examples), and the least used is *103: Anti-Imperialism* (3 examples). Two codes, *102: Foreign Special Rela-*

tionships: Negative and *415: Marxist Analysis: Positive*, do not appear at all in manifestos from the United Kingdom.

Debate transcripts

The Hansard record of House of Commons debates is available for each day on which debates have taken place from 1919 to the present day in `xml` format at `https://www.theyworkforyou.com`, where it is updated daily with the most recent debates. As the record is more complete for recent years, we downloaded all files from May 7th 1997 (the start of that year's session of Parliament) to February 28th 2019. From these we extracted 1,156 motions together with the titles of the debates and the dates on which they were tabled. We manually removed procedural motions (those concerned solely with the workings of Parliament) from the dataset as these do not concern policy preferences and have no equivalents in political manifestos.

In order to approximate the format of the data in the Manifesto Project, and to investigate policy preference detection at different levels of granularity, we divided each motion into smaller units. For convenience, we approximated quasi-sentences in the Hansard data by automatically dividing motions into clauses, which are separated by semi-colons in the transcripts.

5 Annotation

We adapt the Project's *Coding Instructions* (Werner et al., 2011) to provide guidelines for the annotation of debate motions. We use version 4 of these instructions because, although a more recent, more finely grained version exists, there are as yet few example manifestos coded under the newer scheme. To complete the annotation task, we recruited three Political Science Master's students from the University of Mannheim, who worked for a total of 40 hours each over a two month period.

Debate motions

Annotations were carried out in two stages: an initial training phase, followed by labelling of the main dataset. We used the coding instructions of version 4 of the Manifesto Project handbook[9] supplemented by debate motion-specific guidelines including notes based on the annotators' discussions during training.[10] For the training phase, after being introduced to the data and the coding instructions, the annotators individually labelled three batches of motions and their quasi-sentences. In addition to labelling each of these with one of the codes, they were instructed to note examples which they found difficult to decide upon. Between each batch we met to discuss these instances, as well as other examples on which the annotators disagreed, adding notes to the annotation guidelines based on the observations made. Inter-annotator agreement during training ranged from 'fair' to 'substantial', following common interpretation of Fleiss' *kappa* scores (Landis and Koch, 1977) (see Table 3).

The final corpus includes 386 hand-annotated motions and 1,683 quasi-sentences.[11] The majority of these have been labelled by two of the three annotators. Inter-annotator agreement is within the ranges generally interpreted as being 'moderate' to 'substantial' (see Table 4). The slightly higher agreement at the quasi-sentence level than on overall motion labels suggests that it may be difficult in some cases to select a single policy preference code for a whole motion. A subsection of the corpus (41 motions, 180 quasi-sentences) was labelled by all three annotators. Fleiss' *kappa* scores for this subsection are 0.46 at both levels, which indicates 'moderate' agreement. Following Pustejovsky and Stubbs (2012), the gold standard label for each example is obtained by adjudication, which was carried out by the first author.

Manifestos

To validate our labelling procedure, and for comparison with other work, we also asked the annotators to label a small quantity (120) of quasi-sentences from the Manifesto Project. We calculate Fleiss' *kappa* for these annotations to be 0.48, which is comparable to that obtained on the main dataset of debate motions, and higher than those reported by Mikhaylov et al. (2008) on manifestos.

Again, we asked the annotators to mark any examples which they considered to be difficult to decide upon. Agreement (Fleiss' *kappa*) on these 'difficult' cases is only 0.17, with only one ex-

[9] Available at `https://manifestoproject.wzb.eu/down/papers/handbook_2011_version_4.pdf`

[10] These guidelines are available along with the corpus.

[11] These constitute examples with 'gold standard' labels. The corpus also includes examples labelled by a sole annotator ('silver standard') and further unlabelled motions (see Table 5).

Iteration	Motion level			Quasi-sentence level		
	No. of examples	*k*	Interpretation	No. of examples	*k*	Interpretation
Training 1	15	0.41	'moderate'	60	0.35	'fair'
Training 2	12	0.65	'substantial'	60	0.56	'moderate'
Training 3	16	0.48	'moderate'	60	0.40	'fair'

Table 3: Annotator agreement (Fleiss's *kappa*) at two levels of granularity during three iterations of training and development of annotation guidelines for labelling debate motions with codes from the Manifesto Project.

	Annotators	No.	*k*
Motion	All 3	41	0.46
QS	All 3	180	0.46
Motion	1 & 2	139	0.51
	2 & 3	155	0.50
	1 & 3	169	0.49
	All pairs	463	0.50
QS	1 & 2	622	0.58
	2 & 3	650	0.51
	1 & 3	731	0.62
	All pairs	2003	0.58

Table 4: Fleiss' *kappa* scores for three-way agreement and Cohen's *kappa* scores for two-way agreement on the debate motions dataset.

Labels	Motion	Quasi-sentence
Gold standard	386	1,683
Silver standard	87	361
Total labelled	473	2,044
Unlabelled	593	2,587
Overall total	1,066	4,631

Table 5: Statistics for the motion policy preference corpus. Gold standard examples have been labelled by two or three annotators initially and adjudicated on in a final round of annotation. Silver standard examples have been labelled by a single annotator only.

ample marked as such by all three annotators. In this case, two of them used the 'correct' Manifesto Project gold label, while the third annotator applied a different code from the same domain. Overall, of the 47 examples (39.2%) on which all three annotators agree, 36 of these agree with the gold label (30% of the total). Domain-level agreement is 0.56, which is also similar to that achieved on the debate motions.

The Motion Policy Preference Corpus

We make the corpus available for download at https://madata.bib.uni-mannheim.de/308. The number of labelled and unlabelled examples it contains can be seen in Table 5. For the gold-labelled data, motions range in length from one to 13 quasi-sentences (mean = 4.3), with each of these consisting of between four and 163 tokens (mean = 28.7).

6 Automatic Labelling Methods

We investigated two ways of automatically labelling debate motions with the codes from the Manifesto Project: *(1)* similarity matching and *(2)* supervised classification. We tested both at the quasi-sentence level and we additionally experiment with similarity matching methods at the whole motion level, where the lack of sufficient training data prevents application of supervised learning methods. In pre-processing we filtered out any motions that have gold standard labels that appear less than ten times in the corpus, leaving 370 motions and 1,634 quasi-sentences, each annotated with one of the 32 remaining class labels.

Similarity matching

We tested two methods of matching debate motions to codes from the Manifesto Project, comparing a baseline of unigram overlap scores with cosine similarity measurement. In each case, we measured the similarity of the list of tokens $A = A_1, A_2, ..., A_n$ in each motion or quasi-sentence text and the list of tokens in each collection of concatenated manifesto extracts $B = B_1, B_2, ...B_n$.

For unigram overlap, we simply counted the union of the sets of tokens from *A* and *B*. For the latter method, each text was represented by its term frequency-inverse document frequency vector (tf-idf), and cosine similarity calculated as:

$$\frac{\vec{A} \cdot \vec{B}}{||\vec{A}||||\vec{B}||}$$

With both of these approaches, we explored the use of the following combinations of sources of textual unigram features: the debate titles, which have been shown to be highly predictive of a

motion's opinion-topic in a supervised classification setting (Abercrombie and Batista-Navarro, 2018b), the debate motions themselves, and both the titles and motions together.

Supervised Classification

We tested a range of supervised machine learning algorithms for the policy preference classification task, ranging from traditional approaches to recently developed pre-trained deep language representation models. We were particularly interested in assessing the performance of such approaches: *(1)* despite the limited training data available (1.6k motion quasi-sentences); and *(2)* in a cross-domain application (training on over 16k manifesto quasi-sentences, and testing on the motion quasi-sentences).

First, we examined the performance of Support Vector Machines (SVM) trained using lexical (tf-idf) or word embedding (w-emb) features, which act as strong traditional baselines. We tested both pre-trained general purpose word embeddings from `https://fasttext.cc` (Mikolov et al., 2018) and in-domain vectors generated on the Hansard transcripts from Nanni et al. (2019b).

We also report the results of a widely adopted neural network baseline for topic classification (see for instance Glavaš et al. (2017a) and Subramanian et al. (2018) in the context of manifesto quasi-sentences classification): a Convolutional Neural Network (CNN) with single convolution layer and a single max-pooling layer. We again tested the CNN with general purpose and in-domain embeddings.

As final skyline comparisons, we present the performance of *(1)* a pre-trained BERT (large, cased) model (Devlin et al., 2018), with a final soft-max layer; and *(2)* the same pre-trained BERT model, with a CNN and max-pooling layers before the soft-max layer. We additionally experimented with the latter two models in a fine-tuning setting: after training on manifestos, they have been further fine-tuned on motions.

We tested all approaches with a 80/20 split of the dataset, and trained all the neural models for three iterations.

7 Results

We evaluated the predicted labels of each experimental model against the gold standard labels produced by the annotation process. For the machine learning methods, we report F1 scores with both macro and micro weightings in order to offer an understanding of the quality overall, as well as for the different classes.

Motions: Similarity Matching

We evaluate labelling of motions by similarity matching at two levels of granularity: quasi-sentence and whole motion. Cosine similarity matching comfortably outperforms the baseline at both levels of granularity and at both the policy and domain levels (see Figure 1).

Unlike the findings of Abercrombie and Batista-Navarro (2018b), in most settings, we do not find the debate titles to be as powerful indicators of class labels as features derived from the texts of the motions, perhaps due to our larger set of class labels containing more similar (same domain) policy preference codes.

Best performances at both policy and domain levels (F1 macro = 0.59) are obtained using tf-idf features derived from both motion titles and texts, although performance using the texts only is comparable. For most combinations of feature input and similarity measurement method, F1 scores are around twice as good at the domain level as at the policy level.

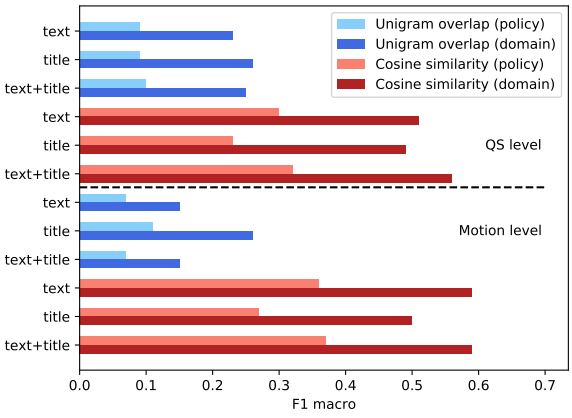

Figure 1: F1 macro scores for unigram overlap and cosine similarity matching at the policy and domain levels using textual features from whole motions. Use of cosine similarity leads to markedly better performance than unigram overlap, and the best performance is achieved using features derived from both the titles and motion texts at policy and domain levels.

Motions: Quasi-sentence Classification

We tested the supervised pipelines at the quasi-sentence level and at the two levels of class label granularity (policy and domain), which allows

Model	Text representation	Data Source	Policy		Domain	
			Macro	Micro	Macro	Micro

Table 6: F1 scores for similarity matching and classification of debate motions at the quasi-sentence level.

us to compare the results with previous work on the Manifesto Project (e.g., Zirn et al. (2016)). As can be seen in Table 6, the use of machine learning methods generally (but not always) leads to a substantial improvement (especially for Micro F1), in comparison to the heuristics that we have discussed above.

Concerning the SVM and CNN baselines, training the classifiers on the large collection of annotated manifestos and then applying them to the motions does not lead to improvements in comparison to the performance of the same architectures on the motions alone. Similarly, we notice that in most cases the use of in-domain embeddings does not improve the results. These two findings might be due to the fact that the style of communication and vocabulary of the employed resources are very different. The size of the training data may also play a role, as can be noticed in particular with the weak performances of the CNNs, especially in comparison to more traditional approaches; in the next section, we return to this issue.

Finally, to further confirm the large potential of BERT, even in tasks which involve many labels, a lack of training data, and a very specific style of communication, we have obtained a clear improvement over all other systems when employing this state-of-the-art architecture, trained on manifesto quasi-sentences and further fine-tuned on motions.

Manifestos: Quasi-sentence Classification

As a final comparison of the presented systems for quasi-sentence classification, we report their performance on the corpus of 16k manifesto quasi-sentences, again with an 80/20 train-test split. The results (see Table 7) are consistent with the performance of supervised pipelines on the Manifesto Corpus presented in previous literature (Glavaš et al., 2017a; Subramanian et al., 2018; Zirn et al., 2016) and in line with the performances we obtained on the motion corpus in Table 6.

Interestingly, we once again notice the weak performances of the CNNs on the collection, even with ten times as much training data. This could be due to a necessity to extend the architecture (for example, by adding more convolutional layers) rather than a simple lack of training data. Con-

Model	Text representation	Policy		Domain	
		Macro	Micro	Macro	Micro
SVM	Tf-idf	0.39	0.54	0.58	0.66
	Domain w-emb	0.35	0.53	0.52	0.64
	Wiki w-emb	0.38	0.54	0.54	0.66
CNN	Domain w-emb	0.28	0.47	0.54	0.58
	Wiki w-emb	0.27	0.44	0.52	0.56
BERT	Large, cased	**0.42**	**0.58**	0.58	0.64
BERT + CNN	Large, cased	**0.42**	**0.58**	**0.60**	**0.70**

Table 7: F1 scores for classification of party political manifestos at the quasi-sentence level.

versely, traditional SVM baselines offer reasonable results, and we achieve state-of-the-art performances when employing BERT.

8 Discussion and Conclusion

Through this work we have been able to make a number of observations about the validity and reliability of the annotations produced and the difficulty of the tasks of labelling both debate motions and manifestos.

In labelling the manifestos, our annotators agreed with each other to roughly the same extent that they agree with the gold labels provided by the Manifesto Project's expert annotators. This level of agreement is also similar to that reported in Mikhaylov et al. (2008), though not as good as that of MARPOR[12] itself (Lacewell and Werner, 2013).

The task does seem to be transferable to parliamentary debate motions, with our inter-annotator agreement scores comparable on both domains. Although automatic labelling with lexical similarity matching is more succesful at the quasi-sentence level than at the motion level, the annotators do not seem to find the coarser grained task much easier.

Overall, this is a hard task for humans. However, despite the issue of annotation reproducibility, political scientists continue to find these labels useful—as evidenced by Volkens et al. (2015), who find 230 articles that use this data in the eight journals they examine. With comparable reliabilty (inter-annotator agreement), the labelled motions could prove equally suitable for many automatic analysis applications.

Concerning automation of the labeling process, we can derive three general findings. The first is that a very simple approach—matching debate motions to coded manifestos using cosine similarity measurement—appears to produce potentially useful outputs, particularly at the domain level, with supervised baselines not necessarily offering consistently better results (especially the CNN architectures). The second is that cross-domain applications (from manifestos to motions) seem to necessitate a further fine-tuning step, perhaps due to the very different styles of communication involved. The third is the significant contribution that the use of BERT provides our supervised pipelines, which are able to achieve state-of-the-art performance on both the motions and manifesto quasi-sentences.

The generated dataset of topically labelled motions along with the trained BERT+CNN classifier can now pave the way for further work at the intersection of natural language processing and political science, which can benefit from these fine-grained policy position annotations: from analysing the sentiment of the motions to measuring the level of disagreement between members of the same party, and up to full-blown argumentation mining of each debate.

Abstract

Neural Machine Translation (NMT) optimized by Maximum Likelihood Estimation (MLE) lacks the guarantee of translation adequacy. To alleviate this problem, we propose an NMT approach that heightens the adequacy in machine translation by transferring the semantic knowledge learned from bilingual sentence alignment. Specifically, we first design a discriminator that learns to estimate sentence aligning score over translation candidates, and then the learned semantic knowledge is transfered to the NMT model under an adversarial learning framework. We also propose a gated self-attention based encoder for sentence embedding. Furthermore, an N-pair training loss is introduced in our framework to aid the discriminator in better capturing lexical evidence in translation candidates. Experimental results show that our proposed method outperforms baseline NMT models on Chinese-to-English and English-to-German translation tasks. Further analysis also indicates the detailed semantic knowledge transfered from the discriminator to the NMT model.

1 Introduction

Recently, with the renaissance of deep learning, end-to-end Neural Machine Translation (NMT) (Kalchbrenner and Blunsom, 2013; Cho et al., 2014a; Sutskever et al., 2014; Bahdanau et al., 2014) has gained remarkable performance (Wu et al., 2016; Gehring et al., 2017; Vaswani et al., 2017). Early NMT solutions are typically optimized to maximize the likelihood estimation (MLE) of each word in the ground truth translations during the training procedure. However, such an objective cannot guarantee the sufficiency of the generated translations in the NMT model, due to the lack of quantitative measurement for the information transformational completeness from the source side to the target side.

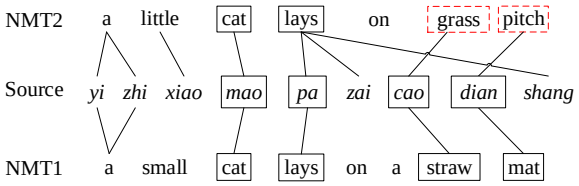

Figure 1: **Comparison between two Chinese-to-English translation examples of two independent NMT systems.** Lines between Source and NMTs represent model generated alignments (each source word cannot be covered more than once). Words in boxes are key words and red dotted dashed boxes indicate incorrect translations. Based on the model generated attention weights, NMT2 covers more source words than NMT1, which is opposite to human judgments.

Some existing work alleviates this problem by directly incorporating coverage or fertility mechanisms to an NMT model (Tu et al., 2016; Feng et al., 2016; Kong et al., 2019). However, the problem is that attention weights based coverage calculation for NMT is insensitive and sometimes even inaccurate to translation errors. Furthermore, it is unreasonable to consider the coverage of all kinds of source words equally, since various words contribute differently to sentences in semantics and syntax. For example, as illustrated in Fig. 1, translation errors are recorded as positive examples, and the alignments between function words also dilute the impact of key words alignments.

In this paper, we address the problem of inadequate translation by introducing a novel sentence alignment constrain under an adversarial training framework (Goodfellow et al., 2014; Lu et al., 2017; Yang et al., 2018). Specifically, our approach contains two sub-models: i) a sentence alignment oriented discriminator D learns to estimate the alignment score and sort the translation candidates by mainly considering the weighted

Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

alignment pairs (Ma, 2006) at a sentence representation level; and ii) a standard NMT model G aims to produce an appropriate translation with the highest ranking score (assigned by D) in the candidate list. To better capture the semantic alignment evidence of the input data, we also propose a novel gated self-attention based encoder for bilingual sentences encoding in discriminator D. Then, an N-pair training loss (Sohn, 2016) is introduced to select appropriate translation results from the candidates. We also leverage Gumbel-Softmax (GS) (Jang et al., 2017; Kusner and Hernández-Lobato, 2016) approximation for G to solve the problem of discrete samples, making the response from D to G differentiable.

To sum up, the proposed approach has the following advantages:

- We apply a novel end-to-end NMT adversarial training framework that heightens adequacy in translation. Under the framework, an NMT model is encouraged to generate translations that match semantic knowledge learned by a discriminator for sentence aligning, which can be viewed as an instance of "knowledge transfer".

- Benefited from the gated self-attention mechanism, the proposed encoder learns to focus on important lexical evidence for sentence aligning and enhance the contribution of the key words. This knowledge will be transfered to G through the proposed framework.

- The N-pair loss (Sohn, 2016; Lu et al., 2017) encourages samples closed to the gold-standard one to get higher score. Unlike a binary classification used in previous work (Yu et al., 2017; Yang et al., 2018; Wu et al., 2018), translations that are correct but different from the ground-truth ones will not be over penalized.

We use one of the state-of-the-art NMT models, Transformer (Vaswani et al., 2017), as the baseline model architecture and conduct experiments on Chinese-to-English and German-to-English translation tasks. Experimental results show that our proposed approach achieves significant improvements on both language pairs. We also evaluate the performance of the discriminator on both sentence alignment and translation candidate reranking tasks, which proves its independence and transferability. Further analyses show the specific alignment-oriented knowledge that the discriminator transfers to the NMT model.

2 Related Work

Most of the state-of-the-art NMT models are optimized by MLE-based objectives (Wu et al., 2016; Gehring et al., 2017; Vaswani et al., 2017), but likelihood fails to measure whether the source information is completely transformed to the target side. Thus, it cannot handle translation adequacy problem (Tu et al., 2017).

One way to alleviate these problems is to apply coverage and fertility to NMT model. Feng et al. (2016) aim at controlling the fertilities of source words by appending additional additive terms to train objectives. Tu et al. (2016) employ coverage vector or coverage ratio as a lexical-level indicator to represent whether a source word is translated or not.

On the other hand, some recent efforts introduce additional source side constraints and explore duality properties of NMT (He et al., 2016; Cheng et al., 2016; Xia et al., 2017; Tu et al., 2017). Cheng et al. (2016) present a semi-supervised approach to train bidirectional NMT models and reconstruct the monolingual corpora using an auto-encoder (Socher et al., 2011). Tu et al. (2017) add a re-constructor to traditional NMT model, which introduces an auxiliary score to measure the adequacy of translation. Dual learning (He et al., 2016) and dual supervised learning (Xia et al., 2017) are also proposed to exploit the probabilistic correlation between dual tasks to regularize the training process. These previous approaches apply a reconstruction reward by comparing the source input and the reconstructed sentence, while we use alignment score directly to model the discrepancy between the source and the translation.

GAN (Goodfellow et al., 2014) is another promising framework to leverage sentence-level objectives in NMT. Recently, there is some remarkable work in NMT (Wu et al., 2018; Yang et al., 2018). The framework comprises of two sub-models: i) an NMT model aims to produce sentences which are hard to be discriminated from the gold-standard sentences; and ii) a discriminator makes efforts to differentiate the model generated translations from the ground-truth ones. A policy gradient method is leveraged to co-train the NMT model and the discriminator. However,

those approaches rarely take account of translation adequacy. Furthermore, the discriminators of those work refer the target sentence in the corpus as the single gold-standard regardless the quality of model generated translations, which will punish too much to the good model generated translations. Kong et al. (2019) propose an adequacy-oriented discriminator which is trained to estimate the Coverage Difference Ratio (CDR) given the source and the generated translation. However, CDR is unable to distinguish translation errors and it also neglects the importance of diversity between different words (as the examples shown in Fig. 1).

Unlike the discriminators in (Wu et al., 2018; Yang et al., 2018; Kong et al., 2019), our alignment-oriented discriminator learns a specific function to measure alignment score between source and target sentences, which is trained totally independently by the NMT generator. The proposed discriminator assigns different weights to words and is sensitive to translation errors. We also apply N-pair loss for training D to ensure that D will not punish the translations closed to the gold-standard overly.

3 Approach

In this section, we describe our approach that can transfer knowledge from a sentence alignment oriented discriminator D to an NMT model G. Our approach mainly consists of two sub-models: i) a discriminator D learns to estimate the alignment score and sort the translation candidates, and ii) an NMT model G aims to generate translations with higher score assigned by D. A sketch of the proposed training framework is shown in Fig. 2: for each sentence pair (X, Y) sampled from the training corpus, the NMT model G generates a translation $\hat{\mathrm{Y}}$ given X, and queries the discriminator D with $\hat{\mathrm{Y}}$ to get feedback and update itself. In order to obtain more stable training, we also leverage a teacher-forcing (Li et al., 2017) step to our approach.

3.1 NMT Generator

In this paper, we take the Transformer (Vaswani et al., 2017), one of the popular state-of-the-art NMT models, as the specific implementation of the NMT model G. This helps to better illustrate the effectiveness of the proposed method. The Transformer in this paper follows the conventional encoder-decoder framework (Cho et al., 2014b). Specifically, the encoder contains a stack of six identical layers. Each layer is consist of two sub-layers: i) a multi-head self-attention mechanism, and ii) a position-wise fully connected feed-forward network. A residual connection is applied around each of the two sub-layers, followed by layer normalization (Ba et al., 2016). The decoder is also composed of a stack of six identical layers. Besides the two sub-layers stated above, a third sub-layer is inserted in each layer that performs multi-head attention over the output of the encoder.

Following the base model setups of the Transformer (Vaswani et al., 2017), we use 8 attention heads, 512-dimensional output vectors for each layer, and 2048-dimensional inner-layer of the feed-forward network.

1: Pre-train a generator G (see section 3.1) and a discriminator D (see section 3.2), individually.
2: **for** number of training iterations **do**
3: Sample $(\mathrm{X}, \mathrm{Y}^{+})$ from training corpus
4: Sample $\hat{\mathrm{Y}} \sim G(\mathrm{X})$ with a Gumbel-Softmax sampler (see section 3.4)
5: Compute loss $\mathcal{L}_G$ for $(\mathrm{X}, \hat{\mathrm{Y}})$ using D (see section 3.3)
6: Update G with the learning rate η:
$$\theta_G \leftarrow \theta_G - \eta \bigtriangledown_{\theta_G} \mathcal{L}_G \quad (1)$$
7: Teacher-Forcing: update G on $(\mathrm{X}, \mathrm{Y}^{+})$ (see section 3.5)
8: **end for**

Figure 2: A brief overview of the proposed training framework. See section 3 for more details.

3.2 Discriminator

For the discriminator D, we propose a gated self-attention based sentence encoder to perform source and target sentence encoding, and then calculate the alignment score using the encodings pair.

Gated Self-Attention Sentence Encoder. As depicted in Fig. 3, we opt a shallow network architecture: one gated hidden layer and one self-attention layer as the sentence encoder. This lightweight encoder mainly captures the lexical meanings of the sentence. The self-attention mechanism helps the encoder select more impor-

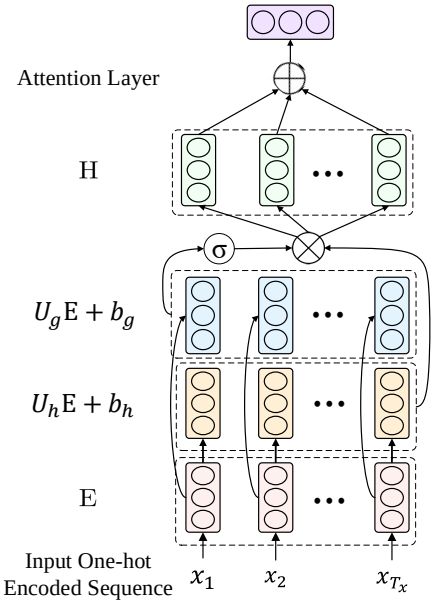

Figure 3: **Model architecture of the gated self-attention sentence encoder.** See section 3.2 for more details.

tant lexical evidences to estimate the alignment score between two sentences.

Given a one-hot encoded input sequence X and a word embedding lookup table $\mathrm{D} \in \mathbb{R}^{|V|\times d}$, where d is the model dimension. The input X will be represented as a corresponding word embedding matrix $\mathrm{E} \in \mathbb{R}^{\mathrm{T_x}\times \mathrm{d}}$. We apply a gating mechanism (Dauphin et al., 2017) to compute the hidden layer H:

$$\mathrm{H} = (U_h\mathrm{E} + b_h) \otimes \sigma(U_g\mathrm{E} + b_g), \tag{2}$$

where U_h and $U_g \in \mathbb{R}^{d\times d}$, $\sigma(\cdot)$ is a logistic sigmoid function and $\otimes$ is element-wise product between matrices. Then the self-attention weights W is computed as:

$$\mathrm{W} = \mathrm{softmax}(\tanh(U_a\mathrm{H})), \tag{3}$$

where $U_a \in \mathbb{R}^{d\times d}$. The output of the gated self-attention encoder is formulated as:

$$e = U_o(\mathrm{W} \times \mathrm{H}) + b_o, \tag{4}$$

where $e \in \mathbb{R}^d$, and $U_o \in \mathbb{R}^{d\times d}$. We add layer normalization (Ba et al., 2016) to the output layer. The model dimension d is set to 512.

Alignment Score and Discriminator Loss. With the source and target sentence encodings e_x and e_y, the alignment score $s_{(\mathrm{X},\mathrm{Y})}$ can be computed as:

$$s_{(\mathrm{X},\mathrm{Y})} = e_x^\top e_y. \tag{5}$$

Given the candidate target sentences list $\mathcal{Y}$, the discriminator produces a distribution over $\mathcal{Y}$ and aims to maximize the log-likelihood of the gold-standard alignment sentence Y^+. Since sentence-level alignments in automatic extracted corpora are usually not very precise, we expect the loss function for training D not to be too strict with candidates that are closed to the gold-standard one. Therefore, following Lu et al. (2017), we apply a metric-learning multi-class N-pair loss (Sohn, 2016) to our model, which can be defined as:

$$\begin{aligned}\mathcal{L}_D &= \mathcal{L}_{N-\mathrm{pair}}(\{\mathrm{X}, \mathrm{Y}^+, \{\mathrm{Y}_n^-\}_{n=1}^{N-1}\}) \\ &= \log(1 + \sum_{n=1}^{N} \exp(s_{(\mathrm{X},\mathrm{Y}_\mathrm{n}^-)} - s_{(\mathrm{X},\mathrm{Y}^+)})),\end{aligned} \tag{6}$$

where Y^+ is alignment target sentence to the source language X, and Y_n^- is one of the $N-1$ unaligned samples.

Compared to cross entropy loss used in previous work (Yu et al., 2017; Yang et al., 2018; Wu et al., 2018), the N-pair objective encourages the score of target sentences which are similar to the given golden-standard one to be higher than the dissimilar ones. In this way, translations that are correct but different from the ground truth will not be over penalized, and thus this can be useful to provide a reliable signal for the generator.

In later sections, we will analyze the semantic information learned by the model through some visualization examples, shown in section 5.1, and the experimental results show that it achieves sufficient accuracy for scoring the alignment between source and target sentences.

3.3 Discriminative Losses for Generative Training

In our framework, G aims to generate a translation score higher than the golden-standard, under the premise of encoders and the scoring function learned by D. Specifically, for each sentence pairs $(\mathrm{X}, \mathrm{Y}^+)$ in training sets, first, G samples translation $\hat{\mathrm{Y}}$ given X with greedy searching. Second, D takes $\hat{\mathrm{Y}}$ as well as $(\mathrm{X}, \mathrm{Y}^+)$ as inputs to compute alignment scores, and then G gets the feedback from D. Eq. (7) gives the perceptual loss that G aims to optimize.

$$\begin{aligned}\mathcal{L}_G &= \mathcal{L}_{1-pair}(\{\mathrm{X}, \mathrm{Y}^+, \hat{\mathrm{Y}}\}) \\ &= \log(1 + \exp(s_{(\mathrm{X},\mathrm{Y}^+)} - s_{(\mathrm{X},\hat{\mathrm{Y}})})).\end{aligned} \tag{7}$$

Intuitively, updating generator parameters to minimize $\mathcal{L}_G$ can be interpreted as learning to produce a translation $\hat{Y}$ that "fools" the discriminator into believing that this answer should score higher than the human response Y^+ under the D's scoring function.

3.4 Gumbel-Softmax Sampler

The process of sampling a translation $\hat{\mathrm{Y}}$ with G is not differentiable, since it includes $\mathrm{argmax}(\cdot)$ operator to perform one-hot encoding. We leverage the Gumbel-softmax (Jang et al., 2017) sampler to solve this problem. Formally, at the decoding step j, suppose that $p_j \in \mathbb{R}^{V_y}$ contains the model output log-probabilities over target vocabulary, and $g_j \in \mathbb{R}^{V_y}$ includes i.i.d samples drawn from the standard distribution $\mathrm{Gumbel}(0, 1)$. A sample y_j is transformed as:

$$\hat{y}_j = \mathrm{softmax}((p_j + g_j)/\tau), \tag{8}$$

where τ is a temperature parameter and is set to 0.5 in our experiments.

3.5 Teacher-forcing Step

Since $\mathcal{L}_G$ in Eq. (7) mainly considers the discrepancy of alignment and integrity between the model output and the ground-truth, it rarely inspects grammar correctness and language fluency. To alleviate this problem, following (Li et al., 2017; Lu et al., 2017), we adopt the similar teacher-forcing step to our training process.

We perform two different teacher-forcing objectives for comparison: i) a likelihood objective O_{LM} and ii) a BLEU score reward ($\mathrm{R}_{\mathrm{BLEU}}$), under the training strategies of MLE and MRT (Shen et al., 2016), respectively.

4 Experiments

4.1 Datasets and Setups[1]

We evaluate the proposed approach on Chinese-to-English (Zh-En) and English-to-German (En-De) translation tasks. For both of the two translation tasks, we tokenize all corpora with the Moses tokenizer[2]. Sentences longer than 100 words are discarded, and all the sentences are encoded with byte-pair encoding (bpe) (Sennrich et al., 2016).

Chinese-to-English. For Chinese-to-English translation, our training data are extracted from four LDC corpora[3]. The training set contains totally 1.3M parallel sentence pairs. For preprocessing, the Chinese part for both training and testing sets is segmented by the LTP Chinese word segmentor (Che et al., 2010) before applying bpe (Sennrich et al., 2016) to the corpus. We get a Chinese vocabulary of about 39K tokens, and an English vocabulary of about 30K tokens. We use NIST2005 dataset for validation and NIST2002, NIST2003, and NIST2004 datasets for testing. In the following parts of the paper, the Chinese examples are presented by segmented italic romanized form, and different Chinese characters are delimited by single quotation marks.

English-to-German. For English-to-German translation, we conduct experiments on the publicly available corpora WMT'14 En-De. The training set of En-De task totally contains 4.5M sentence pairs, and we use a shared source-target vocabulary of about 39K tokens. We use newstest2013 as the validation set and report the results on newstest2014.

Discriminative Corpus Construction. Different from parallel sentence pairs for training generative models, the corpus for training D needs to provide a candidate translations list for each source sentence. Therefore, we need to manually construct the corpus for training D using the original parallel corpus. For each source sentence, we set the size of candidate list to 100. The translation candidates are preferentially obtained from the context of the golden standard translation in the comparable paragraph. If the context sentence number N_c is less than 99, we will randomly sample another $99 - N_c$ sentences from the whole rest target corpus. As for the data format, we follow most of Das et al. (2019).

Evaluation. As for generative models, following Vaswani et al. (2017), we report the result of a single model obtained by averaging the 5 checkpoints around the best model selected on the development set. We apply beam search during decoding with the beam size of 6. The translation results in this paper are measured in case-insensitive BLEU (Papineni et al., 2002) by the

[1]The demo data and source codes will be released online at https://github.com/PolarLion/Sentence-Alignment-Learning

[2]https://github.com/moses-smt/mosesdecoder/blob/master/scripts/tokenizer/tokenizer.perl

[3]LDC2005T10, LDC2003E14, LDC2004T08 and LDC2002E18. Since LDC2003E14 is a document-level alignment comparable corpus, we use Champollion Tool Kit (Ma, 2006) to extract parallel sentence pairs from it.

multi-bleu.perl script[4]. For the discriminator, the performance is evaluated on recall@k and mean rank score.

4.2 Training Details

Pre-train discriminator and NMT model. During the training procedure, we first pre-train the discriminator and the generator separately for a warm start. We pre-train the model until the performance of D and G on development set dose not improve. For training discriminator on all language pairs, we use the Adam optimizer with $\beta_1 = 0.8$, $\beta_2 = 0.99$ and a base learning rate of 4×10^{-4}. The mini-batch size is 100 and the dropout rate is set to 0.1. As for the NMT model, we follow the base model of Transformer (Vaswani et al., 2017) for most of training setups, except the label smoothing (Szegedy et al., 2016).

Frozen discriminator v.s. adversarial discriminator. We also study the effects of two training setups of the discriminator: updating D (adversarial D) or not (frozen D) with the NMT model. When we perform frozen D, the NMT model is learned with a combination discriminative perceptual loss (Lu et al., 2017) and teacher-forcing loss (Li et al., 2017; Lu et al., 2017). Each mini-batch contains 30 sentence pairs due to the limitation of memory size of a single GPU. For the adversarial discriminator, We alternately update G and D under the adversarial learning framework (Yang et al., 2018; Wu et al., 2018; Kong et al., 2019). An adversarial D is to maximize the score of the human translation Y^+ and minimize the score of the generated translation $\hat{\mathrm{Y}}$. Then the training loss for adversarial D can be represented as: $\mathcal{L}_D = -\mathcal{L}_G$.

4.3 Machine Translation Results

We report the experimental results on machine translation in this section. Table 1 shows the BLEU scores of Zh-En and En-De translation tasks. Our approach achieves an improvement up to +0.76 BLEU points averagely on Zh-En testing sets and +0.64 BLEU points on En-De testing set. It should be noted that we do not apply label smoothing (Szegedy et al., 2016) due to using Gumbel-Softmax approximation, which results in a decline in En-De translation performance compared to the reported result of BLEU 27.3 in Vaswani et al. (2017).

We compare two setups of frozen D (Row 3-4) and adversarial D (Row 5-6) for the discriminator. Experimental results show that continuing to update D along with G gains best BLEU score for the both translation tasks. It means that fine-tuning D with the model generated data can further improve training quality. We also evaluate two different training objectives for the teacher-forcing step (Row 3,5 vs Row 4,6) and Row 2 is another baseline for training only on $\mathrm{R}_{\mathrm{BLEU}}$ (similar to MRT (Shen et al., 2016)). We can see from the results that applying MLE or BLEU reward does not make much difference. These results indicate that the proposed method makes up for the shortcomings of MLE training.

4.4 Discriminative Results

The format of the test datasets for discriminator is similar to the training set described in section 4.1, where each input corresponds to one hundred candidate translations extracted from the document context. The goal of the discriminator is to rank the correct translation as high as possible. We present recall@k and mean rank of the discriminator on Zh-En and En-De test sets in Table 2. It shows that for all test sets of both language pairs, our proposed discriminator performs steadily at high recall rate of more than 96% on recall@1 and nearly 100% on recall@5 and recall@10. Both of the high recall@k and ranking mean closed to 1 indicate that the ground-truth translations are always assigned to high alignment score.

Empirical and principled studies indicate that high initial accuracy of binary classification based discriminator may lead to worse model performance for GANs (Salimans et al., 2016; Arjovsky and Bottou, 2017; Yang et al., 2018). In this paper, G is trained with a specific 1-pair loss defined on sentence alignment score, instead of Jensen-Shannon divergence (Arjovsky and Bottou, 2017; Arjovsky et al., 2017) between two data distributions, which could avoid the vanishing gradient problem in GANs. Therefore, the high accuracy of the proposed discriminator would not make negative impact on G.

5 Analysis

In this section, we will study characteristics of the proposed approach and report some detailed ex-

+ adversarial D +$\mathrm{R_{BLEU}}$	11.36

Table 3: **Averaged sentence alignment scores on Zh-En NIST2002∼2004 test sets.** "Align" means the averaged sentence alignment score estimated by D. The higher score represents the better alignment quality in D's view. See section 5.1 for more details.

perimental results. We also give a specific translation example to illustrate how knowledge transferring improves NMT performance.

5.1 What kind of Knowledge Does D Transfer to G?

In this paper, we propose a discriminator that directly learns to measure alignment and then transfers the learned knowledge to an NMT model. D is designed to capture lexical evidence for sentence alignment by learning a self-attention encoder. We give averaged sentence alignment scores between translations and source inputs on different model setups in Table 3. Those alignment scores are estimated by a pre-trained D. Table 3 shows that the output alignment scores of the proposed approaches are all higher than the baseline methods, which illustrates that G can learn the knowledge on measuring alignment from D under the proposed training frameworks.

In order to illustrate the lexical-level knowledge learned by D, we give a visual example in Fig. 4. It shows self-attention weights of the encoders for the given source and the target sentence. In the example, the source sentence is "*bao'wei'er 12'ri yu sha'long ju'xing le hui'tan*" and the target sentence is "Powell hold a talk with Sharon on the 12th ." We notice that the source language words "*bao'wei'er*", "*12'ri*" and "*sha'long*", and their corresponding target language words "Powell", "12th" and "Sharon" are assigned higher attention weights than others. This means that the encoders regard those words as important lexical evidences for estimating the alignment score. Those self-learned attention weights share the same spirit with the weighted translation pairs in Champollion (Ma, 2006). During the training process, G leans to treat those important words carefully and avoid missing them to get higher score with the judgment of D. This process can be considered as transferring the semantic knowledge leaned by D to G.

5.2 Can discriminator distinguish good and bad translation results?

Since D is trained independently in our framework, it is difficult to estimate whether the discriminator can correctly distinguish the good and bad translations generated by the NMT model. Therefore, to verify whether an individual discriminator is suitable for the model generated data,

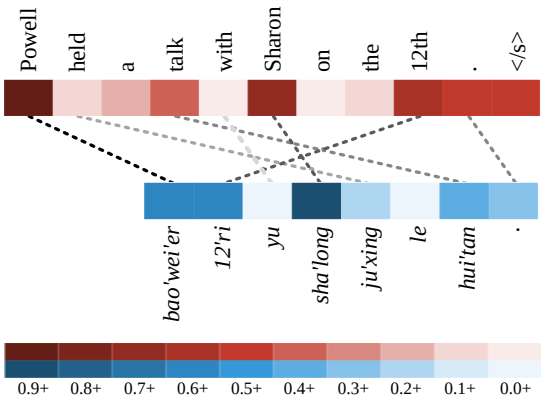

Figure 4: **Example of the self-attention weights for the source (lower) and the target (upper) language encoders.** Sentences in the example are selected from NIST2002 Zh-En test set. All weights in this example are scaled by Min-Max scaling method for better visualization and darker colors represent higher attention weights. Aligned words are manually connected by dashed lines. See section 5.1 for more details.

we conduct further experiments on translation re-ranking task on the baseline Transformer (Vaswani et al., 2017) model on Zh-En translation. Moreover, in order to obtain more translation candidates, we expand the beam size to 24 and then re-order the N-best translation candidates by D. Experimental results are shown in Table 4. We can observe that the larger beam search size leads to the worse performance, since the likelihood score for decoding tends to score short translations higher than long sentences. Larger searching space also brings more good translation candidates, and D re-orders them by alignment score and gains better BLEU scores than most baseline setups as shown in Table 4. The above observation indicates that D can successfully handle the unseen data generated by NMT models. Previous work (Wu et al., 2016; Koehn and Knowles, 2017) introduces length normalization to solve the above beam search decoding problem, whose results are also presented in Table 4 for a fair comparison.

5.3 Example Translations

We provide example translations on Zh-En translation task in Fig. 5. From Fig. 5, we can see that though the translation results of the baseline model is correct in syntax, its logic is wrong on account of missing an important source information of "went to Hong Kong on Saturday for a visa". All the translations generated by our proposed method do not make this mistake, since it is learned and

Setups	NIST02	NIST03	NIST04
beam 6	41.56	39.95	42.05
beam 24	40.72	38.64	41.13
+length penalty	41.93	**40.26**	42.49
+re-ranking	**42.22**	40.20	**42.56**

Table 4: **BLEU scores on Zh-En translation re-ranking task.** The "beam N" represents the decoding beam search size. The "+length penalty" means using length normalization (Wu et al., 2016) when performing beam search. The "+re-ranking" represents that the translation candidates are re-ranked by D. See section 5.2 for more details.

transfered from the discriminator where the verb "went", nouns 'Saturday' and "visa" are important lexical evidence for estimating alignment score. We also show a translation re-ranking example, which gains a similar result to other proposed methods. An alignment score evaluated by the discriminator and a sentence-level BLEU[5] (Papineni et al., 2002) score are also shown under the corresponding translations. Both the golden reference and the model generated translations gain higher alignment score from D, which illustrates the rationality of discriminator design.

6 Conclusion

In this work, we propose a novel training framework which achieves sentence alignment oriented knowledge transfer to improve the NMT. We design a discriminator to measure sentence alignment by mainly considering lexical evidence via a gated self-attention mechanism. Then, a discriminative loss as well as a teacher-forcing objective is used to make NMT model generate sufficient and fluent translations during training procedure. Experimental results on different language pairs show that our proposed approach outperforms standard NMT models. Further analysis indicates the proposed discriminator well captures the weighted lexical relationships among sentences and successfully transfers the knowledge to the NMT model.

In the future, we would like to make discriminator learn more semantic related knowledge like dependency, and combine our approach with other advanced techniques in reinforcement learning and adversarial learning (Yu et al., 2017; Yang et al., 2018; Kong et al., 2019).

Abstract

Training code-switched language models is difficult due to lack of data and complexity in the grammatical structure. Linguistic constraint theories have been used for decades to generate artificial code-switching sentences to cope with this issue. However, this require external word alignments or constituency parsers that create erroneous results on distant languages. We propose a sequence-to-sequence model using a copy mechanism to generate code-switching data by leveraging parallel monolingual translations from a limited source of code-switching data. The model learns how to combine words from parallel sentences and identifies when to switch one language to the other. Moreover, it captures code-switching constraints by attending and aligning the words in inputs, without requiring any external knowledge. Based on experimental results, the language model trained with the generated sentences achieves state-of-the-art performance and improves end-to-end automatic speech recognition.

1 Introduction

Code-switching is a common linguistic phenomenon in multilingual communities, in which a person begins speaking or writing in one language and then switches to another in the same sentence.[1] It is motivated in response to social factors as a way of communicating in a multicultural society. In its practice, code-switching varies due to the traditions, beliefs, and normative values in the respective communities. Linguists have studied the code-switching phenomenon and proposed a number of linguistic theories (Poplack, 1978; Pfaff, 1979; Poplack, 1980; Belazi et al., 1994). Code-switching is not produced indiscriminately, but follows syntactic constraints. Many linguists have formulated various constraints to define a general rule for code-switching (Poplack, 1978, 1980; Belazi et al., 1994). However, these constraints cannot be postulated as a universal rule for all code-switching scenarios, especially for languages that are syntactically divergent (Berk-Seligson, 1986), such as English and Mandarin since they have word alignments with an inverted order.

Building a language model (LM) and an automatic speech recognition (ASR) system that can handle intra-sentential code-switching is known to be a difficult research challenge. The main reason lies in the unpredictability of code-switching points in an utterance and data scarcity. Creating a large-scale code-switching dataset is also very expensive. Therefore, code-switching data generation methods to augment existing datasets are a useful workaround.

Existing methods that apply equivalence constraint theory to generate code-switching sentences (Li and Fung, 2012; Pratapa et al., 2018) may suffer performance issues as they receive erroneous results from the word aligner and the part-of-speech (POS) tagger. Thus, this approach is not reliable and effective. Recently, Garg et al. (2018) proposed a SeqGAN-based model to generate code-switching sentences. Indeed, the model learns how to generate new synthetic sentences. However, the distribution of the generated sentences is very different from real code-switching data, which leads to underperforming results.

To overcome the challenges in the existing works, we introduce a neural-based code-switching data generator model using pointer-generator networks (Pointer-Gen) (See et al., 2017) to learn code-switching constraints from a limited source of code-switching data and leverage their translations in both languages. Intu-

[1] Code-switching refers to mixing of languages following the definitions in Poplack (1980). We use "intra-sentential code-switching" interchangeably with "code-mixing".

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 271–280
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

itively, the copy mechanism can be formulated as an end-to-end solution to copy words from parallel monolingual sentences by aligning and reordering the word positions to form a grammatical code-switching sentence. This method solves the two issues in the existing works by removing the dependence on the aligner or tagger, and generating new sentences with a similar distribution to the original dataset. Interestingly, this method can learn the alignment effectively without a word aligner or tagger. As an additional advantage, we demonstrate its interpretability by showing the attention weights learned by the model that represent the code-switching constraints. Our contributions are summarized as follows:

- We propose a language-agnostic method to generate code-switching sentences using a pointer-generator network (See et al., 2017) that learns when to switch and copy words from parallel sentences, without using external word alignments or constituency parsers. By using the generated data in the language model training, we achieve the state-of-the-art performance in perplexity and also improve the end-to-end ASR on an English-Mandarin code-switching dataset.

- We present an implementation applying the equivalence constraint theory to languages that have significantly different grammar structures, such as English and Mandarin, for sentence generation. We also show the effectiveness of our neural-based approach in generating new code-switching sentences compared to the equivalence constraint and SeqGAN (Garg et al., 2018).

- We thoroughly analyze our generation results and further examine how our model identifies code-switching points to show its interpretability.

2 Generating Code-Switching Data

In this section, we describe our proposed model to generate code-switching sentences using a pointer-generator network. Then, we briefly list the assumptions of the equivalence constraint (EC) theory, and explain our application of EC theory for sentence generation. We call the dominant language the matrix language (L_1) and the inserted language the embedded language (L_2), following the definitions from Myers-Scotton (2001). Let us define $Q = \{Q_1, ..., Q_T\}$ as a set of L_1 sentences and $E = \{E_1, ..., E_T\}$ as a set of L_2 sentences with T number of sentences, where each $Q_t = \{q_{1,t}, ..., q_{m,t}\}$ and $E_t = \{e_{1,t}, ..., e_{n,t}\}$ are sentences with m and n words. E is the corresponding parallel sentences of Q.

2.1 Pointer-Gen

Initially, Pointer-Gen was proposed to learn when to copy words directly from the input to the output in text summarization, and they have since been successfully applied to other natural language processing tasks, such as comment generation (Lin et al., 2019). The Pointer-Gen leverages the information from the input to ensure high-quality generation, especially when the output sequence consists of elements from the input sequence, such as code-switching sequences.

We propose to use Pointer-Gen by leveraging parallel monolingual sentences to generate code-switching sentences. The approach is depicted in Figure 1. The pointer-generator model is trained from concatenated sequences of parallel sentences (Q,E) to generate code-switching sentences, constrained by code-switching texts. The words of the input are fed into the encoder. We use a bidirectional long short-term memory (LSTM), which, produces hidden state h_t in each step t. The decoder is a unidirectional LSTM receiving the word embedding of the previous word. For each decoding step, a generation probability $p_{gen} \in [0,1]$ is calculated, which weights the probability of generating words from the vocabulary, and copying words from the source text. p_{gen} is a soft gating probability to decide whether to generate the next token from the decoder or to copy the word from the input instead. The attention distribution a_t is a standard attention with general scoring (Luong et al., 2015). It considers all encoder hidden states to derive the context vector. The vocabulary distribution $P_{voc}(w)$ is calculated by concatenating the decoder state s_t and the context vector h_t^*:

$$p_{gen} = \sigma(w_{h^*}^T h_t^* + w_s^T s_t + w_x^T x_t + b_{ptr}), \quad (1)$$

where w_{h^*}, w_s, and w_x are trainable parameters and b_{ptr} is the scalar bias. The vocabulary distribution $P_{voc}(w)$ and the attention distribution a^t are weighted and summed to obtain the final distribution $P(w)$, which is calculated as follows:

$$P(w) = p_{gen} P_{voc}(w) + (1 - p_{gen}) \sum_{i:w_i=w} a_i^t. \quad (2)$$

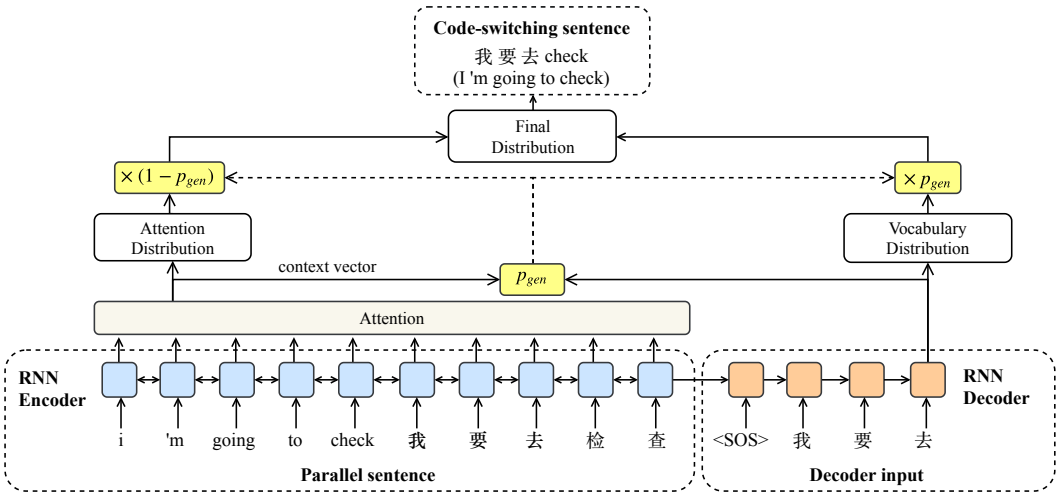

Figure 1: **Pointer-Gen** model, which includes an RNN encoder and RNN decoder. The parallel sentence is the input of the encoder, and in each decoding step, the decoder generates a new token.

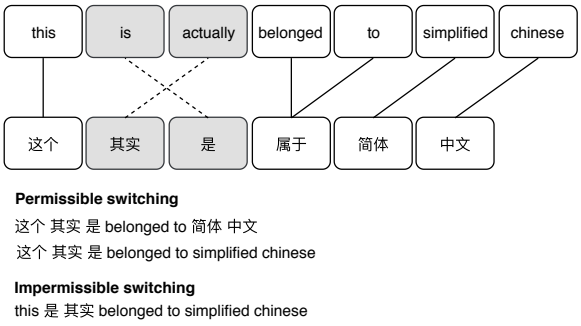

Figure 2: Example of equivalence constraint (Li and Fung, 2012). Solid lines show the alignment between the matrix language (top) and the embedded language (bottom). The dotted lines denote impermissible switching.

We use a beam search to select the N-best code-switching sentences.

2.2 Equivalence Constraint

Studies on the EC (Poplack, 1980, 2013) show that code-switching only occurs where it does not violate the syntactic rules of either language. An example of a English-Mandarin mixed-language sentence generation is shown in Figure 2, where EC theory does not allow the word "其实" to come after "是" in Chinese, or the word "is" to come after "actually". Pratapa et al. (2018) apply the EC in English-Spanish language modeling with a strong assumption. We are working with English and Mandarin, which have distinctive grammar structures (e.g., part-of-speech tags), so applying a constituency parser would give us erroneous results. Thus, we simplify sentences into a linear structure, and we allow lexical substitution on non-crossing alignments between parallel sentences. Alignments between an L_1 sentence Q_t and an L_2 sentence E_t comprise a source vector with indices $u_t = \{a_1, a_2, ..., a_m\} \in \mathbb{W}^m$ that has a corresponding target vector $v_t = \{b_1, b_2, ..., b_m\} \in \mathbb{W}^m$, where u is a sorted vector of indices in an ascending order. The alignment between a_i and b_i does not satisfy the constraint if there exists a pair of a_j and b_j, where ($a_i < a_j$, and $b_i > b_j$) or ($a_i > a_j$, and $b_i < b_j$). If the switch occurs at this point, it changes the grammatical order in both languages; thus, this switch is not acceptable. During the generation step, we allow any switches that do not violate the constraint. We propose to generate synthetic code-switching data by the following steps:

1. Align the L_1 sentences Q and L_2 sentences E using `fast_align`[2] (Dyer et al., 2013). We use the mapping from the L_1 sentences to the L_2 sentences.

2. Permute alignments from step (1) and use them to generate new sequences by replacing the phrase in the L_1 sentence with the aligned phrase in the L_2 sentence.

3. Evaluate generated sequences from step (2) if they satisfy the EC theory.

3 End-to-End Code-Switching ASR

To show the effectiveness of our proposed method, we build a transformer-based end-to-end code-

[2]The code implementation can be found at https://github.com/clab/fast_align.

switching ASR system. The end-to-end ASR model accepts a spectrogram as the input, instead of log-Mel filterbank features (Zhou et al., 2018), and predicts characters. It consists of N layers of an encoder and decoder. Convolutional layers are added to learn a universal audio representation and generate input embedding. We employ multi-head attention to allow the model to jointly attend to information from different representation subspaces at a different position.

For proficiency in recognizing individual languages, we train a multilingual ASR system trained from monolingual speech. The idea is to use it as a pretrained model and transfer the information while training the model with code-switching speech. This is an effective method to initialize the parameters of low-resource ASR such as code-switching. The catastrophic forgetting issue arises when we train one language after the other. Therefore, we solve the issue by applying a multi-task learning strategy. We jointly train speech from both languages by taking the same number of samples for each language in every batch to keep the information of both tasks.

In the inference time, we use beam search, selecting the best sub-sequence scored using the softmax probability of the characters. We define $P(Y)$ as the probability of the sentence. We incorporate language model probability $p_{lm}(Y)$ to select more natural code-switching sequences from generation candidates. A word count is added to avoid generating very short sentences. $P(Y)$ is calculated as follows:

$$P(Y) = \alpha P_{trans}(Y|X) + \beta p_{lm}(Y) + \gamma \sqrt{wc(Y)} \quad (3)$$

where α is the parameter to control the decoding probability from the probability of characters from the decoder $P_{trans}(Y|X)$, β is the parameter to control the language model probability $p_{lm}(Y)$, and γ is the parameter to control the effect of the word count $wc(Y)$.

4 Experiments

4.1 Data Preparation

We use speech data from SEAME Phase II, a conversational English-Mandarin Chinese code-switching speech corpus that consists of spontaneously spoken interviews and conversations (Nanyang Technological University, 2015). We split the corpus following information from Winata et al. (2018a). The details are depicted in Table 1. We tokenize words using the Stanford NLP toolkit (Manning et al., 2014). For monolingual speech datasets, we use HKUST (Liu et al., 2006), comprising spontaneous Mandarin Chinese telephone speech recordings, and Common Voice, an open-accented English dataset collected by Mozilla.[3] We split Chinese words into characters to avoid word boundary issues, similarly to Garg et al. (2018). We generate L_1 sentences and L_2 sentences by translating the training set of SEAME Phase II into English and Chinese using the Google NMT system (To enable reproduction of the results, we release the translated data).[4] Then, we use them to generate 270,531 new pieces of code-switching data, which is thrice the number of the training set. Table 2 shows the statistics of the new generated sentences. To calculate the complexity of our real and generated code-switching corpora, we use the following measures:

Switch-Point Fraction (SPF) This measure calculates the number of switch-points in a sentence divided by the total number of word boundaries (Pratapa et al., 2018). We define "switch-point" as a point within the sentence at which the languages of words on either side are different.

Code Mixing Index (CMI) This measure counts the number of switches in a corpus (Gambäck and Das, 2014). At the utterance level, it can be computed by finding the most frequent language in the utterance and then counting the frequency of the words belonging to all other languages present. We compute this metric at the corpus level by averaging the values for all the sentences in a corpus. The computation is shown as follows:

$$C_u(x) = \frac{N(x) - max(\ell_i \in \ell\{t_{\ell_i}(x)\}) + P(x)}{N(x)}, \quad (4)$$

where $N(x)$ is the number of tokens of utterance x, t_{ℓ_i} is the tokens in language ℓ_i, and $P(x)$ is the number of code-switching points in utterance x. We compute this metric at the corpus-level by averaging the values for all sentences.

[3]The dataset is available at https://voice.mozilla.org/.

[4]We have attached the translated data in the Supplementary Materials.

4.2 LM Training Strategy Comparison

We generate code-switching sentences using three methods: EC theory, SeqGAN (Garg et al., 2018), and Pointer-Gen. To find the best way of leveraging the generated data, we compare different training strategies as follows:

(1) rCS, **(2a)** EC, **(2b)** SeqGAN,
(2c) Pointer-Gen, **(3a)** EC & rCS,
(3b) SeqGAN & rCS, **(3c)** Pointer-Gen & rCS
(4a) EC → rCS **(4b)** SeqGAN → rCS,
(4c) Pointer-Gen → rCS

(1) is the baseline, training with real code-switching data. **(2a–2c)** train with only augmented data. **(3a–3c)** train with the concatenation of augmented data with rCS. **(4a–4c)** run a two-step training, first training the model only with augmented data and then fine-tuning with rCS. Our early hypothesis is that the results from **(2a)** and **(2b)** will not be as good as the baseline, but when we combine them, they will outperform the baseline. We expect the result of **(2c)** to be on par with **(1)**, since Pointer-Gen learns patterns from the rCS dataset, and generates sequences with similar code-switching points.

4.3 Experimental Setup

In this section, we present the settings we use to generate code-switching data, and train our language model and end-to-end ASR.

Pointer-Gen The pointer-generator model has 500-dimensional hidden states. We use 50k words as our vocabulary for the source and target. We optimize the training by Stochastic Gradient Descent with an initial learning rate of 1.0 and decay of 0.5. We generate the three best sequences using beam search with five beams, and sample 270,531 sentences, thrice the amount of the code-switched training data.

EC We generate 270,531 sentences, thrice the amount of the code-switched training data. To make a fair comparison, we limit the number of switches to two for each sentence to get a similar number of code-switches (SPF and CMI) to Pointer-Gen.

SeqGAN We implement the SeqGAN model using a PyTorch implementation[5], and use our best trained LM baseline as the generator in SeqGAN. We sample 270,531 sentences from the generator, thrice the amount of the code-switched training data (with a maximum sentence length of 20).

[5]To implement SeqGAN, we use code from https://github.com/suragnair/seqGAN.

LM In this work, we focus on sentence generation, so we evaluate our data with the same two-layer LSTM LM for comparison. It is trained using a two-layer LSTM with a hidden size of 200 and unrolled for 35 steps. The embedding size is equal to the LSTM hidden size for weight tying (Press and Wolf, 2017). We optimize our model using SGD with an initial learning rate of 20. If there is no improvement during the evaluation, we reduce the learning rate by a factor of 0.75. In each step, we apply a dropout to both the embedding layer and recurrent network. The gradient is clipped to a maximum of 0.25. We optimize the validation loss and apply an early stopping procedure after five iterations without any improvements. In the fine-tuning step of training strategies **(4a–4c)**, the initial learning rate is set to 1.

End-to-end ASR We convert the inputs into normalized frame-wise spectrograms from 16-kHz audio. Our transformer model consists of two encoder and decoder layers. An Adam optimizer and Noam warmup are used for training with an initial learning rate of 1e-4. The model has a hidden size of 1024, a key dimension of 64,

Table 3: Results of perplexity (PPL) on a valid set and test set for different training strategies. We report the overall PPL, and code-switching points **(en-zh)** and **(zh-en)**, as well as the monolingual segments PPL **(en-en)** and **(zh-zh)**.

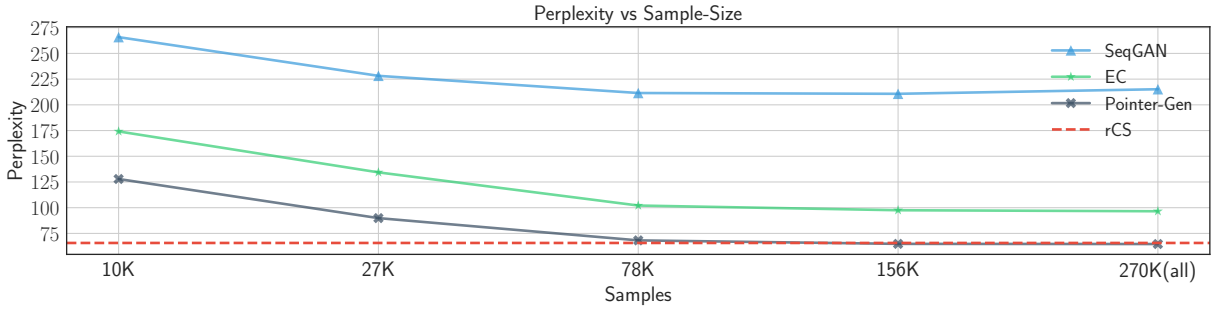

Figure 3: Results of perplexity (PPL) on different numbers of generated samples. The graph shows that Pointer-Gen attains a close performance to the real training data, and outperforms *SeqGAN* and *EC*.

and a value dimension of 64. The training data are randomly shuffled every epoch. Our character set is the concatenation of English letters, Chinese characters found in the corpus, spaces, and apostrophes. In the multilingual ASR pretraining, we train the model for 18 epochs. Since the sizes of the datasets are different, we over-sample the smaller dataset. The fine-tuning step takes place after the pretraining using code-switching data. In the inference time, we explore the hypothesis using beam search with eight beams and a batch size of 1.

4.4 Evaluation Metrics

We employ the following metrics to measure the performance of our models.

Token-level Perplexity (PPL) For the LM, we calculate the PPL of characters in Mandarin Chinese and words in English. The reason is that some Chinese words inside the SEAME corpus are not well tokenized, and tokenization results are not consistent. Using characters instead of words in Chinese can alleviate word boundary issues. The PPL is calculated by taking the exponential of the sum of losses. To show the effectiveness of our approach in calculating the probability of the switching, we split the perplexity computation into monolingual segments **(en-en)** and **(zh-zh)**, and code-switching segments **(en-zh)** and **(zh-en)**.

Character Error Rate (CER) For our ASR, we compute the overall CER and also show the individual CERs for Mandarin Chinese **(zh)** and English **(en)**. The metric calculates the distance of two sequences as the *Levenshtein Distance*.

5 Results & Discussion

LM In Table 3, we can see the perplexities of the test set evaluated on different training strategies. Pointer-Gen consistently performs better than state-of-the-art models such as *EC* and *SeqGAN*. Comparing the results of models trained using only generated samples, **(2a-2b)** leads to

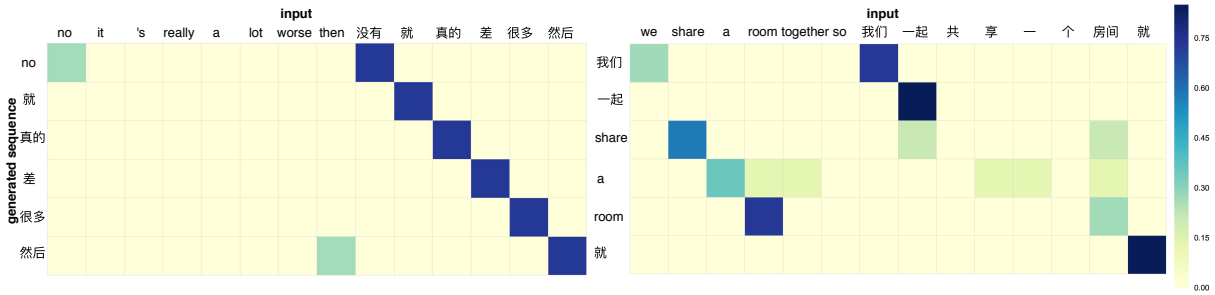

Figure 4: The visualization of pointer-generator attention weights on input words in each time-step during the inference time. The y-axis indicates the generated sequence, and the x-axis indicates the word input. In this figure, we show the code-switching points when our model attends to words in the L_1 and L_2 sentences: **left:** ("no","没有") and ("then","然后"), **right:** ("we","我们"), ("share", "一起") and ("room","房间").

the undesirable results that are also mentioned by Pratapa et al. (2018), but it does not apply to Pointer-Gen (2c). We can achieve a similar results with the model trained using only real code-switching data, rCS. This demonstrates the quality of our data generated using Pointer-Gen. In general, combining any generated samples with real code-switching data improves the language model performance for both code-switching segments and monolingual segments. Applying concatenation is less effective than the two-step training strategy. Moreover, applying the two-step training strategy achieves the state-of-the-art performance.

As shown in Table 2, we generate new n-grams including code-switching phrases. This leads us to a more robust model, trained with both generated data and real code-switching data. We can see clearly that Pointer-Gen-generated samples have a distribution more similar to the real code-switching data compared with *SeqGAN*, which shows the advantage of our proposed method.

Effect of Data Size To understand the importance of data size, we train our model with different amounts of generated data. Figure 3 shows the PPL of the models with different amounts of generated data. An interesting finding is that our model trained with only 78K samples of Pointer-Gen data (same number of samples as rCS) achieves a similar PPL to the model trained with only rCS, while SeqGAN and EC have a significantly higher PPL. We can also see that 10K samples of Pointer-Gen data is as good as 270K samples of EC data. In general, the number of samples is positively correlated with the improvement in performance.

Model	Overall	en	zh
Baseline	34.40%	41.79%	35.94%
+ Pre-training	32.76%	40.06%	32.44%
+ LM (rCS)	32.25%	39.45%	31.90%
+ LM (Pointer-Gen → rCS)	**31.07%**	**38.39%**	**30.85%**

Table 4: ASR evaluation, showing the performance on all sequences (Overall), English segments (en), and Mandarin Chinese segments (zh).

ASR Evaluation We evaluate our proposed sentence generation method on an end-to-end ASR system. Table 4 shows the CER of our ASR systems, as well as the individual CER on each language. Based on the experimental results, pre-training is able to reduce the error rate by 1.64%, as it corrects the spelling mistakes in the prediction. After we add LM (rCS) to the decoding step, the error rate can be reduced to 32.25%. Finally, we replace the LM with LM (Pointer-Gen → rCS), and it further decreases the error rate by 1.18%.

Model Interpretability We can interpret a Pointer-Gen model by extracting its attention matrices and then analyzing the activation scores. We show the visualization of the attention weights in Figure 4. The square in the heatmap corresponds to the attention score of an input word. In each time-step, the attention scores are used to select words to be generated. As we can observe in the figure, in some cases, our model attends to words that are translations of each other, for example, the words ("no","没有"), ("then","然后") , ("we","我们"), ("share", "一起"), and ("room","房间"). This indicates the model can identify code-switching points, word alignments, and translations without being given any explicit information.

rCS		Pointer-Gen		
POS tags	**ratio**	**POS tags**	**ratio**	**examples**
English				
NN (noun)	56.16%	NN (noun)	55.45%	那 个 **consumer** 是 不 (that consumer is not)
RB (adverb)	10.34%	RB (adverb)	10.14%	okay **so** 其 实 (okay so its real)
JJ (adjective)	7.04%	JJ (adjective)	7.16%	我 很 **jealous** 的 每 次 (i am very jealous every time)
VB (verb)	5.88%	VB (verb)	5.89%	**compared** 这 个 (compared to this)
Chinese				
VV (other verbs)	23.77%	VV (other verbs)	23.72%	讲 的 要 用 microsoft word (i want to use microsoft word)
M (measure word)	16.83%	M (measure word)	16.49%	我 们 有 这 个 god of war (we have this god of war)
DEG (associative)	9.12%	DEG (associative)	9.13%	我 们 的 result (our result)
NN (common noun)	9.08%	NN (common noun)	8.93%	我 应 该 不 会 讲 话 because intimidated by another (i shouldn't talk because intimidated by another)

Table 5: The most common English and Mandarin Chinese part-of-speech tags that trigger code-switching. We report the frequency ratio from **Pointer-Gen**-generated sentences compared to the real code-switching data. We also provide an example for each POS tag.

Code-Switching Patterns Table 5 shows the most common English and Mandarin Chinese POS tags that trigger code-switching. The distribution of word triggers in the Pointer-Gen data are similar to the real code-switching data, indicating our model's ability to learn similar code-switching points. Nouns are the most frequent English word triggers. They are used to construct an optimal interaction by using cognate words and to avoid confusion. Also, English adverbs such as "then" and "so" are phrase or sentence connectors between two language phrases for intra-sentential and inter-sentential code-switching. On the other hand, Chinese transitional words such as the measure word "个" or associative word "的" are frequently used as inter-lingual word associations.

6 Related Work

Code-switching language modeling research has been focused on building a model that handles mixed-language sentences and on generating synthetic data to solve the data scarcity issue. The first statistical approach using a linguistic theory was introduced by Li and Fung (2012), who adapted the EC on monolingual sentence pairs during the decoding step of an ASR system. Ying and Fung (2014) implemented a functional-head constraint lattice parser with a weighted finite-state transducer to reduce the search space on a code-switching ASR system. Then, Adel et al. (2013a) extended recurrent neural networks (RNNs) by adding POS information to the input layer and a factorized output layer with a language identifier. The factorized RNNs were also combined with an n-gram backoff model using linear interpolation (Adel et al., 2013b), and syntactic and semantic features were added to them (Adel et al., 2015). Baheti et al. (2017) adapted an effective curriculum learning by training a network with monolingual corpora of two languages, and subsequently trained on code-switched data. A further investigation of EC and curriculum learning showed an improvement in English-Spanish language modeling (Pratapa et al., 2018), and a multi-task learning approach was introduced to train the syntax representation of languages by constraining the language generator (Winata et al., 2018a). Garg et al. (2018) proposed to use SeqGAN (Yu et al., 2017) for generating new mixed-language sequences. Winata et al. (2018b) leveraged character representations to address out-of-vocabulary words in the code-switching named entity recognition. Finally, Winata et al. (2019) proposed a method to represent code-switching sentence using language-agnostic meta-representations.

7 Conclusion

We propose a novel method for generating synthetic code-switching sentences using Pointer-Gen by learning how to copy words from parallel cor-

pora. Our model can learn code-switching points by attending to input words and aligning the parallel words, without requiring any word alignments or constituency parsers. More importantly, it can be effectively used for languages that are syntactically different, such as English and Mandarin Chinese. Our language model trained using outperforms equivalence constraint theory-based models. We also show that the learned language model can be used to improve the performance of an end-to-end automatic speech recognition system.

Abstract

In this paper, we alleviate the local optimality of back-translation by learning a policy (takes the form of an encoder-decoder and is defined by its parameters) with future rewarding under the reinforcement learning framework, which aims to optimize the global word predictions for unsupervised neural machine translation. To this end, we design a novel reward function to characterize high-quality translations from two aspects: n-gram matching and semantic adequacy. The n-gram matching is defined as an alternative for the discrete BLEU metric, and the semantic adequacy is used to measure the adequacy of conveying the meaning of the source sentence to the target. During training, our model strives for earning higher rewards by learning to produce grammatically more accurate and semantically more adequate translations. Besides, a variational inference network (VIN) is proposed to constrain the corresponding sentences in two languages have the same or similar latent semantic code. On the widely used WMT'14 English-French, WMT'16 English-German and NIST Chinese-to-English benchmarks, our models respectively obtain 27.59/27.15, 19.65/23.42 and 22.40 BLEU points without using any labeled data, demonstrating consistent improvements over previous unsupervised NMT models.

1 Introduction

Neural Machine Translation (Sutskever et al., 2014; Bahdanau et al., 2015) directly models the entire translation process through training an encoder-decoder model that has achieved remarkable performance (Wu et al., 2016; Gehring et al., 2017; Vaswani et al., 2017) when provided with massive amounts of parallel corpora. However, the lack of large-scale parallel data is a serious problem for the vast majority of language pairs.

As a result, several works have recently tried to get rid of the dependence on parallel corpora using unsupervised setting, in which the NMT model only has access to two independent monolingual corpora with one for each language (Lample et al., 2018a; Artetxe et al., 2018b; Yang et al., 2018). Among these works, the encoder and decoder act as a standard auto-encoder (AE) that are trained to reconstruct the inputs from their noised versions. Due to the lack of cross-language signals, unsupervised NMT usually requires pseudo parallel data generated with the back-translation method for achieving the final goal of translating between source and target languages.

Back-translation typically uses beam search (Sennrich et al., 2016a) or just greedy search (Lample et al., 2018a,b) to generate synthetic sentences. Both are approximate algorithms to identify the maximum a posteriori (MAP) output, i.e. the sentence with the highest estimated probability given an input. Although back-translation with MAP prediction has been proved to be successful, it suffers from several apparent issues when trained with maximum likelihood estimation (MLE) only, including exposure bias and loss-evaluation mismatch. Thus, this method often fails to produce the optimal synthetic sentences for the subsequent training.

In this paper, we address the problem mentioned above with future rewarding for unsupervised NMT. The basic idea is to model the future direction of a translation and optimize the global word predictions under the policy gradient reinforcement learning framework. More concretely, we sample N translations via the policy for each input sentence and build a new objective function by combining the cross-entropy loss used in prior works with sequence-level rewards from policy gradient reinforcement learning. We consider the sequence-level reward from two aspects: 1) n-

gram matching, which is the precision or recall of all sub-sequences of 1, 2, 3 and 4 tokens in generated sequence and is responsible for measuring the accuracy of surface word predictions; 2) semantic adequacy, which is the similarity between the underlying semantic representations of the generated translation and the input sentence. These two aspects of rewards are inspired by the general criteria of what properties a high-quality translation should have and are complementary to each other. Additionally, a variational inference network (VIN) is proposed to model the underlying semantics of monolingual sentences explicitly. It is used to map the source and target languages into a shared semantic space during auto-encoding, as well as constrain the sentences and their translated counterparts have the same or similar semantic code during cross-language training.

The major contributions of this paper can be summarized as follows:

- We propose a novel learning paradigm for unsupervised NMT that models future rewards to optimize the global word predictions via policy gradient reinforcement learning. To enforce the underlying semantic space, we introduce a VIN into our model.
- We introduce an effective reward function that jointly accounts for the n-gram matching and the semantic adequacy of generated translations.
- We conduct extensive experiments on English-French, English-German and NIST Chinese-to-English translation tasks. Experimental results show that the proposed approach achieves significant improvements across different language pairs.

2 Unsupervised Neural Machine Translation

In this section, we first describe the composition of the introduced model and then give details of the newly proposed unsupervised training method.

2.1 Model Composition

The introduced translation model consists of six components: including two encoders with sharing last few layers, two completely independent decoders with one for each language, and two newly introduced VINs with one for each language. For the encoders and decoders, we follow

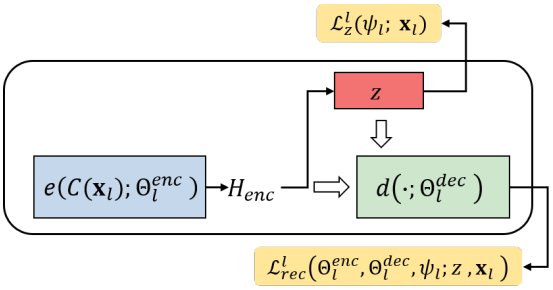

Figure 1: Illustration of Variational Denosing Auto-Encoding. The newly introduced VIN is highlighted in red. Two aspects of losses are respectively abbreviated as $\mathcal{L}_z^l$ and $\mathcal{L}_{rec}^l$.

the recently emerged Transformer (Vaswani et al., 2017). Specifically, each encoder is composed of a stack of four identical layers, and each layer consists of a multi-head self-attention sub-layer and a fully connected feed-forward sub-layer. The encoders of the source and target languages are respectively parameterized as Θ_{src}^{enc} and Θ_{tgt}^{enc}, and the encoding operation is denoted as $e(\mathbf{x}_l; \Theta_l^{enc})$, $\mathbf{x}_l$ is the input sequence of word embeddings, $l \in \{src, tgt\}$. The decoders are also composed of four identical layers. In addition to the two sub-layers in each encoder layer, the decoder inserts a third sub-layer, which performs multi-head attention over the output of the encoder stack, the details we refer the reader to (Vaswani et al., 2017). Similar to encoders, we denote source decoder as Θ_{src}^{dec}, target decoder as Θ_{tgt}^{dec}, and decoding operation as $d(\mathbf{x}_l; \Theta_l^{dec})$, $l \in \{src, tgt\}$. For VINs, each of them is composed of a standard Gaussian distribution $\mathcal{N}(0, \mathbf{1})$ as the *prior*, and a *neural posterior* that is implemented as feed-forward neural network and parameterized by ψ_l, $l \in \{src, tgt\}$.

In this work, the entire model is trained in an unsupervised manner by optimizing two objectives: 1) variational denoising auto-encoding; 2) cross-language training with future rewarding.

2.2 Variational Denoising Auto-Encoding

Firstly, two auto-encoders are respectively trained to learn to reconstruct their inputs. In this form, each encoder should learn to compose the input sentence of its corresponding language, and each decoder is expected to learn to recover the original input sentence from this composition. However, without any constraint, the auto-encoder would make very literal word-by-word copies, without capturing any internal structure of the input sentence involved. To address this issue, prior works

often adapt the same strategy as Denosing Auto-Encoding (DAE) (Vincent et al., 2008), and add some noise to the input sentences (Hill et al., 2016). As shown in Figure 1, we augment the DAE with a variational inference network (VIN) to model underlying semantics of monolingual sentences explicitly, which assumes that there exists a latent variable $\mathbf{z}$ from this semantic space. And this variable, together with the noised input sentence, guides the decoding process. With this assumption, we define the objective function of reconstruction as follow:

$$\mathcal{L}^l_{rec} = \log P_{\Theta_{l\to l}}(\mathbf{x}_l|\mathbf{z}, C(\mathbf{x}_l)) \quad (1)$$

where $\Theta_{l\to l} = \Theta^{enc}_l \circ \Theta^{dec}_l \circ \boldsymbol{\psi}_l$ represents the combination of Θ^{enc}_l, Θ^{dec}_l and $\boldsymbol{\psi}_l$, $l \in \{src, tgt\}$. C denotes a stochastic noise model, in which we apply the same method as in (Lample et al., 2018a).

The continuous latent variable $\mathbf{z}$, acts as the underlying semantics here, is approximated by a *neural posterior* inference network $q_{\boldsymbol{\psi}_l}(\mathbf{z}|\mathbf{x}_l)$. Following (Kingma and Welling, 2014; Kingma et al., 2014), the posterior approximation is regarded as a diagonal Gaussian $\mathcal{N}(\mu, diag(\sigma^2))$, and its mean μ and variance σ^2 are parameterized with deep neural networks. We also reparameterize $\mathbf{z}$ as a function of μ and σ (i.e., $\mathbf{z} = \mu + \sigma \odot \varepsilon$, ε is a standard Gaussian variable that plays a role of introducing noises) rather than using the standard sampling method. We aim to map source and target languages into a shared semantic space and use the following objective function for VINs:

$$\mathcal{L}^l_z = -\mathrm{KL}(q_{\boldsymbol{\psi}_l}(\mathbf{z}|\mathbf{x}_l)||\mathcal{N}(0, \mathbf{1})) \quad (2)$$

where $l \in \{src, tgt\}$. $\mathrm{KL}(Q||P)$ is the Kullback-Leibler divergence between Q and P.

We finally incorporate the auto-encoder and the VIN into an end-to-end neural network, and the overall training objective of auto-encoding is to minimize the following loss function:

$$\mathcal{L}^l_{ae} = -(\mathcal{L}^l_z + \mathcal{L}^l_{rec}) \quad (3)$$

2.3 Cross-language Training with Future Rewarding

In spite of the auto-encoding, the second objective of unsupervised NMT is to constrain the model to be able to map an input sentence from the source (target) language to the target (source) language.

Due to the lack of alignment information between two independent monolingual corpora, the back-translation (Sennrich et al., 2016a) method is used to synthetise a pseudo parallel corpus for cross-language training. More concretely, given an input sentence in one language, which can be firstly translated into the other language (i.e. use the corresponding encoder and the decoder of the other language) by applying the model in inference mode with greedy decoding. And then, the model is trained to reconstruct the original sentence from this translation. The most widely used method in previous works to train the model for sequence generation, called maximum likelihood estimation (MLE for short), it assumes that the ground-truth is provided at each step during training. The objective of MLE is defined as the maximization of the following log-likelihood:

$$\mathcal{L}^{l_1}_{mle} = \log P_{\Theta_{l_2\to l_1}}(\mathbf{x}_{l_1}|\mathbf{z}_p, \tilde{\mathbf{x}}_{l_2}) \quad (4)$$

where $\Theta_{l_2\to l_1} = \Theta^{enc}_{l_2} \circ \Theta^{dec}_{l_1} \circ \boldsymbol{\psi}_{l_2}$ represents the combination of $\Theta^{enc}_{l_2}$, $\Theta^{dec}_{l_1}$ and $\boldsymbol{\psi}_{l_2}$. $\mathbf{z}_p$ is approximated by the introduced VIN (i.e., reparameterized from the Gaussian $q_{\boldsymbol{\psi}_{l_2}}(\mathbf{z}_p|\tilde{\mathbf{x}}_{l_2})$). $\tilde{\mathbf{x}}_{l_2} = d(e(\mathbf{x}_{l_1}; \Theta^{enc}_{l_1}); \Theta^{dec}_{l_2})$ is obtained by greedy decoding in inference mode ($l_1 = src, l_2 = tgt$ or $l_1 = tgt, l_2 = src$).

2.3.1 Future Rewarding

Unfortunately, maximizing $\mathcal{L}^{l_1}_{mle}$ does not always produce the best results on discrete evaluation metrics such as BLEU (Papineni et al., 2002), as the accumulation of errors caused by exposure bias as well as the inconsistency between training and testing measurements lead to the models tend to be short-sighted. We bridge the discrepancy between training and testing modes caused by MLE through learning a policy to model future rewards, which can directly optimize the global word predictions and is made possible with reinforcement learning, as illustrated in Figure 2. To reduce the variance of the model, we use the self-critical policy gradient learning algorithm (Rennie et al., 2017).

For self-critical policy gradient learning, we produce two separate output sequences at each training iteration: $\hat{\mathbf{x}}$, the sampled translation, which is obtained by sampling from the final output probability distribution, and $\hat{\mathbf{x}}^g$, the baseline output, obtained by performing a greedy search. Thus, the objective function of cross-language training can be redefined as the expected advantages of the sampled sequence over the baseline

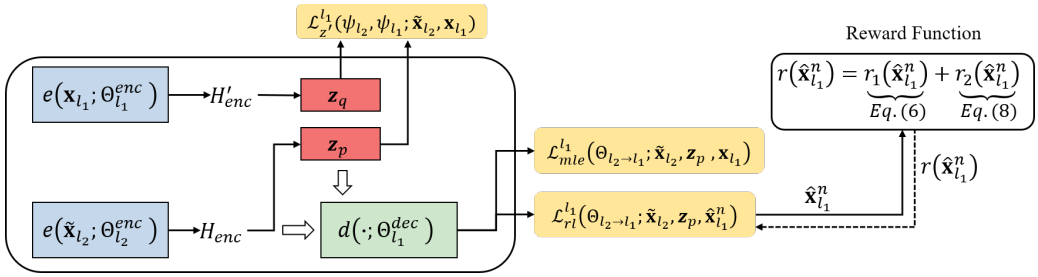

Figure 2: Illustration of the proposed method for cross-language training with future rewarding. Three aspects of losses are respectively abbreviated as $\mathcal{L}^{l_1}_{z'}$, $\mathcal{L}^{l_1}_{mle}$ and $\mathcal{L}^{l_1}_{rl}$. And $\mathcal{L}^{l_1}_{z'}$ is an auxiliary function that constrains the sentences and their translated counterparts in other language have the same or similar semantic codes.

sequence:

$$\begin{aligned}\mathcal{L}^{l_1}_{rl} =& \mathbb{E}_{P_{\Theta_{l_2\to l_1}}(\hat{\mathbf{x}}_{l_1}|\mathbf{z}_p,\tilde{\mathbf{x}}_{l_2})}[r(\hat{\mathbf{x}}_{l_1}) - r(\hat{\mathbf{x}}^g_{l_1})] \\ =& \log P_{\Theta_{l_2\to l_1}}(\hat{\mathbf{x}}_{l_1}|\mathbf{z}_p,\tilde{\mathbf{x}}_{l_2}) \times [r(\hat{\mathbf{x}}_{l_1}) - r(\hat{\mathbf{x}}^g_{l_1})]\end{aligned} \tag{5}$$

where a terminal reward r is observed after the generation reaches the end of each sentence. It is worth noting that considering a baseline reward into training objective can reduce the variance of the model. And we can see that maximizing $\mathcal{L}_{rl}$ is equivalent to maximizing the conditional likelihood of the sampled sequence $\hat{\mathbf{x}}$ if it obtains a higher reward than the baseline $\hat{\mathbf{x}}^g$, thus increasing the expected reward of our model.

2.3.2 Reward

r in Equation 5 denotes the sequence-level reward that evaluates the quality of generated translations. In this subsection, we discuss two major factors that contribute to the success of a translation, that is, n-gram matching and semantic adequacy, and describe how to approximate these factors through computable reward functions.

N-gram matching For a translation generated by a NMT model, we need to measure the accuracy of surface word predictions. For that purpose, the BLEU (Papineni et al., 2002) score is often utilized in previous works. However, the BLEU score has some undesirable properties when used for single sentences, as it was designed to be a corpus measure. Thus, we apply the smoothed version of GLEU (Wu et al., 2016) as the reward for measuring n-gram precision or recall. More concretely, given a generated translation $\hat{\mathbf{x}}_{l_1}$ in one language and the ground-truth reference $\mathbf{x}_{l_1}$, we record all sub-sequences of 1, 2, 3 and 4 tokens in $\hat{\mathbf{x}}_{l_1}$ and $\mathbf{x}_{l_1}$, and start all n-gram counts from 1 instead of 0. Then we compute a recall R_{gleu}, which is the ratio of the number of matching n-grams to the number of total n-grams in $\mathbf{x}_{l_1}$ (ground-truth), and a precision P_{gleu}, which is the ratio of the number of matching n-grams to the number of total n-grams in $\hat{\mathbf{x}}_{l_1}$ (generated output). Finally, the reward of the generated translation $\hat{\mathbf{x}}_{l_1}$ on n-gram matching is defined as:

$$r_1(\hat{\mathbf{x}}_{l_1}) = \min\{R_{gleu}, P_{gleu}\} \tag{6}$$

where r_1 ranges from zero to one and it is symmetrical when switching $\hat{\mathbf{x}}$ and $\mathbf{x}$.

Semantic adequacy We want the model can adequately convey the meaning of the source sentence to the target as much as possible. Thus, we introduce another crucial reward function that is used to measure the semantic adequacy of the generated translations. More concretely, for a generated translation $\hat{\mathbf{x}}_{l_1}$ in one language, we compute the representation of $\hat{\mathbf{x}}_{l_1}$ as:

$$\begin{aligned} e_i &= \text{TFIDF}(w_i), w_i \in \hat{\mathbf{x}}_{l_1} \\ \mathbf{w}_i &= e_i / \text{Sum}(e_1, e_2, ..., e_{T_{\hat{\mathbf{x}}_{l_1}}}) \\ c_{\hat{\mathbf{x}}_{l_1}} &= \sum_{i=1}^{T_{\hat{\mathbf{x}}_{l_1}}} \mathbf{w}_i \hat{\mathbf{x}}^i_{l_1} \end{aligned} \tag{7}$$

Identically, for the corresponding input sentence in another language, its representation $c_{\tilde{\mathbf{x}}_{l_2}}$ can be extracted from the embedding matrix $\tilde{\mathbf{x}}_{l_2}$. As the source and target word embeddings are often mapped to a shared-latent space in unsupervised NMT, we therefore can directly use the following cosine similarity as the reward for semantic adequacy:

$$r_2(\hat{\mathbf{x}}_{l_1}) = \frac{(c_{\hat{\mathbf{x}}_{l_1}}, c_{\tilde{\mathbf{x}}_{l_2}})}{\|c_{\hat{\mathbf{x}}_{l_1}}\| \cdot \|c_{\tilde{\mathbf{x}}_{l_2}}\|} \tag{8}$$

where $(,)$ indicates the dot product operation.

The final reward for a translation $\hat{\mathbf{x}}_{l_1}$ is a linear combination of the rewards discussed above:

$$r(\hat{\mathbf{x}}_{l_1}) = r_1(\hat{\mathbf{x}}_{l_1}) + r_2(\hat{\mathbf{x}}_{l_1}) \quad (9)$$

where $r_1(\hat{\mathbf{x}}_{l_1})$ and $r_2(\hat{\mathbf{x}}_{l_1})$ complement to each other and work jointly to guide the learning of our model. Note that the combination of these two aspects of rewards helps because it can prevent the cases that the generated translation with high n-gram matching but low semantic adequacy to have relatively high rewards, and vice versa.

2.3.3 Overall Objective Function

In addition to the aforementioned MLE objective function (Eq. 4) and the RL objective function (Eq. 5), there is an auxiliary function that constrains the sentences and their translated counterparts have the same or similar semantic code and is defined as:

$$\mathcal{L}_{z'}^{l_1} = -\mathrm{KL}(q_{\psi_{l_1}}(\mathbf{z}_q|\mathbf{x}_{l_1})||q_{\psi_{l_2}}(\mathbf{z}_p|\tilde{\mathbf{x}}_{l_2})) \quad (10)$$

Finally, the overall training objective of cross-language training is to minimize the following loss function with hyperparameters η:

$$\mathcal{L}_{cl}^{l_1} = -((1-\eta)(\mathcal{L}_{mle}^{l_1} + \mathcal{L}_{z'}^{l_1}) + \eta\mathcal{L}_{rl}^{l_1}) \quad (11)$$

where η is a scaling factor. In the beginning of the training $\eta = 0$, while as we move on with the training we can increase the η to slowly reduce the effect of MLE loss. And η is updated as follows:

$$\eta = \min(0.8, \max(0.0, \frac{steps - n_s}{n_e - n_s})) \quad (12)$$

where $steps$ is the global steps that the model has been updated, n_s and n_e are the start and end steps for increasing η respectively.

2.4 Training Procedure

There are two stages in the proposed unsupervised training. In the first stage, we pre-train the proposed model with denoising auto-encoding and cross-language training, until no improvement is achieved on the development set. This ensures that the model starts with a much better policy than random because now the model can focus on the good part of the search space. In the second state, we use an annealing schedule to teach the model to produce stable sequences gradually. That is, after the initial pre-training steps, we continue training the model with future rewarding. During each iteration, we perform one batch of denoising auto-encoding and cross-language training for the source as well as target languages alternately.

For model selection, we randomly extract 3000 source and target sentences to form a development set. Following (Lample et al., 2018a), we translate the source sentences to the target language and then convert the resulting sentences back to the source language. The quality of the model is then evaluated by computing the BLEU score over the original inputs and their reconstructions via this two-step translation process. The performance is finally averaged over two directions, and the selected model is the one with the highest score.

3 Experiments

We mainly evaluate the proposed approach on the widely used English-German, English-French and NIST Chinese-to-English[1] translation tasks.

3.1 Datasets

For English-French and English-German, we use 30M sentences from the WMT monolingual News Crawl datasets from years 2007 through 2017. We use the publicly available implementation of Moses[2] scripts for tokenization. Besides, we use a shared vocabulary for source and target languages with 60K subword tokens based on byte-pair encoding (Sennrich et al., 2016b). We remove sentences longer than 50 subword-tokens. Experimental results are reported on *newstest2014* for English-French translation and *newstest2016* for English-German translation. We adopt the same method as in (Lample et al., 2018b) to obtain cross-lingual embeddings.

For NIST Chinese-to-English translation, our training data consists of 1.6M sentence pairs randomly extracted from LDC corpora[3], which has been widely utilized by previous works. Similar to (Yang et al., 2018), we build the monolingual dataset by randomly shuffling the Chinese and English sentences respectively since the data set is not big enough. We set the vocabulary size to 30K for both Chinese and English. The average BLEU score over *NIST02∼06* is reported

[1]The reason that we do not conduct experiments on English-to-Chinese translation is that we do not get public test sets for English-to-Chinese.

Table 1: Results of the proposed method in comparison to existing unsupervised NMT systems (BLEU).

in this paper. To pre-train cross-lingual embeddings, we utilize the monolingual corpora to train the embeddings for each language independently by using word2vec (Mikolov et al., 2013). Then we apply the public implementation[4] proposed by Artetxe et al. (2017) to map these embeddings into a shared latent space and keep the mapped embeddings fixed during training.

For NIST Chinese-to-English, we apply case-insensitive NIST BLEU computed by the script *mteval-v13a.pl* to evaluate the translation performance. For English-German and English-French, we evaluate the translation performance with the script *multi-belu.pl*.

3.2 Hyper-parameters

We set the following hyper-parameters: word embedding dimension as 512, hidden size of self-attention as 512, hidden size of fully connected layers as 1024 and the head number as 8. We share the last one layer of encoders in both languages. The dropout rate is set as 0.1, 0.3 and 0.2 during the training for En-Fr, En-De and Zh-to-En, respectively. We perform a fixed number of iterations (500K) to train each model, and set $n_s = 300$K, $n_e = 400$K, for gradually increasing the effect of future rewarding. We use the Adam optimizer with a simple learning rate schedule: we start with a learning rate of 10^{-4}, after 300K updates, we begin to halve the learning rate every 100K steps. We set the mini-batch size as 64. At decoding time, we use greedy search.

3.3 Overall Results

Our method is compared with several previous unsupervised NMT systems (Artetxe et al., 2018b; Lample et al., 2018a,b; Yang et al., 2018; Wu et al., 2019; Song et al., 2019). Although, Song et al. (2019) have achieved comparable results with supervised NMT systems with larger monolingual data (Wikipedia data) and bigger model[5], we still list the results that obtained with the same data and model as ours for fair comparison. We also consider a "Baseline" model, with the same architecture as described in Section 2.1 except for the variational inference network and is trained using MLE only. We directly copy the experimental results of previous models reported in their papers and report the BLEU scores on English-French, English-German and NIST Chinese-to-English test sets in Table 1.

As shown in Table 1, our approach achieves BLEU score of 27.59 and 27.15 on En→Fr and Fr→En translations respectively, which outperforms Lample et al. (2018b) by more than 2 BLEU points on both En→Fr and Fr→En. For the En-De, we achieve 19.65 and 23.42 BLEU scores on En→De and De→En respectively, with up to +10.09 BLEU points improvement over previous unsupervised NMT models. For the Chinese-to-English translation, the proposed method leads to a substantial improvement (up to 54%) over the previous system showed in Yang et al. (2018). Compared to baseline, our approach demonstrates significant improvements by more than 2 BLEU points over three benchmarks. These results indicate that the newly proposed training method that models future rewards to optimize global word predictions for unsupervised NMT is promising and enables the model to generate quality translations.

[4]https://github.com/artetxem/vecmap

[5]Our model can also adopt such an advanced pre-training technique, we leave this for feature work.

3.4 Analysis

In this section, we conduct some analysis over the proposed method by taking English-French translation as an example.

3.4.1 Ablation Study

To understand the importance of different components of the proposed system, we perform an ablation study by training multiple versions of our model with some missing components: the variational inference network and the future rewarding method. Results are reported in Table 2. From the table, we can see that removing the future rewarding, and the accuracy drops by 0.98/1.02 BLEU points. Without the variational inference networks, the accuracy decreases with 0.62/0.69 BLEU points. These findings demonstrate that both the future rewarding and the VIN are important, and both contribute to the improvement of translation accuracy. The more critical component is the future rewarding technology, which is vital to optimize the global word predictions.

Without VINs	26.97	26.46
Without Future Rewarding	26.61	26.13

Table 2: Ablation study of our method on English-French translation task.

3.4.2 Qualitative Comparison of Back-translating

We perform qualitative evaluation on the pseudo parallel data generated with the back-translation method. To this end, we conduct a "round-trip" translation (e.g., $src \rightarrow \tilde{tgt} \rightarrow \hat{src}$), where src and $\tilde{tgt}$ form a pseudo parallel corpus, $\hat{src}$ is the reconstruction from $\tilde{tgt}$. We explore three settings for qualitative evaluation: 1) *UNKs*, the ratio of the number of unknown words to the number of total words in $\tilde{tgt}$; 2) the average over all sentences in $\tilde{tgt}$ with respect of their semantic adequacy, denoted as *SA*; 3) the BLEU scores over the original inputs and their reconstructions, denoted as *r-BLEU*. All settings are finally averaged over two directions.

Results are shown in Table 3. The proposed training method introduces significant boosts in all of the three settings, with reducing 1.34% of unknown words, increasing the semantic adequacy by 0.088 and improving r-BLEU points by 5.85. This is in line with our expectations, as the proposed future rewarding method is not optimized to predict the next token, but rather to increase long-term reward.

	UNKs	SA	r-BLEU
Baseline	3.51%	0.794	54.23
+Future Rewarding	2.17%	0.882	60.08

Table 4: Translation examples from English-French test set (English-to-French is above the dotted line and French-to-English is below the dotted line). **B**: the baseline model; **O**: our proposed model.

3.4.3 Example Translations

Table 4 shows four example translations. The first part shows examples for which the proposed model reached a higher BLEU score than the baseline model. We find that the translation produced

by the baseline model doesn't adequately convey the meaning of the source sentence to the target. By contrast, the proposed future rewarding method enables the model to generate translations that are more diversity while ensuring the meaning of the source sentences, such as "***circonstance***" and "***come to light***". The possible reason is that we apply the semantic adequacy to reward translations that have different syntax structures and expressions but share the same meaning as the ground-truth sentence. The second part contains examples where the baseline achieved better BLEU score than our model, that is, in a few cases, our model chooses inappropriate words that under the same topic as reference words.

4 Related Work

In order to reduce the exposure bias and optimize the metrics used to evaluate sequence modeling tasks (like BLEU, ROUGE or METEOR) directly, reinforcement learning (RL) has been widely used in many of recent works on machine translation (Ranzato et al., 2016; Shen et al., 2016; He et al., 2017; Bahdanau et al., 2017; Li et al., 2017), text summarization (Paulus et al., 2018; Wu and Hu, 2018; Li et al., 2018; Wang et al., 2018), dialogue generation (Li et al., 2016), and question answering (Hu et al., 2018). However, our proposed method is the first use in combination with reinforcement learning for unsupervised NMT to explicitly enhance back-translation.

Recently, motivated by the success of cross-lingual embeddings (Artetxe et al., 2016; Zhang et al., 2017; Conneau et al., 2017), several works have tried to train NMT or SMT models using unsupervised setting, in which the model only has access to unlabeled data. For example, Lample et al. (2018a) propose a model that consists of a single encoder and a single decoder for both languages, respectively responsible for encoding source and target sentences to a shared latent space and to decode from that latent space to the source or target domain. Different from (Lample et al., 2018a), Artetxe et al. (2018b) introduce a shared encoder but two independent decoders with one for each language. Both of these two works mentioned above utilize denoising auto-encoding to reconstruct their noisy inputs and incorporate back-translation into cross-language training procedure. Further, Yang et al. (2018) extend the single encoder by using two independent encoders but sharing some partial weights, which are responsible for alleviating the weakness in keeping language-specific characteristics of the shared encoder. And the entire system is fine-tuned by introducing two global GANs with one for each language. More recently, Artetxe et al. (2018a) and Lample et al. (2018b) propose an alternative approach based on phrase-based statistical machine translation, which profits from the modular architecture of SMT. In addition, Lample et al. (2018b) also introduce a novel cross-lingual embedding training method which is particularly suitable for related languages (e.g., English-French and English-German). Ren et al. (2019) introduce SMT models as posterior regularization, in which SMT and NMT models boost each other through iterative back-translation in a unified EM training algorithm. Wu et al. (2019) propose an alternative for back-translation, , extract-edit, to extract and then edit real sentences from the target monolingual corpora. Lample and Conneau (2019) and Song et al. (2019) propose to pretrain cross-lingual language models for the initialization stage of unsupervised neural machine translation, which is critical to the performance of their proposed model. In contrast to theirs, we propose an effective training method for unsupervised NMT that models future rewards to optimize the global word predictions via neural policy reinforcement learning, which can be applied to arbitrary architectures and language pairs easily.

5 Conclusion

In this paper, we have proposed a novel learning paradigm for unsupervised NMT that models future rewards to optimize the global word predictions via reinforcement learning, in which we design an effective reward function that jointly accounts for the n-gram matching and the semantic adequacy of generated translations. To constrain the corresponding sentences in two languages have the same or similar semantic code, we also introduce a variational inference network into the proposed model.

We test the proposed model on WMT'14 English-French, WMT'16 English-German and NIST Chinese-to-English translation tasks. Experiment results show that our approach leads to significant improvements over various language pairs, especially on distantly-related languages such as Chinese and English.

Automatically Extracting Challenge Sets for Non-local Phenomena in Neural Machine Translation

Abstract

We show that the state-of-the-art Transformer MT model is not biased towards monotonic reordering (unlike previous recurrent neural network models), but that nevertheless, long-distance dependencies remain a challenge for the model. Since most dependencies are short-distance, common evaluation metrics will be little influenced by how well systems perform on them. We therefore propose an automatic approach for extracting challenge sets replete with long-distance dependencies, and argue that evaluation using this methodology provides a complementary perspective on system performance. To support our claim, we compile challenge sets for English-German and German-English, which are much larger than any previously released challenge set for MT. The extracted sets are large enough to allow reliable automatic evaluation, which makes the proposed approach a scalable and practical solution for evaluating MT performance on the long-tail of syntactic phenomena.[1]

1 Introduction

The assumption that proximate source words are more likely to correspond to proximate target words has often been introduced as a bias (henceforth, *locality bias*) into statistical MT systems (Brown et al., 1993; Koehn et al., 2003; Chiang, 2005). While reordering phenomena, abundant for some language pairs, violate this simplifying assumption, it has often proved to be a useful inductive bias in practice, especially when complemented with targeted techniques for addressing non-monotonic translation (e.g., Och, 2002; Chiang, 2005). For example, if an adjective precedes a noun in one language and modifies it syntactically, it is likely that their corresponding words will appear close to each other in the translation — i.e., they may not be immediately adjacent or even in the same order in the translation, but it is unlikely that they will be arbitrarily distant from one another.

In the era of Neural Machine Translation (NMT), such biases are implicitly introduced by the sequential nature of the LSTM architecture (Bahdanau et al., 2015, see §2). The influential Transformer model (Vaswani et al., 2017) replaces the sequential LSTMs with self-attention, which does not seem to possess this bias. We show that the default implementation of the Transformer does retain some bias, but that it can be relieved by using learned positional embeddings (§3).

Long-distance dependencies (LDD) between words and phrases present a long-standing problem for MT (Sennrich, 2016), as they are generally more difficult to detect (indeed, they pose an ongoing challenge for parsing as well (Xu et al., 2009)), and often result in non-monotonic translation if the target differs from the source in terms of its word order and lexicalization patterns. The Transformer's indifference to the absolute position of the tokens raises the question of whether long-distance dependencies are still an open problem.

We address this question by proposing an automatic method to compile challenge sets for evaluating system performance on LDD (§4). We distinguish between two main LDD types: (1) reordering LDD, namely cases where source and target words largely correspond to one another but are ordered differently; (2) lexical LDD, where the way a word or a contiguous expression on the target side is translated is dependent on non-adjacent words on the source side.

We define a methodology for extracting both LDD types. For reordering LDD, we build on Birch (2011), whereas for lexical LDD we compile a list of linguistic phenomena that yield LDD,

[1]Our extracted challenge sets and codebase are found in https://github.com/borgr/auto_challenge_sets.

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 291–303
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

and use a dependency parser to find instances of these phenomena in the source side of a parallel corpus. As a test case, we apply this method to construct challenge sets (§4.2) for German-English and English-German. The approach can be easily scaled to other languages for which a good enough parser exists.

Experimenting both with RNN and self-attention NMT architectures, we find that although the latter presents no locality bias, LDD remain challenging. Moreover, lexical LDD become increasingly challenging with their distance, suggesting that syntactic distance remains an important determinant of performance in state-of-the-art (SoTA) NMT.

We conclude that evaluating LDD using targeted challenge sets gives a detailed picture of MT performance, and underscores challenges the field has yet to fully address. As particular types of LDD are not frequent enough to significantly affect coarse-grained measures, such as BLEU (Papineni et al., 2002) or TER (Snover et al., 2006), our evaluation approach provides a complementary perspective on system performance.

2 Related Work

2.1 Long-distance Dependencies in MT

A common architecture for text-to-text generation tasks is the (Bi)LSTM encoder-decoder (Bahdanau et al., 2015). This architecture consists of several LSTM layers for the encoder and the decoder and a thin attention layer connecting them. LSTM is a recurrent network with a state vector it updates. At every step, it discards some of the current and past information and aggregates the rest into the state. Any information about the past comes from this state, which is a learned "summary" of the previous states (cf. Greff et al., 2017). Hence, for information to reach a certain prediction step, it should be stored and then kept throughout the intermediate steps (tokens). While theoretically information could be kept indefinitely (Hochreiter and Schmidhuber, 1997), practical evidence shows that LSTMs performance decreases with the distance between the trigger and the prediction (Linzen et al., 2016; Liu et al., 2018), and that they have difficulties generalizing over sequence lengths (Suzgun et al., 2018).

Despite being affected by absolute distances between syntactically dependent tokens (Linzen et al., 2016), LSTMs tend to learn to a certain extent structural information even without being instructed to do so explicitly (Gulordava et al., 2018). Futrell and Levy (2018) discuss similar linguistic phenomena to what we discuss in §4.2, and show that LSTM encoder-decoder systems handle them better than previous N-gram based systems, despite being profoundly affected by distance.

Transformer (Vaswani et al., 2017) models are also encoder-decoder, but instead of LSTMs, they use self-attention. Self-attention is based on gating all outputs of the previous layer as inputs for the current one; put differently, it aggregates all the input in one step. This approach makes information from all parts of the input sequence equally reachable. While this is not the only architecture with such attributes (van den Oord et al., 2016), we focus on it due to its SoTA results for MT (Lakew et al., 2018). The Transformer's use of self-attention inspired other works in related fields (Devlin et al., 2018), some of which attributed their performance gains to the model's ability to capture long-range context (Müller et al., 2018).

As the Transformer does not aggregate input sequentially, token positions must be represented through other means. For that purpose, the embedding of each input token W is concatenated with an embedding of its position in the source sentence P. While positional embeddings can generally be any vectors, two implementations are commonly used (Tebbifakhr et al., 2018; Guo et al., 2018): learned positional embeddings (learnedPEs; P is randomly initialized), and sine positional embeddings (SinePEs) defined as:

$$P_{(pos,2i)} = sin(pos/10,000^{2i/dim})$$
$$P_{(pos,2i+1)} = cos(pos/10,000^{2i/dim})$$

where dim is the dimension of the embedding. Vaswani et al. (2017) report that they see no benefit in learnedPEs, and hence use SinePEs, which have much fewer parameters.

Most of the dependencies between words are short. Short-distance linguistic dependencies include some of the most common phenomena in language, such as determination, modification by an adjective and compounding. For example, 62% of the dependencies in the standard UD EWT training set (Silveira et al., 2014) are between tokens that are up to one word apart. It stands to reason that the locality bias is useful in these cases. Nevertheless, as system quality improves, rarer, more challenging dependencies become a priority,

and languages present a countless number of long-distance reordering phenomena (Deng and Xue, 2017). One example is subject-verb agreement, where a correct translation requires that the verb is inflected according to the headword of the subject (e.g., in English "dogs that ..., bark", while "a dog that ..., barks"). When translating such cases, a locality bias may impede performance, by biasing the model not to attend to both the subject's head and the main verb (which may be arbitrarily distant), thereby disallowing it to correctly inflect the main verb.

Due to the benefits of the locality bias, it featured prominently in statistical MT, including in the IBM models, where alignments are constrained not to cross too much (Brown et al., 1993), and in predicting probabilities of reorderings (Koehn et al., 2003; Chiang, 2005). Difficulties in handling LDD have motivated the development of syntax-based MT (Yamada and Knight, 2001), that can effectively represent reordering at the phrase level, such as when translating between VSO and SOV languages. However, syntax-based MT models remain limited in their ability to map between arbitrarily different word orders (Sun et al., 2009; Xiong et al., 2012). For example, reorderings that violate the assumption that the trees form contiguous phrases would be difficult for most such models to capture. In the next section (§3) we show that the Transformer, when implemented with learnedPEs, presents no locality bias, and hence can, in principle, learn dependencies between any two positions of the source, and use them at any step during decoding.

2.2 MT Evaluation

With major improvements in system performance, crude assessments of performance are becoming less satisfying, i.e., evaluation metrics do not give an indication on the performance of MT systems on important challenges for the field (Isabelle and Kuhn, 2018). String-similarity metrics against a reference are known to be partial and coarse-grained aspects of the task (Callison-Burch et al., 2006), but are still the common practice in various text generation tasks. However, their opaqueness and difficulty to interpret have led to efforts to improve evaluation measures so that they will better reflect the requirements of the task (Anderson et al., 2016; Sulem et al., 2018; Choshen and Abend, 2018b), and to increased interest in defining more interpretable and telling measures (Lo and Wu, 2011; Hodosh et al., 2013; Birch et al., 2016; Choshen and Abend, 2018a).

A promising path forward is complementing string-similarity evaluation with linguistically meaningful challenge sets. Such sets have the advantage of being interpretable: they test for specific phenomena that are important for humans and are crucial for language understanding. Interpretability also means that evaluation artefacts are more likely to be detected earlier. So far, such challenge sets were constructed for French-English (Isabelle et al., 2017; Isabelle and Kuhn, 2018) and English-Swedish (Ahrenberg, 2018) [2]. Previous challenge sets were compiled by manually searching corpora for specific phenomena of interest (e.g., yes-no questions which are formulated differently in English and French). These corpora are carefully made but are small in size (ten examples per phenomenon), which means that evaluation must be done manually as well.

As our methodology extracts sentences automatically based on parser output, we are able to compile much larger challenge sets, which allows us to apply standard MT measures to each subcorpus corresponding to a specific phenomenon. The methodology is, therefore, more flexible, and can be straightforwardly adapted to accommodate future advances in MT evaluation.

3 Locality in SoTA NMT

In this section we show that encoder-decoder models based on BiLSTM with attention (see §2), do exhibit a locality bias, but that the Transformer, whose encoder is based on self-attention, and in which token position is encoded only through learnedPEs, does not present any such bias.

3.1 Methodology

In order to test whether an NMT system presents a locality bias in a controlled environment, we examine a setting of arbitrary absolute order of the source-side tokens. In this case, systems that are predisposed towards monotonic decoding are likely to present lower performance, while systems that have no predisposition as to the order of the target side tokens relative to the source-side tokens are not expected to show any change in per-

[2] In WMT 2019 English-German phenomena were tested with a new corpus, using both human and automatic evaluation. It is not possible, however, to use this evaluation outside the competition (Avramidis et al., 2019).

formance. In order to create a controlled setting, where source-side token order is arbitrary, we extract fixed length sentences, and apply the same permutation to all of them. We then train systems with the permuted source-side data (and the same target-side data), and compare results to a control condition where no permutation is applied.

Concretely, we experiment on a German-English setting, extracting all sentences of the most common length (18) from the WMT2015 (Bojar et al., 2015) training data. This results in 130,983 sentences, of which we hold out 1,000 sentences for testing. It is comparable in training set size to a low-resource language setting.

We set a fixed permutation $\sigma : [18] \rightarrow [18]$ and train systems on three versions of the training data (settings): (1) REGULAR, to be used for control; (2) PERMUTED source-side, in which we apply σ over all source-side tokens; (3) PERPOSEMB where the positional embeddings of the source-side tokens are permuted;[3] and (4) REVERSED, where tokens are input in a reverse order.

We apply the following permutation, σ, to the source-side tokens:

$$\begin{pmatrix} 0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 & 13 & 14 & 15 & 16 & 17 \\ 11 & 5 & 9 & 15 & 8 & 14 & 10 & 1 & 3 & 16 & 12 & 2 & 0 & 6 & 17 & 4 & 13 & 7 \end{pmatrix}$$

We did not find any property that would deem this permutation special (examining, e.g., its decomposition into cycles). We therefore assume that similar results will hold for other σs as well.

We train a Transformer model, optimizing using Adam (Kingma and Ba, 2015). We set the embedding size to 512, dropout rate of 0.1, 6 stack layers in both the encoder and the decoder and 8 attention heads. We use tokenization, truecasing and BPE (Sennrich et al., 2016) as preprocessing, following the same protocol as (Yang et al., 2018).

We experiment both with learnedPEs, and with SinePEs. We train the BiLSTM model using the Nematus implementation (Sennrich et al., 2017b), and use their supplied scripts for preprocessing, training and testing, changing only the datasets used. For all models, we report the highest BLEU score on the test data for any epoch during training, and perform early stopping after 10 consecutive epochs without improvement.

In the Transformer with learnedPEs, 5 repetitions were done in the REGULAR setting, and 5 for the other settings: 5 repetitions for PERMUTED, 1 for PERPOSEMB and 1 for REVERSED. In addition, we trained the BiLSTM model and the Transformer with SinePEs both in the REGULAR condition and in PERMUTED, each was trained once.

[3] Formally, if the source sentence is $(t_1, ..., t_{18})$, then the input to the Transformer is $\left(\left[W(t_1); P(t_{\sigma(1)})\right], ..., \left[W(t_{18}); P(t_{\sigma(18)})\right]\right)$.

Model	Positional	Setting	BLEU
Transformer	LearntPE	REGULAR	24.81
	LearntPE	PERMUTED	24.87 (+0.06)
	LearntPE	REVERSE	24.84 (+0.03)
	LearntPE	PERPOSEMB	24.82 (+0.01)
Transformer	SinePEs	REGULAR	25.08
	SinePEs	PERMUTED	23.90 (-1.18)
Nematus		REGULAR	22.32
		PERMUTED	19.67 (-2.65)

Table 1: BLEU score for various Transformer settings on regular and permuted data. In brackets are the differences from REGULAR. Nematus and Transformer using SinePEs show decreased performance when permuting the input. Transformer with learnedPEs does not. Rows correspond to the different models used (Model), which positional embeddings are fed to the Transformer (Positional), and the order of the input tokens (Setting; see text).

3.2 Results

Table 1 presents our results. We find that Nematus BiLSTM suffers substantially from permuting the source-side tokens, but that the Transformer does not exhibit a locality bias. Indeed, for learnedPEs in all settings (REGULAR, PERMUTED, REVERSED and PERPOSEMB), BLEU scores are essentially the same. We also find that the common practice of using fixed SinePEs does introduce some bias, as attested by the small performance drop between REGULAR and PERMUTED. Like Vaswani et al. (2017), we find that in the REGULAR settings, learnedPEs are not superior in performance to SinePEs, despite having more expressive power. However, our results suggest that the decision between learnedPEs and SinePEs is not without consequences: learnedPEs are preferable if a locality bias is undesired (this is potentially the case for highly divergent language pairs).

3.3 Discussion

Finding that Transformers do not present a locality bias has implications on how to construct their input in MT settings, as well as in other tasks that use self-attention encoders, such as image captioning (You et al., 2016). It is common practice to augment the source-side with globally-applicable

information, e.g., the target language in multilingual MT (Johnson et al., 2017). Having no locality bias implies this additional information can be added at any fixed point in the sequence fed to a Transformer, provided that the positional embeddings do not themselves introduce such a bias. This is not the case with BiLSTMs, which often require introducing the same information at each input token to allow them to be effectively used by the system (Yao et al., 2017; Rennie et al., 2017).

4 LDD Challenge Sets

One of the stated motivations of the Transformer model is to effectively tackle long-distance dependencies, which are "a key challenge in many sequence transduction tasks" (Vaswani et al., 2017). Our results from the previous section show that indeed fixed reordering patterns are completely transparent for Transformers. This, however, still leaves the question of how Transformers handle linguistic reordering patterns, which may involve varying distances between dependent tokens.

4.1 Methodology

We propose a method for scalably compiling challenge sets to support fine-grained MT evaluation for different types of LDD. We address two main types:

Reordering LDD are cases where the words on the two sides of the parallel corpus largely correspond to one another, but are ordered differently. These cases may require attending to source words in a highly non-monotonic order, but the generation of each target word is localized to a specific region in the source sentence. For example, in English-German, the verb in a subordinated clause appears in a final position, while the verb in the English source appears right after the subject. Consider "The man that is sitting on the chair", and the corresponding German "Der Mann, der auf dem Stuhl sitzt" (lit. *the man, that on the chair sits*) — while the verb is placed at different clause positions in the two cases, the words mostly have direct correspondents. Our methodology follows Birch (2011) in detecting such phenomena based on alignment. Concretely, we extract a word alignment between corresponding sentences, and collect all sentences that include a pair of aligned words in the source and target sides, whose indices have a difference of at least $d \in \mathbb{N}$.

Lexical LDD are cases where the translation of a single word or phrase is determined by non-adjacent words on the source side. This requires attending to two or more regions that can be arbitrarily distant from one another. Several phenomena, such as light verbs (Isabelle and Kuhn, 2018), are known from the linguistic and MT literature to yield lexical LDD. Our methodology takes a predefined set of such phenomena, and defines rules for detecting each of them over dependency parses of the source-side. See §4.2 for the list of phenomena we experiment on in this paper.

Focusing on LDD, we restrict ourselves to instances where the absolute distance between the word and the dependent is at least $d \in \mathbb{N}$. Selecting large enough d entails that the extracted phenomena are unlikely to be memorized as a phrase with a specific meaning (e.g., encode "*make* the whole thing *up*" [$d = 3$] as a phrase, rather than as a discontiguous phrase "make ... up" with an argument "the whole thing"). This increases the probability that such cases, if translated correctly, reflect the MT systems' ability to recognize that such discontiguous units are likely to be translated as a single piece.

We note, that by extracting the challenge set based on syntactic parses, we by no means assume these representations are internally represented by the MT systems in any way, or assume such a representation is required for succeeding in correctly translating such constructions. The extraction method is merely a way of finding phenomena we have a reason to believe are difficult to translate, and meaningful for language understanding. We use Universal Dependencies (UD; Nivre et al., 2016) as a syntactic representation, due to its cross-lingual consistency (about 90 languages are supported so far), which allows research on difficult LDD phenomena that recur across languages.

Our extraction methods resemble previous challenge set approaches (Isabelle et al., 2017; Isabelle and Kuhn, 2018; Ahrenberg, 2018), in using linguistically motivated sets of sentence pairs to assess translation quality. However, as our extraction method is fully automatic, it allows for the compilation of much larger challenge sets over many language pairs. The challenge sets we extract contain hundreds or thousands of pairs (§4.2). The size of the sets allows using any MT evaluation measures to measure performance, and is thus a much more scalable solution than manual inspection, as

is commonly done in challenge set approaches.

On the other hand, an automatic methodology has the side-effect of being noisier, and not necessarily selecting the most representative sentences for each phenomenon. For instance *befinden sich* (lit. *to determine*) includes a verb and a reflexive pronoun, which do not necessarily appear contiguously in German. However, as *befinden* always appears with the reflexive *sich*, it might not pose a challenge to NMT systems, which can essentially ignore the reflexive pronoun upon translation.

4.2 A Test Case on Extracting Sets

Next, we discuss the compilation of German-English and English-German corpora. We select these pairs, as they are among the most studied in MT, and comparatively high results are obtained for them (Bojar et al., 2017). Hence, they are more likely to benefit from a fine-grained analysis.

For the reordering LDD corpus, we align each source and target sentences using FastAlign (Dyer et al., 2013) and collect all sentences with at least one pair of source-side and target-side tokens, whose indices have a difference of at least $d = 5$. For example:

> **Source:** *Wäre es ein großer Misserfolg, nicht den Titel in der Ligue 1 zu gewinnen, wie dies in der letzten Saison der Fall war?*
> **Gloss:** *Would-be it a big failure, not the title in the Ligue 1 to win, as this in the last season the case was?*
> **Target:** *In Ligue 1, would not winning the title, like last season, be a big failure?*

We extract lexical LDD using simple rules over source-side parse trees, parsed with UDPipe (Straka and Straková, 2017). For a sentence to be selected, at least one word should separate the detected pair of words. We picked several well-known challenging constructions for translation that involve discontiguous phrases: reflexive-verb, verb-particle constructions and preposition stranding. We note that while these constructions often yield lexical LDDs, and are thus expected to be challenging on average, some of their instances can be translated literally (e.g., *amuse oneself* is translated to *amüsieren sich*).

Reflexive Verbs. Prototypically, reflexivity is the case where the subject and object corefer. Reflexive pronouns in English end with *self* or *selves* (e.g., yourselves) and in German include *sich*, *dich*, *mich* and *uns* among others. However, reflexive pronouns can often change the meaning of a verb unpredictably, and may thus lead to different translations for non-reflexive instances of a verb, compared to reflexive ones. For example, *abheben* in German means taking off (as of a plane), but *sich abheben* means standing out. Similarly, in the example below, *drängte sich* translates to *intrude*, while *drängte* normally translates to *pushed*.

A source sentence is said to include a reflexive verb if one of its tokens is parsed with a reflexive morphological feature (`refl=yes`).
For example:

> **Source:** *[...] es ertragen zu müssen, daß eine unsympathische Fremde* ***sich*** *unaufhörlich in ihren Familienkreis* ***drängte****.*
> **Target:** *[...] to see an uncongenial alien permanently* ***intruded*** *on her own family group.*

Phrasal Verbs are verbs that are made up of a verb and a particle (or several particles), which may change the meaning of the verb unpredictably. Examples of English phrasal verbs include *run into* (in the sense of *meet*) and *give in*, and in German they include examples such as *einladen* (*invite*), consisting morphologically of the particle *ein* and the verb *laden* (*load*).

A source sentence is said to include a phrasal verb if a particle dependent (UD labels of `compound:prt` or `prt`) exists in the parse. *trat* in itself means *stepped*, but in the extracted example below, *trat... entgegen* translates to *received*.
For example:

> **Source:** *[...] ich* **trat** *ihm in wahnsinniger Wut* **entgegen**.
> **Target:** *[...] I* **received** *him in frantic sort.*

Preposition Stranding is the case where a preposition does not appear adjacent to the object it refers to. In English, it will often appear at the end of the sentence or a clause. For example, *The banana she stepped* ***on*** or *The boy I read the book* ***to***. Preposition stranding is common in English and other languages such as Scandinavian languages or Dutch (Hornstein and Weinberg, 1981). However, in German, it is not a part of standard written language (Beermann and Ik-Han, 2005), although it does (rarely) appear (Fanselow, 1983). We, therefore, extract this challenge set only with English as the source side.

While preposition stranding is often regarded as a syntactic phenomenon, we consider it here a lexical LDD, since the translation of prepositions

	Phenomena	Books	Newstest2013
De↔En	Reorder	7,457	306
	Baseline (full dataset)	51,467	3,000

Table 2: Sizes of reordering and baseline corpora.

		Min Distance				
	Phenomena	All	≥1	≥2	≥3	News
De→En	Particle	8,361	7,584	6,261	4,780	232
	Reflexive	13,207	8,122	5,598	4,226	281
En→De	Particle	4,636	786	111	36	17
	Reflexive	3,225	1,188	460	274	11
	Preposition Stranding	682	191	85	40	8

Table 3: Sizes of Lexical LDD corpora. Challenge sets are partitioned (in order of appearance) by the language pairs, the phenomenon type, and the minimal distance between the head and the dependent. Phenomenon appears in the source. Statistics for the Newstest2013 corpora with miminal distance ≥ 1 are at the rightmost column, the rest are on Books.

(and in some cases their accompanying verbs) is dependent on the prepositional object, which in the case of preposition stranding, may be distant from the preposition itself. For example, translating *the* **car** *we looked* **for** into German usually uses the verb *suchen* (*search*), while translating *the* **car** *we looked* **at** does not. Translating prepositions is difficult in general (Hashemi and Hwa, 2014), but preposition stranding is especially so, as there is no adjacent object to assist disambiguation.

A source sentence is said to include preposition stranding if it contains two nodes with an edge of the type `obl` (oblique) or a subcategory thereof between them, and the UD POS tag of the dependent is adposition (ADP).

For example,

Source: *[...] wherever she wanted to* **send** *the hedgehog* **to** *[...]*
Gloss: *[...] where she the hedgehog rolled-towards wanted [...]*
Target: *[...] wo sie den Igel hinrollen wollte [...]*

4.3 Experiments

We turn to evaluate SoTA NMT performance on the extracted challenge sets.

Experimental Setup. We trained the Transformer on WMT2015 training data (Bojar et al., 2015), for parameters see §3.1. For Nematus we used the non-ensemble pre-trained model from (Sennrich et al., 2017a). Each of the test sets, either a baseline or a challenge sets, for the Transformer and Nematus used a maximum of 10k and 1k sentences per set respectively.[4]

		Transformer		Nematus	
		Books	News	Books	News
De→En	Baseline	9.02	28.23	16.26	26.32
	Reorder	7.16	22.68	13.88	22.73
	Particle	7.52	27.46	15.41	23.98
	Reflexive	8.15	27.84	14.91	27.04
En→De	Baseline	6.33	23.7	12.25	22.03
	Reorder	4.31	19.4	9.02	20.38
	Particle	5.30	17.83	9.55	16.72
	Reflexive	5.07	15.77	9.97	21.81
	Preposition Stranding	5.37	11.82	9.73	6.27

Table 4: BLEU scores on the challenge sets. Minimum distance between head and dependent $d \geq 1$. A clear, consistent drop from the Baseline (full corpus) score is observed in all cases. The top part of the table corresponds to German-to-English (De→En) sets, and bottom part to English-to-German (En→De) sets. Within each part, rows correspond to various linguistic phenomena (second column), including reordering LDD (Reorder), Verb-Particle Constructions (Particle), Reflexive Verbs (Reflexive) and Preposition Stranding. Columns correspond to the models (Tranformer/Nematus), and the domains (Books/News).

Two parallel corpora were used for extracting the challenge sets. One is newstest2013 (Bojar et al., 2015) from the news domain that is commonly used as a development set for English-German. The other is the relatively unused Books corpus (Tiedemann, 2012) from the more challenging domain of literary translation. The corpora are of sizes 51K and 3K respectively. For lexical LDD, we took the distance (d) between the relevant words to be at least 1, meaning there is at least one word separating them. See Tables 2, 3 for the sizes of the extracted corpora.

For evaluation, we use the MOSES implementation of BLEU (Papineni et al., 2002; Koehn et al., 2007), and for reordering LDD, also RIBES (Isozaki et al., 2010), which focuses on reordering. RIBES measures the correlation of n-gram ranks between the output and the reference, where n-gram appears uniquely and in both.

Manual Validation. To assess the ability of our procedure to extract relevant LDDs, we manually analyzed over 180 source German sentences ex-

[4]We subsample a smaller test set for Nematus, since the most competitive model for the language pair requires Theano. As Theano is deprecated for two years now, it cannot run on our GPUs, which entails long inference time.

	Language	Phenomena	BLEU All	BLEU ≥1	BLEU ≥2	BLEU ≥3	Spearman
Transformer	German	Particle	7.56	7.52	7.5	7.49	-0.96
		Reflexive	8.26	8.15	8.04	-	-1
	English	Particle	4.96	5.3	4.96	6.01	0.73
		Reflexive	5.41	5.07	5.25	5.04	-0.63
		Preposition Stranding	5	5.37	4.42	4.64	-0.63
Nematus	German	Particle	15.48	15.41	14.45	12.36	-0.92
		Reflexive	15.27	14.91	15.13	13.14	-0.80
	English	Particle	10.14	9.55	9.36	8.82	-0.98
		Reflexive	9.46	9.97	9.54	9.35	-0.36
		Preposition Stranding	10.01	9.73	9.14	9.04	-0.97

Table 5: The effect of dependency distance for lexical LDDs on SoTA performance . Results are in BLEU over the Books challenge sets. Columns correspond to the minimum distance, where *All* does not restrict distance (control). The rightmost column presents the Spearman correlation of the phenomena's score with the minimum distance used. All correlations but one are highly negative, implying that distance has a negative effect on performance.

tracted from Books, and 81 English ones including all the instances extracted from News and 45 extracted from Books, where instances are evenly distributed between phenomena and distance of exactly 1,2 or 5. We find that 85% of German sentences, 87% of the English News sentences and 86% of the Books ones indeed contain the target phenomenon. For details of the manual evaluation of the extraction procedure, see Appendix 1.

		News	Books
German	Baseline	0.82	0.57
	Reorder	0.79	0.54
English	Baseline	0.79	0.56
	Reorder	0.77	0.53

Table 6: RIBES scores on the reordering LDD challenge sets. Sentences extracted as being challenging to reorder are harder for the Transformer (lower score). This trend is consistent with our experiments with BLEU. First column indicates the source language.

Results. Comparison of the overall BLEU scores of the NMT models (Table 4) against their performance on the challenge sets, shows that the phenomena are challenging for both models. Both in the small development set of newstest2013 and the large set of Books, the challenge subparts are more challenging across the board. For reordering LDD, we further apply RIBES and find a similar trend: RIBES score is lower for the reorder challenge set than the baseline (see Table 6).

In order to confirm that the distance between the head and dependent (the "length" of the dependency) is related to the observed performance drop in the case of lexical LDD, we partition each of the challenge sets according to their length (d), and compare the results to a control condition, where all instances of the phenomena listed in §4.2 are extracted, including non-LDD instances, i.e., sentences where the head and the dependent are adjacent. System performance on the sliced challenge sets (Table 5) shows that performance indeed decreases with d. Results thus indicate that it is not only the presence of the phenomena that make these sets challenging, but that the challenge increases with the distance.

We validate this main finding using manual annotation of German to English cases. Using two annotators (with high agreement between them; κ=0.79), we find that the decrease in performance with d is replicated. We measure how many of the detected lexical LDD are correctly translated, ignoring the rest of the source and output, as done in manual challenge set approaches. We find that 60%, 54% and 38% of the cases are translated correctly for $d \in (1, 2, 5)$, respectively. This suggests that the extracted phenomena and the distance indeed pose a challenge, and that the automatic metric we use shows the correct trend in these cases. See Appendix 2 for details.

Discussion. Interestingly, these results hold true for the Transformer despite its indifference to the absolute word order. Therefore, word distance in itself is not what makes such phenomena challenging, contrary to what one might expect from the definition of LDD. It seems then that these

phenomena are especially challenging due to the non-standard linguistic structure (e.g., syntactic and lexical structure), and the varying distances in which LDD manifest themselves. The models, therefore, seem to be unable to learn the linguistic structure underlying these phenomena, which may motivate more explicit modelling of linguistic biases into NMT models, as proposed by, e.g., Eriguchi et al. (2017) and Song et al. (2019).

We note that our experiments were not designed to compare the performance of BiLSTM and self-attention models. We, therefore, do not see the Transformer's inferior performance on Books, relative to Nematus as an indication of the general ability of this model in out-of-domain settings. What is evident from the results is that translating Books is a challenge in itself, probably due to the register of the language, and the presence of frequent non-literal translations.

A potential confound is that performance might change with the length of the source in BiLSTMs (Carpuat et al., 2013; Murray and Chiang, 2018), in Transformers it was reported to increase (Zhang et al., 2018). Length is generally greater in the challenge set than in the full test set, and generally increases with d, showing if anything a decrease of performance by length. To assess whether our corpora are challenging due to a length bias, we randomly sample from Books 1,000 corpora with 1,000, 100 and 10 sentences each. The correlation between their corresponding average length and the Transformers' BLEU score on them was 0.06,0.09 and 0.03 respectively. While this suggests length is not a strong predictor of performance, to verify that difficulty is not a result of the distribution of lengths in the challenge sets we conduct another experiment.

For each challenge set and each value of d (0–3), we sample 100 corpora. For each sentence in a given challenge set, we sample a sentence of no more than a difference of 1 in length. This results in a corpus with a similar length distribution, but sampled from the overall population of Books sentences. Results show that the BLEU score of the challenge sets in all German to English cases is lower than any randomly sampled corpus.[5] In the English-German cases, trends are similar, albeit less pronounced. This may be due to the low number of long English sentences, which lead to more homogeneous samples. Overall, results suggest that length is extremely unlikely to be the only cause for the observed trends.

[5]Most sampled corpora actually had better scores than the baseline. We believe this is because very short sentences which are mostly noise, are never sampled.

5 Conclusion

As NMT system performance is constantly improving, more reliable methods for identifying and classifying their failures are needed. Much research effort is therefore devoted to developing more fine-grained and interpretable evaluation methods, including challenge-set approaches. In this paper, we showed that, using a UD parser, it is possible to extract challenge sets that are large enough to allow scalable MT evaluation of important and challenging phenomena.

An accumulating body of research is devoted to the ability of modern neural architectures such as LSTMs (Linzen et al., 2016) and pretrained embeddings (Hewitt and Manning, 2019; Liu et al., 2019; Jawahar et al., 2019) to represent linguistic features. This paper makes a contribution to this literature in confirming that the Transformer model can indeed be made indifferent to the absolute order of the words, but also shows that this does not entail that the model can overcome the difficulties of LDD in naturalistic data. We may carefully conclude then that despite the remarkable feats of current NMT models, inducing linguistic structure in its more evasive and challenging instances is still beyond the reach of state-of-the-art NMT, which motivates exploring more linguistically-informed models.

Abstract

Despite advances in dependency parsing, languages with small treebanks still present challenges. We assess recent approaches to multilingual contextual word representations (CWRs), and compare them for crosslingual transfer from a language with a large treebank to a language with a small or nonexistent treebank, by sharing parameters between languages in the parser itself. We experiment with a diverse selection of languages in both simulated and truly low-resource scenarios, and show that multilingual CWRs greatly facilitate low-resource dependency parsing even without crosslingual supervision such as dictionaries or parallel text. Furthermore, we examine the non-contextual part of the learned language models (which we call a "decontextual probe") to demonstrate that polyglot language models better encode crosslingual lexical correspondence compared to aligned monolingual language models. This analysis provides further evidence that polyglot training is an effective approach to crosslingual transfer.

1 Introduction

Dependency parsing has achieved new states of the art using distributed word representations in neural networks, trained with large amounts of annotated data (Dozat and Manning, 2017; Dozat et al., 2017; Ma et al., 2018; Che et al., 2018). However, many languages are low-resource, with small or no treebanks, which presents a severe challenge in developing accurate parsing systems in those languages. One way to address this problem is with a crosslingual solution that makes use of a language with a large treebank and raw text in both languages. The hypothesis behind this approach is that, although each language is unique, different languages manifest similar characteristics (e.g., morphological, lexical, syntactic) which can be exploited by training a single *polyglot* model with data from multiple languages (Ammar, 2016).

Recent work has extended contextual word representations (CWRs) multilingually either by training a polyglot language model (LM) on a mixture of data from multiple languages (*joint training* approach; Mulcaire et al., 2019; Lample and Conneau, 2019) or by aligning multiple monolingual language models crosslingually (*retrofitting* approach; Schuster et al., 2019; Aldarmaki and Diab, 2019). These multilingual representations have been shown to facilitate crosslingual transfer on several tasks, including Universal Dependencies parsing and natural language inference. In this work, we assess these two types of methods by using them for low-resource dependency parsing, and discover that the joint training approach substantially outperforms the retrofitting approach. We further apply multilingual CWRs produced by the joint training approach to diverse languages, and show that it is still effective in transfer between distant languages, though we find that phylogenetically related source languages are generally more helpful.

We hypothesize that joint polyglot training is more successful than retrofitting because it induces a degree of lexical correspondence between languages that the linear transformation used in retrofitting methods cannot capture. To test this hypothesis, we design a *decontextual probe*. We *decontextualize* CWRs into non-contextual word vectors that retain much of CWRs' task-performance benefit, and evaluate the crosslingual transferability of language models via word translation. In our decontextualization framework, we use a single LSTM cell without recurrence to obtain a context-independent vector, thereby allowing for a direct probe into the LSTM networks in-

[*] Equal contribution. Random order.

dependent of a particular corpus. We show that decontextualized vectors from the joint training approach yield representations that score higher on a word translation task than the retrofitting approach or word type vectors such as fastText (Bojanowski et al., 2017). This finding provides evidence that polyglot language models encode crosslingual similarity, specifically crosslingual lexical correspondence, that a linear alignment between monolingual language models does not.

2 Models

We examine crosslingual solutions to low-resource dependency parsing, which make crucial use of multilingual CWRs. All models are implemented in AllenNLP, version 0.7.2 (Gardner et al., 2018) and the hyperparameters and training details are given in the appendix.

2.1 Multilingual CWRs

Prior methods to produce multilingual contextual word representations (CWRs) can be categorized into two major classes, which we call *joint training* and *retrofitting*.[1] The joint training approach trains a single polgylot language model (LM) on a mixture of texts in multiple languages (Mulcaire et al., 2019; Lample and Conneau, 2019; Devlin et al., 2019),[2] while the retrofitting approach trains separate LMs on each language and aligns the learned representations later (Schuster et al., 2019; Aldarmaki and Diab, 2019). We compare example approaches from these two classes using the same LM training data, and discover that the joint training approach generally yields better performance in low-resource dependency parsing, even without crosslingual supervision.

Retrofitting Approach Following Schuster et al. (2019), we first train a bidirectional LM with two-layer LSTMs on top of character CNNs for each language (ELMo, Peters et al., 2018), and then align the monolingual LMs across languages. Denote the hidden state in the jth layer for word i in context c by $\mathbf{h}_{i,c}^{(j)}$. We use a trainable weighted average of the three layers (character-CNN and two LSTM layers) to compute the contextual representation $\mathbf{e}_{i,c}$ for the word: $\mathbf{e}_{i,c} = \sum_{j=0}^{2} \lambda_j \mathbf{h}_{i,c}^{(j)}$ (Peters et al., 2018).[3] In the first step, we compute an "anchor" $\mathbf{h}_i^{(j)}$ for each word by averaging $\mathbf{h}_{i,c}^{(j)}$ over all occurrences in an LM corpus. We then apply a standard dictionary-based technique[4] to create multilingual word embeddings (Mikolov et al., 2013; Conneau et al., 2018). In particular, suppose that we have a word-translation dictionary from source language s to target language t. Let $\mathbf{H}_s^{(j)}, \mathbf{H}_t^{(j)}$ be matrices whose columns are the anchors in the jth layer for the source and corresponding target words in the dictionary. For each layer j, find the linear transformation $\mathbf{W}^{*(j)}$ such that

$$\mathbf{W}^{*(j)} = \underset{\mathbf{W}}{\operatorname{argmin}} ||\mathbf{W}\mathbf{H}_s^{(j)} - \mathbf{H}_t^{(j)}||_F$$

The linear transformations are then used to map the LM hidden states for the source language to the target LM space. Specifically, contextual representations for the source and target languages are computed by $\sum_{j=0}^{2} \lambda_j \mathbf{W}^{*(j)} \mathbf{h}_{i,c}^{(j)}$ and $\sum_{j=0}^{2} \lambda_j \mathbf{h}_{i,c}^{(j)}$ respectively. We use publicly available dictionaries from Conneau et al. (2018)[5] and align all languages to the English LM space, again following Schuster et al. (2019).

Joint Training Approach Another approach to multilingual CWRs is to train a single LM on multiple languages (Tsvetkov et al., 2016; Ragni et al., 2016; Östling and Tiedemann, 2017). We train a single bidirectional LM with charater CNNs and two-layer LSTMs on multiple languages (Rosita, Mulcaire et al., 2019). We then use the polyglot LM to provide contextual representations. Similarly to the retrofitting approach, we represent word i in context c as a trainable weighted average of the hidden states in the trained polyglot LM: $\sum_{j=0}^{2} \lambda_j \mathbf{h}_{i,c}^{(j)}$. In contrast to retrofitting, crosslinguality is learned implicitly by sharing all network parameters during LM training; no crosslingual dictionaries are used.

[1] This term was originally used by Faruqui et al. (2015) to describe updates to word vectors, after estimating them from corpora, using semantic lexicons. We generalize it to capture the notion of a separate update to fit something other than the original data, applied after conventional training.

[2] Multilingual BERT is documented in https://github.com/google-research/bert/blob/master/multilingual.md.

[3] Schuster et al. (2019) only used the first LSTM layer, but we found a performance benefit from using all layers in preliminary results.

[4] Conneau et al. (2018) developed an unsupervised alignment technique that does not require a dictionary. We found that their unsupervised alignment yielded substantially degraded performance in downstream parsing in line with the findings of Schuster et al. (2019).

[5] https://github.com/facebookresearch/MUSE#ground-truth-bilingual-dictionaries

Refinement after Joint Training It is possible to combine the two approaches above; the alignment procedure used in the retrofitting approach can serve as a refinement step on top of an already-polyglot language model. We will see only a limited gain in parsing performance from this refinement in our experiments, suggesting that polyglot LMs are already producing high-quality multilingual CWRs even without crosslingual dictionary supervision.

FastText Baseline We also compare the multilingual CWRs to a subword-based, non-contextual word embedding baseline. We train 300-dimensional word vectors on the same LM data using the fastText method (Bojanowski et al., 2017), and use the same bilingual dictionaries to align them (Conneau et al., 2018).

2.2 Dependency Parsers

We train polyglot parsers for multiple languages (Ammar et al., 2016) on top of multilingual CWRs. All parser parameters are shared between the source and target languages. Ammar et al. (2016) suggest that sharing parameters between languages can alleviate the low-resource problem in syntactic parsing, but their experiments are limited to (relatively similar) European languages. Mulcaire et al. (2019) also include experiments with dependency parsing using polyglot contextual representations between two language pairs (English/Chinese and English/Arabic), but focus on high-resource tasks. Here we explore a wider range of languages, and analyze the particular efficacy of a crosslingual approach to dependency parsing in a low-resource setting.

We use a strong graph-based dependency parser with BiLSTM and biaffine attention (Dozat and Manning, 2017), which is also used in related work (Schuster et al., 2019; Mulcaire et al., 2019). Crucially, our parser only takes as input word representations. Universal parts of speech have been shown useful for low-resource dependency parsing (Duong et al., 2015; Ammar et al., 2016; Ahmad et al., 2019), but many realistic low-resource scenarios lack reliable part-of-speech taggers; here, we do not use parts of speech as input, and thus avoid the error-prone part-of-speech tagging pipeline. For the fastText baseline, word embeddings are not updated during training, to preserve crosslingual alignment (Ammar et al., 2016).

Lang	Code	Genus	WALS 81A	Size
English	ENG	Germanic	SVO	–
Arabic	ARA	Semitic	VSO/SVO	5241

Uyghur	UIG	Turkic	SOV	1656
Kazakh	KAZ	Turkic	SOV	31
Turkish	TUR	Turkic	SOV	3685

Table 1: List of the languages used in our UD v2.2 experiments. Each shaded/unshaded section corresponds to a pair of "related" languages. WALS 81A denotes Feature 81A in WALS, Order of Subject, Object, and Verb (Dryer and Haspelmath, 2013). "Size" represents the downsampled size in # of sentences used for source treebanks. The four languages in bold face are truly low resource languages ($<$ 2000 trees).

3 Experiments

We first conduct a set of experiments to assess the efficacy of multilingual CWRs for low-resource dependency parsing.

3.1 Zero-Target Dependency Parsing

Following prior work on low-resource dependency parsing and crosslingual transfer (Zhang and Barzilay, 2015; Guo et al., 2015; Ammar et al., 2016; Schuster et al., 2019), we conduct multi-source experiments on six languages (German, Spanish, French, Italian, Portuguese, and Swedish) from Google universal dependency treebank version 2.0 (McDonald et al., 2013).[6] We train language models on the six languages and English to produce multilingual CWRs. For each tested language, we train a polyglot parser with the multilingual CWRs on the five other languages and English, and apply the parser to the test data for the target language. Importantly, the parsing annotation scheme is shared among the seven languages. Our results will show that the joint training approach for CWRs substantially outperforms the retrofitting approach.

[6] http://github.com/ryanmcd/uni-dep-tb

3.2 Diverse Low-Resource Parsing

The previous experiment compares the joint training and retrofitting approaches in low-resource dependency parsing only for relatively similar languages. In order to study the effectiveness more extensively, we apply it to a more typologically diverse set of languages. We use five pairs of languages for "low-resource simulations," in which we reduce the size of a large treebank, and four languages for "true low-resource experiments," where only small UD treebanks are available, allowing us to compare to other work in the low-resource condition (Table 1). Following de Lhoneux et al. (2018), we selected these language pairs to represent linguistic diversity. For each target language, we produce multilingual CWRs by training a polyglot language model with its related language (e.g., Arabic and Hebrew) as well as English (e.g., Arabic and English). We then train a polyglot dependency parser on each language pair and assess the crosslingual transfer in terms of target parsing accuracy.

Each pair of related languages shares features like word order, morphology, or script. For example, Arabic and Hebrew are similar in their rich transfixing morphology (de Lhoneux et al., 2018), and Dutch and German share most of their word order features. We chose Chinese and Japanese as an example of a language pair which does *not* share a language family but does share characters.

We chose Hungarian, Vietnamese, Uyghur, and Kazakh as true low-resource target languages because they had comparatively small amounts of annotated text in the UD corpus (Vietnamese: 1,400 sentences, 20,285 tokens; Hungarian: 910 sentences, 20,166 tokens; Uyghur: 1,656 sentences, 19,262 tokens; Kazakh: 31 sentences, 529 tokens;), yet had convenient sources of text for LM pretraining (Zeman et al., 2018).[7] Other small treebanks exist, but in most cases another larger treebank exists for the same language, making domain adaptation a more likely option than crosslingual transfer. Also, recent work (Che et al., 2018) using contextual embeddings was top-ranked for most of these languages in the CoNLL 2018 shared task on UD parsing (Zeman et al., 2018).[8]

We use the same Universal Dependencies (UD) treebanks (Nivre et al., 2018) and train/development/test splits as the CoNLL 2018 shared task (Zeman et al., 2018).[9] The annotation scheme is again shared across languages, which facilitates crosslingual transfer. For each triple of two related languages and English, we downsample training and development data to match the language with the smallest treebank size. This allows for fairer comparisons because within each triple, the source language for any parser will have the same amount of training data. We further downsample sentences from the target train/development data to simulate low-resource scenarios. The ratio of training and development data is kept 5:1 throughout the simulations, and we denote the number of sentences in training data by $|D_\tau|$. For testing, we use the CoNLL 2018 script on the gold word segmentations. For the truly low-resource languages, we also present results with word segmentations from the system outputs of Che et al. (2018) (HUN, VIE, UIG) and Smith et al. (2018) (KAZ) for a direct comparison to those languages' best previously reported parsers.[10]

4 Results and Discussion

In this section we describe the results of the various parsing experiments.

4.1 Zero-Target Parsing

Table 2 shows results on zero-target dependency parsing. First, we see that all CWRs greatly improve upon the fastText baseline. The joint training approach (Rosita), which uses no dictionaries, consistently outperforms the dictionary-dependent retrofitting approach (ELMos+Alignment). As discussed in the previous section, we can apply the alignment method to refine the already-polyglot Rosita using dictionaries. However, we observe a relatively limited gain in overall performance (74.5 vs. 73.9 LAS points), suggesting that Rosita (polyglot language model) is already developing useful multilingual CWRs for parsing without crosslingual supervision. Note that the degraded overall performance of our ELMo+Alignment compared to Schuster et al. (2019)'s reported results (71.2 vs. 73.1) is likely

[7] The one exception is Uyghur where we only have 3M words in the raw LM data from Zeman et al. (2018).

[8] In Kazakh, Che et al. (2018) did not use CWRs due to the extremely small treebank size.

[9] See Appendix for a list of UD treebanks used.

[10] System outputs for all shared task systems are available at https://lindat.mff.cuni.cz/repository/xmlui/handle/11234/1-2885

Table 3: Zero-target results in LAS with gold UPOS.

due to the significantly reduced amount of LM data we used in all of our experiments (50M words per language, an order of magnitude reduction from the full Wikipedia dumps used in Schuster et al. (2019)). Schuster et al. (2019) (no dictionaries) is the same retrofitting approach as ELMos+Alignment except that the transformation matrices are learned in an unsupervised fashion without dictionaries (Conneau et al., 2018). The absence of a dictionary yields much worse performance (69.2 vs. 73.1) in contrast with the joint training approach of Rosita, which also does not use a dictionary (73.9).

We also present results using gold universal part of speech to compare to previous work in Table 3. We again see Rosita's effectiveness and a marginal benefit from refinement with dictionaries. It should also be noted that the reported results for French, Italian and German in Schuster et al. (2019) outperform all results from our controlled comparison; this may be due to the use of abundant LM training data. Nevertheless, joint training, with or without refinement, performs best on average in both gold and predicted POS settings.

4.2 Diverse Low-Resource Parsing

Low-Resource Simulations Figure 1 shows simulated low-resource results.[11] Of greatest interest are the significant improvements over monolingual parsers when adding English or related-language data. This improvement is consistent across languages and suggests that crosslingual transfer is a viable solution for a wide range of languages, even when (as in our case) language-specific tuning or annotated resources like parallel corpora or bilingual dictionaries are not available. See Figure 2 for a visualization of the differences in performance with varying training size. The polyglot advantage is minor when the target language treebank is large, but dramatic in the condition where the target language has only 100 sentences. The fastText approaches consistently underperform the language model approaches, but show the same pattern.

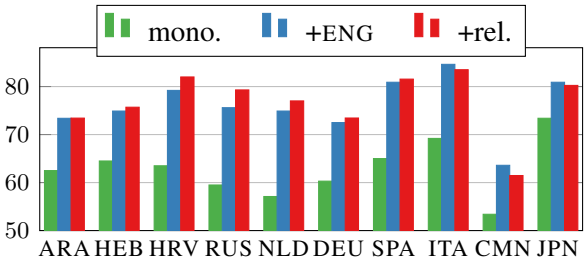

Figure 1: LAS for UD parsing results in a simulated low-resource setting where the size of the target language treebank ($|D_\tau|$) is set to 100 sentences.

In addition, related-language polyglot ("+rel.") outperforms English polyglot in most cases in the low-resource condition. The exceptions to this pattern are Italian (whose treebank is of a different genre from the Spanish one), and Japanese and Chinese, which differ significantly in morphology and word order. The CMN/JPN result suggests that such typological features influence the degree of crosslingual transfer more than orthographic

[11] A table with full details including different size simulations is provided in the appendix.

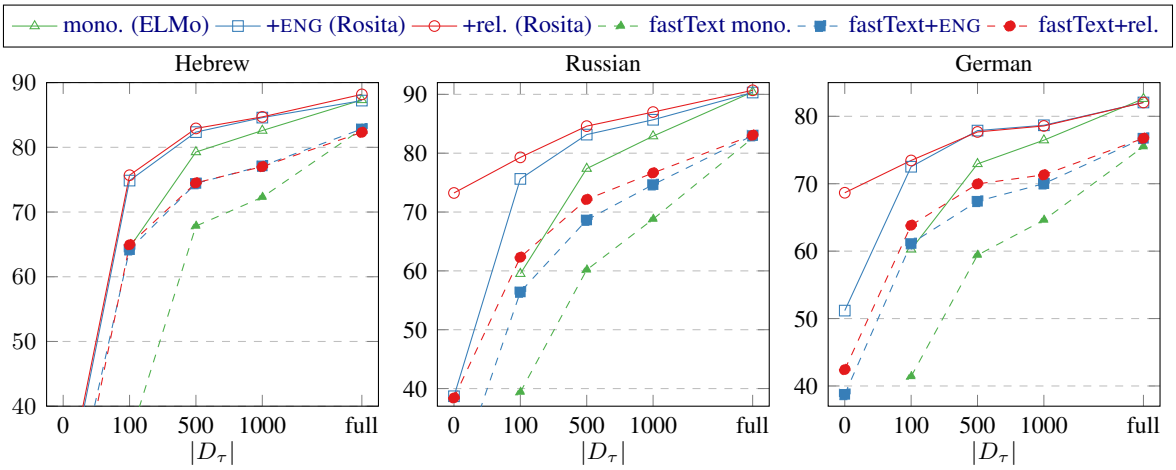

Figure 2: Plots of parsing performance vs. target language treebank size for several example languages. The size 0 target treebank point indicates a parser trained *only* on the source language treebank but with polyglot representations, allowing transfer to the target test treebank using no target language training trees. See Appendix for results with zero-target-treebank and intermediate size data ($|D_\tau| \in \{0, 100, 500, 1000\}$) for all languages.

properties like shared characters. This result in crosslingual transfer also mirrors the observation from prior work (Gerz et al., 2018) that typological features of the language are predictive of *monolingual* LM performance. The related-language improvement also vanishes in the full-data condition (Figure 2), implying that the importance of shared linguistic features can be overcome with sufficient annotated data. It is also noteworthy that variations in word order, such as the order of adjective and noun, do not affect performance: Italian, Arabic, and others use a noun-adjective order while English uses an adjective-noun order, but their +ENG and +rel. results are comparable.

The Croatian and Russian results are notable because of shared heritage but different scripts. Though Croatian uses the Latin alphabet and Russian uses Cyrillic, transfer between HRV+RUS is clearly more effective than HRV+ENG (82.00 vs. 79.21 LAS points when $|D_\tau| = 100$). This suggests that character-based LMs can implicitly learn to transliterate between related languages with different scripts, even without parallel supervision.

Truly Low Resource Languages Finally we present "true low-resource" experiments for four languages in which little UD data is available (see Section 3.2). Table 4 shows these results. Consistent with our simulations, our parsers on top of Rosita (multilingual CWRs from the joint training approach) substantially outperform the parsers with ELMos (monolingual CWRs) in all languages, and establish a new state of the art

Model	gold	pred.
Hungarian (HUN)		
Che et al. (2018) (HUN, ensemble)	–	82.66
Che et al. (2018) (HUN)	–	80.96
ELMo (HUN)	81.89	81.54
Rosita (HUN +ENG)	85.34	84.89
Rosita (HUN +FIN)	**85.40**	**84.96**
Vietnamese (VIE)		
Che et al. (2018) (VIE, ensemble)	–	55.22
ELMo (VIE)	62.67	55.72
Rosita (VIE +ENG)	**63.07**	**56.42**
Uyghur (UIG)		
Che et al. (2018) (UIG, ensemble)	–	**67.05**
Che et al. (2018) (UIG)	–	66.20
ELMo (UIG)	66.64	63.98
Rosita (UIG +ENG)	67.85	65.55
Rosita (UIG +TUR)	**68.08**	65.73
Kazakh (KAZ)		
Rosa and Mareček (2018) (KAZ +TUR)	–	26.31
Smith et al. (2018) (KAZ +TUR)	–	31.93
Schuster et al. (2019) (KAZ +TUR)	–	36.98
Rosita (KAZ +ENG)	48.02	46.03
Rosita (KAZ +TUR)	**53.98**	**51.96**

Table 4: LAS (F_1) comparison for truly low-resource languages. The gold and pred. columns show results under gold segmentation and predicted segmentation. The languages in the parentheses indicate the languages used in parser training.

in Hungarian, Vietnamese, and Kazakh. Consistent with our simulations, we see that training parsers with the target's related language is more effective than with the more distant language, English. It is particularly noteworthy that the Rosita models, which do not use a parallel corpus or dictionary, dramatically improve over the best previously reported result from Schuster et al. (2019) when either the related language of Turkish (51.96 vs. 36.98) or even the more distant language of English (46.03 v.s. 36.98) is used. Schuster et al. (2019) aligned the monolingual ELMos for Kazakh and Turkish using the KAZ-TUR dictionary that Rosa and Mareček (2018) derived from parallel text. This result further corroborates our finding that the joint training approach to multilingual CWRs is more effective than retrofitting monolingual LMs.

4.3 Comparison to Multilingual BERT Embeddings

We also evaluate the diverse low-resource language pairs using pretrained multilingual BERT (Devlin et al., 2019) as text embeddings (Figure 3). Here, the same language model (multilingual cased BERT,[12] covering 104 languages) is used for all parsers, with the only variation being in the training treebanks provided to each parser. Parsers are trained using the same hyperparameters and data as in Section 3.2.[13]

There are two critical differences from our previous experiments: multilingual BERT is trained on much larger amounts of Wikipedia data compared to other LMs used in this work, and the WordPiece vocabulary (Wu et al., 2016) used in the cased multilingual BERT model has been shown to have a distribution skewed toward Latin alphabets (Ács, 2019). These results are thus not directly comparable to those in Figure 1; nevertheless, it is interesting to see that the results obtained with ELMo-like LMs are comparable to and in some cases better than results using a BERT model trained on over a hundred languages. Our results broadly fit with those of Pires et al. (2019), who found that multilingual BERT was useful for zero-shot crosslingual syntactic transfer. In particular, we find nearly no performance benefit from cross-script transfer using BERT in a language pair (English-Japanese) for which they reported poor performance in zero-shot transfer, contrary to our results using Rosita (Section 4.2).

[12] Available at https://github.com/google-research/bert/

[13] AllenNLP version 0.9.0 was used for these experiments.

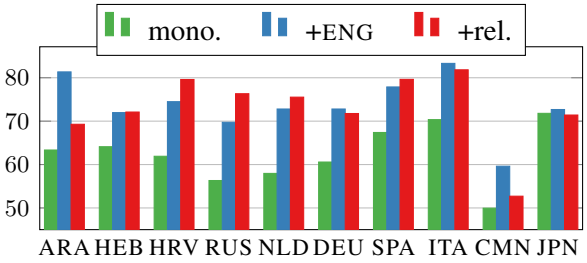

Figure 3: LAS for UD parsing results in a simulated low-resource setting ($(|D_\tau| = 100)$ using multilingual BERT embeddings in place of Rosita. Cf. Figure 1.

5 Decontextual Probe

We saw the success of the joint polyglot training for multilingual CWRs over the retrofitting approach in the previous section. We hypothesize that CWRs from joint training provide useful representations for parsers by inducing *nonlinear* similarity in the vector spaces of different languages that we cannot retrieve with a simple alignment of monolingual pretrained language models. In order to test this hypothesis, we conduct a *decontextual probe* comprised of two steps. The decontextualization step effectively distills CWRs into word type vectors, where each unique word is mapped to exactly one embedding regardless of the context. We then conduct linear transformation-based word translation (Mikolov et al., 2013) on the decontextualized vectors to quantify the degree of crosslingual similarity in the multilingual CWRs.

5.1 Decontextualization

Recall from Section 2 that we produce CWRs from bidirectional LMs with character CNNs and two-layer LSTMs. We propose a method to remove the dependence on context c for the two LSTM layers (the CNN layer is already context-independent by design). During LM training, the hidden states of each layer h_t are computed by the standard LSTM equations:

$$
\begin{aligned}
i_t &= \sigma\left(W_i x_t + + U_i h_{t-1} + b_i\right) \\
f_t &= \sigma\left(W_f x_t + U_f h_{t-1} + b_f\right) \\
\tilde{c}_t &= \tanh\left(W_c x_t + U_c h_{t-1} + b_c\right) \\
o_t &= \sigma\left(W_o x_t + U_o h_{t-1} + b_o\right) \\
c_t &= f_t \odot c_{t-1} + i_t \odot \tilde{c}_t \\
h_t &= o_t \odot \tanh\left(c_t\right)
\end{aligned}
$$

Representations	UD	SRL	NER
GloVe	83.78	80.01	83.90
fastText	83.93	80.27	83.40
Decontextualization	86.88	81.41	87.72
ELMo	88.71	82.12	88.65

Table 5: Context independent vs. dependent performance in English. All embeddings are 512-dimensional and trained on the same English corpus of approximately 50M tokens for fair comparisons. We also concatenate 128-dimensional character LSTM representations with the word vectors in every configuration to ensure all models have character input. UD scores are LAS, and SRL and NER are F_1.

We produce contextless vectors from pretrained LMs by removing recursion in the computation (i.e. setting h_{t-1} and c_{t-1} to 0):

$$
\begin{aligned}
i_t &= \sigma\left(W_i x_t + b_i\right) \\
f_t &= \sigma\left(W_f x_t + b_f\right) \\
\tilde{c}_t &= \tanh\left(W_c x_t + b_c\right) \\
o_t &= \sigma\left(W_o x_t + b_o\right) \\
c_t &= i_t \odot \tilde{c}_t \\
h_t &= o_t \odot \tanh\left(c_t\right)
\end{aligned}
$$

This method is fast to compute, as it does not require recurrent computation and only needs to see each word once. This way, each word is associated with a set of exactly three vectors from the three layers.

Performance of decontextualized vectors We perform a brief experiment to find what information is successfully retained by the decontextualized vectors, by using them as inputs to three tasks (in a monolingual English setting, for simplicity). For Universal Dependencies (UD) parsing, semantic role labeling (SRL), and named entity recognition (NER), we used the standard train/development/test splits from UD English EWT (Zeman et al., 2018) and Ontonotes (Pradhan et al., 2013). Following Mulcaire et al. (2019), we use strong existing neural models for each task: Dozat and Manning (2017) for UD parsing, He et al. (2017) for SRL, and Peters et al. (2017) for NER.

Table 5 compares the decontextualized vectors with the original CWRs (ELMo) and the conventional word type vectors, GloVe (Pennington et al., 2014) and fastText (Bojanowski et al., 2017). In all three tasks, the decontextualized vectors substantially improve over fastText and GloVe vectors, and perform nearly on par with contextual ELMo. This suggests that while part of the advantage of CWRs is in the incorporation of context, they also benefit from rich context-*independent* representations present in deeper networks.

Vector	DEU	SPA	FRA	ITA	POR	SWE
fastText	31.6	54.8	56.7	50.2	55.5	43.9
ELMos						
Layer 0	19.7	41.5	41.1	36.9	44.6	27.5
Layer 1	24.4	46.4	47.6	44.2	48.3	36.3
Layer 2	19.9	40.5	41.9	38.1	42.5	30.9
Rosita						
Layer 0	37.9	**56.6**	**58.2**	57.5	**56.6**	50.6
Layer 1	**40.3**	56.3	57.2	**58.1**	56.5	**53.7**
Layer 2	38.8	51.1	52.7	53.6	50.7	50.8

Table 6: Crosslingual alignment results (precision at 1) from decontextual probe. Layers 0, 1, and 2 denote the character CNN, first LSTM, and second LSTM layers in the language models respectively.

5.2 Word Translation Test

Given the decontextualized vectors from each layer of the bidirectional language models, we can measure the crosslingual lexical correspondence in the multilingual CWRs by performing word translation. Concretely, suppose that we have training and evaluation word translation pairs from the source to the target language. Using the same word alignment objective discussed as in Section 2.1, we find a linear transform by aligning the decontextualized vectors for the training source-target word pairs. Then, we apply this linear transform to the decontextualized vector for each source word in the evaluation pairs. The closest target vector is found using the cross-domain similarity local scaling (CSLS) measure (Conneau et al., 2018), which is designed to remedy the hubness problem (where a few "hub" points are nearest neighbors to many other points each) in word translation by normalizing the cosine similarity according to the degree of hubness.

We again take the dictionaries from Conneau et al. (2018) with the given train/test split, and always use English as the target language. For each language, we take all words that appear three times or more in our LM training data and compute decontextualized vectors for them. Word translation is evaluated by choosing the closest vector among the English decontextualized vectors.

5.3 Results

We present word translation results from our decontextual probe in Table 6. We see that the first

LSTM layer generally achieves the best crosslingual alignment both in ELMos and Rosita. This finding mirrors recent studies on layerwise transferability; representations from the first LSTM layer in a language model are most transferable across a range of tasks (Liu et al., 2019). Our decontextual probe demonstrates that the first LSTM layer learns the most generalizable representations not only across tasks but also across languages. In all six languages, Rosita (joint LM training approach) outperforms ELMos (retrofitting approach) and the fastText vectors. This shows that for the polyglot (jointly trained) LMs, there is a preexisting similarity between languages' vector spaces beyond what a linear transform provides. The resulting language-agnostic representations lead to polyglot training's success in low-resource dependency parsing.

6 Further Related Work

In addition to the work mentioned above, much previous work has proposed techniques to transfer knowledge from a high-resource to a low-resource language for dependency parsing. Many of these methods use an essentially (either lexicalized or delexicalized) joint polyglot training setup (e.g., McDonald et al., 2011; Cohen et al., 2011; Duong et al., 2015; Guo et al., 2016; Vilares et al., 2016; Falenska and Çetinoğlu, 2017 as well as many of the CoNLL 2017/2018 shared task participants: Lim and Poibeau (2017); Vania et al. (2017); de Lhoneux et al. (2017); Che et al. (2018); Wan et al. (2018); Smith et al. (2018); Lim et al. (2018)). Some use typological information to facilitate crosslingual transfer (e.g., Naseem et al., 2012; Täckström et al., 2013; Zhang and Barzilay, 2015; Wang and Eisner, 2016; Rasooli and Collins, 2017; Ammar et al., 2016). Others use bitext (Zeman et al., 2018), manually-specified rules (Naseem et al., 2012), or surface statistics from gold universal part of speech (Wang and Eisner, 2018a,b) to map the source to target. The methods examined in this work to produce multilingual CWRs do not rely on such external information about the languages, and instead use relatively abundant LM data to learn crosslinguality that abstracts away from typological divergence.

Recent work has developed several probing methods for (monolingual) contextual representations (Liu et al., 2019; Hewitt and Manning, 2019; Tenney et al., 2019). Wada and Iwata (2018) showed that the (contextless) input and output word vectors in a polyglot word-based language model manifest a certain level of lexical correspondence between languages. Our decontextual probe demonstrated that the *internal* layers of polyglot language models capture crosslinguality and produce useful multilingual CWRs for downstream low-resource dependency parsing.

7 Conclusion

We assessed recent approaches to multilingual contextual word representations, and compared them in the context of low-resource dependency parsing. Our parsing results illustrate that a joint training approach for polyglot language models outperforms a retrofitting approach of aligning monolingual language models. Our decontextual probe showed that jointly trained LMs learn a better crosslingual lexical correspondence than the one produced by aligning monolingual language models or word type vectors. Our results provide a strong basis for multilingual representation learning and for further study of crosslingual transfer in a low-resource setting beyond dependency parsing.

Abstract

Recently, pre-trained language models have achieved remarkable success in a broad range of natural language processing tasks. However, in multilingual setting, it is extremely resource-consuming to pre-train a deep language model over large-scale corpora for each language. Instead of exhaustively pre-training monolingual language models independently, an alternative solution is to pre-train a powerful multilingual deep language model over large-scale corpora in hundreds of languages. However, the vocabulary size for each language in such a model is relatively small, especially for low-resource languages. This limitation inevitably hinders the performance of these multilingual models on tasks such as sequence labeling, wherein in-depth token-level or sentence-level understanding is essential.

In this paper, inspired by previous methods designed for monolingual settings, we investigate two approaches (i.e., joint mapping and mixture mapping) based on a pre-trained multilingual model BERT for addressing the out-of-vocabulary (OOV) problem on a variety of tasks, including part-of-speech tagging, named entity recognition, machine translation quality estimation, and machine reading comprehension. Experimental results show that using mixture mapping is more promising. To the best of our knowledge, this is the first work that attempts to address and discuss the OOV issue in multilingual settings.

1 Introduction

It has been shown that performance on many natural language processing tasks drops dramatically on held-out data when a significant percentage of words do not appear in the training data, i.e., out-of-vocabulary (OOV) words (Søgaard and Johannsen, 2012; Madhyastha et al., 2016). A higher OOV rate (i.e., the percentage of the unseen words in the held-out data) may lead to a more severe performance drop (Kaljahi et al., 2015). OOV problems have been addressed in previous works under monolingual settings, through replacing OOV words with their semantically similar in-vocabulary words (Madhyastha et al., 2016; Kolachina et al., 2017) or using character/word information (Kim et al., 2016, 2018; Chen et al., 2018) or subword information like byte pair encoding (BPE) (Sennrich et al., 2016; Stratos, 2017).

Recently, fine-tuning a pre-trained deep language model, such as Generative Pre-Training (GPT) (Radford et al., 2018) and Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018), has achieved remarkable success on various downstream natural language processing tasks. Instead of pre-training many monolingual models like the existing English GPT, English BERT, and Chinese BERT, a more natural choice is to develop a powerful multilingual model such as the multilingual BERT.

However, all those pre-trained models rely on language modeling, where a common trick is to tie the weights of softmax and word embeddings (Press and Wolf, 2017). Due to the expensive computation of softmax (Yang et al., 2017) and data imbalance across different languages, the vocabulary size for each language in a multilingual model is relatively small compared to the monolingual BERT/GPT models, especially for low-resource languages. Even for a high-resource language like Chinese, its vocabulary size 10k in the multilingual BERT is only half the size of that in the Chinese BERT. Just as in monolingual settings, the OOV problem also hinders the performance of a multilingual model on tasks that are sensitive to token-level or sentence-level information. For ex-

ample, in the POS tagging problem (Table 2), 11 out of 16 languages have significant OOV issues (OOV rate $\geq 5\%$) when using multilingual BERT.

According to previous work (Radford et al., 2018; Devlin et al., 2018), it is time-consuming and resource-intensive to pre-train a deep language model over large-scale corpora. To address the OOV problems, instead of pre-training a deep model with a large vocabulary, we aim at enlarging the vocabulary size when we fine-tune a pre-trained multilingual model on downstream tasks.

We summarize our contributions as follows: (i) We investigate and compare two methods to alleviate the OOV issue. To the best of our knowledge, this is the first attempt to address the OOV problem in multilingual settings. (ii) By using English as an interlingua, we show that bilingual information helps alleviate the OOV issue, especially for low-resource languages. (iii) We conduct extensive experiments on a variety of token-level and sentence-level downstream tasks to examine the strengths and weaknesses of these methods, which may provide key insights into future directions[1].

2 Approach

We use the multilingual BERT as the pre-trained model. We first introduce the pre-training procedure of this model (Section 2.1) and then introduce two methods we investigate to alleviate the OOV issue by expanding the vocabulary (Section 2.2). Note that these approaches are not restricted to BERT but also applicable to other similar models.

2.1 Pre-Trained BERT

Compared to GPT (Radford et al., 2018) and ELMo (Peters et al., 2018), BERT (Devlin et al., 2018) uses a **bidirectional** transformer, whereas GPT pre-trains a left-to-right transformer (Liu et al., 2018); ELMo (Peters et al., 2018) independently trains left-to-right and right-to-left LSTMs (Peters et al., 2017) to generate representations as additional features for end tasks.

In the pre-training stage, Devlin et al. (2018) use two objectives: masked language model (LM) and next sentence prediction (NSP). In masked LM, they randomly mask some input tokens and then predict these masked tokens. Compared to unidirectional LM, masked LM enables representations to fuse the context from both directions. In the NSP task, given a certain sentence, it aims to predict the next sentence. The purpose of adding the NSP objective is that many downstream tasks such as question answering and language inference require sentence-level understanding, which is not directly captured by LM objectives.

After pre-training on large-scale corpora like Wikipedia and BookCorpus (Zhu et al., 2015), we follow recent work (Radford et al., 2018; Devlin et al., 2018) to fine-tune the pre-trained model on different downstream tasks with minimal architecture adaptation. We show how to adapt BERT to different downstream tasks in Figure 1 (left).

2.2 Vocabulary Expansion

Devlin et al. (2018) pre-train the multilingual BERT on Wikipedia in 102 languages, with a shared vocabulary that contains 110k subwords calculated from the WordPiece model (Wu et al., 2016). If we ignore the shared subwords between languages, on average, each language has a 1.1k vocabulary, which is significantly smaller than that of a monolingual pre-trained model such as GPT (40k). The OOV problem tends to be less serious for languages (e.g., French and Spanish) that belong to the same language family of English. However, this is not always true, especially for morphologically rich languages such as German (Ataman and Federico, 2018; Lample et al., 2018). OOV problem is much more severe in low-resource scenarios, especially when a language (e.g., Japanese and Urdu) uses an entirely different character set from high-resource languages.

We focus on addressing the OOV issue at subword level in multilingual settings. Formally, suppose we have an embedding E_{bert} extracted from the (non-contextualized) embedding layer in the multilingual BERT (i.e., the first layer of BERT). And suppose we have another set of (non-contextualized) sub-word embeddings $\{E_{l_1}, E_{l_2}, \ldots, E_{l_n}\} \cup \{E_{en}\}$, which are pre-trained on large corpora using any standard word embedding toolkit. Specifically, E_{en} represents the pre-trained embedding for English, and E_{l_i} represents the pre-trained embedding for non-English language l_i at the subword level. We denote the vocabulary of E_{bert}, E_{en}, and E_{l_i} by V_{bert}, V_{en}, and V_{l_i}, respectively. For each subword w in V_{bert}, we use $E_{bert}(w)$ to denote the pre-trained embedding of word w in E_{bert}. $E_{l_i}(\cdot)$ and $E_{en}(\cdot)$ are defined in a similar way as $E_{bert}(\cdot)$. For

[1]Improved models will be available at https://github.com/sohuren/multilingul-bert.

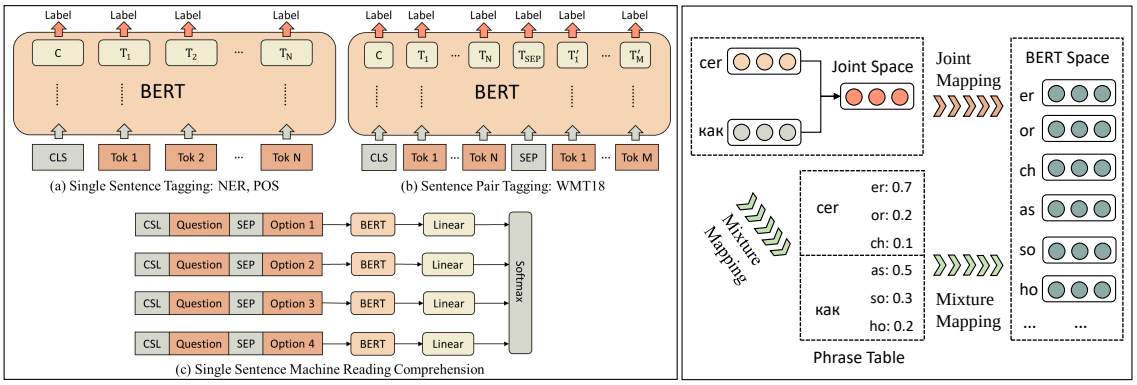

Figure 1: Left: fine-tuning BERT on different kinds of end tasks. Right: illustration of joint and mixture mapping (in this example, during mixture mapping, we represent $\boldsymbol{e}(cer) = 0.7 * \boldsymbol{e}(er) + 0.2 * \boldsymbol{e}(or) + 0.1 * \boldsymbol{e}(ch)$).

each non-English language $l \in \{l_1, l_2, \ldots, l_n\}$, we aim to enrich E_{bert} with more subwords from the vocabulary in E_{l_i} since E_{l_i} contains a larger vocabulary of language l_i compared to E_{bert}.

As there is no previous work to address multilingual OOV issues, inspired by previous solutions designed for monolingual settings, we investigate the following two methods, and all of them can be applied at both word/subword level, though we find subword-level works better (Section 3).

Joint Mapping For each non-English language l, we first construct a joint embedding space E'_l through mapping E_l to E_{en} by an orthogonal mapping matrix B_l (i.e., $E'_l = E_l B_l$). When a bilingual dictionary $f_l : V_l \rightarrow V_{en}$ is available or can be constructed based on the shared common subwords (Section 3.1), we obtain B_l by minimizing:

$$\sum_{w' \in V_l \cap \{w : f_l(w) \in V_{en}\}} \left\| E_l(w') B_l - E_{en}(f_l(w')) \right\|_F^2$$

where $\|\cdot\|_F$ denotes the Frobenius norm. Otherwise, for language pair (e.g., English-Urdu) that meets neither of the above two conditions, we obtain B_l by an unsupervised word alignment method from MUSE (Conneau et al., 2018).

We then map E'_l to E_{bert} by an orthogonal mapping matrix A'_l, which is obtained by minimizing

$$\sum_{w \in f_l(V_l) \cap V_{bert}} \left\| E'_l(w) A'_l - E_{bert}(w) \right\|_F^2$$

We denote this method by M_J in our discussion below, where the subscript J stands for "joint".

Mixture Mapping Following the work of Gu et al. (2018) where they use English as *"universal tokens"* and map all other languages to English to obtain the subword embeddings, we represent each subword in E'_l (described in joint mapping) as a mixture of English subwords where those English subwords are already in the BERT vocab V_{bert}. This method, denoted by M_M, is also a joint mapping without the need for learning the mapping from E'_l to E_{bert}. Specifically, for each $w \in V_l$, we obtain its embedding $\boldsymbol{e}(w)$ in the BERT embedding space E_{bert} as follows.

$$\boldsymbol{e}(w) = \sum_{u \in \mathcal{T}(w)} p(u \mid w) E_{bert}(u)$$

where $\mathcal{T}(w)$ is a set to be defined later, and the mixture coefficient $p(u|w)$ is defined by

$$p(u \mid w) = \frac{\exp(\text{CSLS}(E_l(u), E_{en}(w)))}{\sum_{v \in \mathcal{T}(w)} \exp(\text{CSLS}(E_l(v), E_{en}(w)))}$$

where CSLS refers to the distance metric Cross-domain Similarity Local Scaling (Conneau et al., 2018). We select five $v \in V_{en} \cup V_{bert}$ with the highest $\text{CSLS}(E_l(v), E_{en}(w))$ to form set $\mathcal{T}(w)$. In all our experiments, we set the number of nearest neighbors in CSLS to 10. We refer readers to Conneau et al. (2018) for details. Figure 1 (right) illustrates the joint and mixture mapping.

3 Experiment

3.1 Experiment Settings

We obtain the pre-trained embeddings of a specific language by training fastText (Bojanowski et al., 2017) on Wikipedia articles in that language, with context window 5 and negative sampling 5. Before training, we first apply BPE (Sennrich et al., 2016) to tokenize the corpus with subword vocabulary size 50k. For joint mapping method M_J,

we use bilingual dictionaries provided by Conneau et al. (2018). For a language pair where a bilingual dictionary is not easily available, if two languages share a significant number of common subwords (this often happens when two languages belong to the same language family), we construct a bilingual dictionary based on the assumption that identical subwords have the same meaning (Søgaard et al., 2018). We add all unseen subwords from 50k vocabulary to BERT. We define a word as an OOV word once it cannot be represented as a single word. For example, in BERT, the sentence *"Je sens qu' entre ça et les films de médecins et scientifiques"* is represented as *"je sens qu ##' entre [UNK] et les films de [UNK] et scientifiques"*, where **qu'** is an OOV word since it can only be represented by two subword units: **qu** and **##'**, but it is not OOV at subword level; **ça** and **médecins** cannot be represented by any single word or combination of subword units, and thus they are OOV at both word and subword level.

We use the **multilingual BERT** with default parameters in all our experiments, except that we tune the batch size and training epochs. To have a thorough examination about the pros and cons of the explored methods, we conduct experiments on a variety of token-level and sentence-level classification tasks: part of speech (POS) tagging, named entity recognition (NER), machine translation quality estimation, and machine reading comprehension. See more details in each subsection.

3.2 Discussions about Mapping Methods

Previous work typically assumes a linear mapping exists between embedding spaces of different languages if their embeddings are trained using similar techniques (Xing et al., 2015; Madhyastha et al., 2016). However, it is difficult to map embeddings learned with different methods (Søgaard et al., 2018). Considering the differences between BERT and fastText: e.g., the objectives, the way to differentiate between different subwords, and the much deeper architecture of BERT, it is very unlikely that the (non-contextualized) BERT embedding and fastText embedding reside in the same geometric space. Besides, due to that BERT has a relatively smaller vocabulary for each language, when we map a pre-trained vector to its portion in BERT indirectly as previous methods, the supervision signal is relatively weak, especially for low-resource languages. In our experiment, we find that the accuracy of the mapping from our pre-trained English embedding to multilingual BERT embedding (English portion) is lower than 30%. In contrast, the accuracy of the mapping between two regular English embeddings that are pre-trained using similar methods (e.g., CBOW or SkipGram (Mikolov et al., 2013)) could be above 95% (Conneau et al., 2018).

Besides the **joint mapping** method M_J (Section 2.2), another possible method that could be used for OOV problem in multilingual setting is that, for each language l, we map its pre-trained embedding space E_l to embedding E_{bert} by an orthogonal mapping matrix A_l, which is obtained by minimizing $\sum_{w \in V_l \cap V_{bert}} \|E_l(w)A_l - E_{bert}(w)\|_F^2$. This approach is similar to (Madhyastha et al., 2016), and is referred as **independent mapping** method below. However, we use examples to demonstrate why these kind of methods are less promising. In Table 1, the first two rows are results obtained by mapping our pre-trained English embedding (using fastText) to the (non-contextualized) BERT embedding. In this new unified space, we align words with CSLS metric, and for each subword that appears in English Wikipedia, we seek its closest neighbor in the BERT vocabulary. Ideally, each word should find itself if it exists in the BERT vocabulary. However, this is not always true. For example, although *"however"* exists in the BERT vocabulary, independent mapping fails to find it as its own closest neighbor. Instead, it incorrectly maps it to irrelevant Chinese words "盘" (*"plate"*) and "龙" (*"dragon"*). A similar phenomenon is observed for Chinese. For example, "册" is incorrectly aligned to Chinese words "书" and "卷".

Source Lang	Source	Target	probability
English	however	盘(plate)	0.91
	however	龙(dragon)	0.05
Chinese	册(booklet)	书(book)	0.49
	册(booklet)	卷(volume)	0.46

Table 1: Alignment from Independent Mapping.

Furthermore, our POS tagging experiments (Section 3.3) further show that joint mapping M_J does not improve (or even hurt) the performance of the multilingual BERT. Therefore, we use **mixture mapping** M_M to address and discuss OOV issues in the remaining sections.

3.3 Monolingual Sequence Labeling Tasks

POS Tagging: We use the Universal Dependencies v1.2 data (McDonald et al., 2013). For languages with token segmentation ambiguity, we use the gold segmentation following Plank et al. (2016). We consider languages that have sufficient training data and filter out languages that have unsatisfying embedding alignments with English (accuracy is lower than 20.0% measured by word alignment accuracy or 0.25 by unsupervised metric in MUSE (Conneau et al., 2018)). Finally, we keep 16 languages. We use the original multilingual BERT (without using CRF (Lafferty et al., 2001) on top of it for sequence labeling) to tune hyperparameters on the dev set and use the fixed hyperparameters for the expanded multilingual model. We do not tune the parameters for each model separately. As shown in Table 2, at both the word and subword level, the OOV rate in this dataset is quite high. Mixture mapping improves the accuracy on 10 out of 16 languages, leading to a 1.97% absolute gain in average. We discuss the influence of alignments in Section 3.6.

Chinese NER: We are also interested in investigating the performance gap between the expanded multilingual model and a monolingual BERT that is pre-trained on a large-scale monolingual corpus. Currently, pre-trained monolingual BERT models are available in English and Chinese. As English has been used as the interlingua, we compare the expanded multilingual BERT and the Chinese BERT on a Chinese NER task, evaluated on the Weibo NER dataset constructed from social media by Peng and Dredze (2015). In the training set, the token-level OOV rate is 2.17%, and the subword-level OOV rate is 0.54%. We tune the hyperparameters of each model based on the development set separately and then use the best hyperparameters of each model for evaluation on the test set.

As shown in Table 3, the expanded model outperforms the multilingual BERT on the Weibo NER dataset. We boost the F1 score from 59.0%

to 61.4%. Compared to the Chinese BERT (66.9%), there still exists a noticeable performance gap. One possible reason could be the grammatical differences between Chinese and English. As BERT uses the language model loss function for pre-training, the pre-trained Chinese BERT could better capture the language-specific information comapred to the multilingual BERT.

3.4 Code-Mixed Sequence Labeling Tasks

As the multilingual BERT is pre-trained over 102 languages, it should be able to handle code-mixed texts. Here we examine its performance and the effectiveness of the expanded model in mixed language scenarios, using two tasks as case studies.

Code-Switch Challenge: We first evaluate on the CALCS-2018 code-switched task (Aguilar et al., 2018), which contains two NER tracks on Twitter social data: mixed English&Spanish (en-es) and mixed Modern Standard Arabic&Egyptian (ar-eg). Compared to traditional NER datasets constructed from news, the dataset contains a significant portion of uncommon tokens like hashtags and abbreviations, making it quite challenging. For example, in the en-es track, the token-level OOV rate is 44.6%, and the subword-level OOV rate is 3.1%; in the ar-eg track, the token-level OOV rate is 64.0%, and the subword-level OOV rate is 6.0%. As shown in Table 4, on ar-eg, we boost the F1 score from 74.7% to 77.3%. However, we do not see similar gains on the en-es dataset, probably because that English and Spanish share a large number of subwords, and adding too many new subwords might prevent the model from utilizing the well pre-trained subwords embedding. See Section 3.6 for more discussions.

Machine Translation Quality Estimation: All previous experiments are based on well-curated data. Here we evaluate the expanded model on a language generation task, where sometimes the generated sentences are out-of-control.

We choose the automatic Machine Translation Quality Estimation task and use Task 2 – word-level quality estimation – in WMT18 (Bojar et al., 2018). Given a source sentence and its translation (i.e., target), this task aims to estimate the translation quality (*"BAD"* or *"OK"*) at each position: e.g., each token in the source and target sentence, each **gap** in the target sentence. We use English to German (en-de) SMT translation. On all three categories, the expanded model consistently outperforms the original multilingual BERT (Table 5)[2].

3.5 Sequence Classification Tasks

Finally, we evaluate the expanded model on sequence classification in a mixed-code setting, where results are less sensitive to unseen words.

Code-Mixed Machine Reading Comprehension: We consider the mixed-language machine reading comprehension task. Since there is no such public available dataset, we construct a new Chinese-English code-mixed machine reading comprehension dataset based on 37,436 unduplicated utterances obtained from the transcriptions of a Chinese and English mixed speech recognition corpus King-ASR-065-1[3]. We generate a multiple-choice machine reading comprehension problem (i.e., a question and four answer options) for each utterance. A question is an utterance with an English text span removed (we randomly pick one if there are multiple English spans) and the correct answer option is the removed English span. Distractors (i.e., wrong answer options) come from the top three closest English text spans, which appear in the corpus, based on the cosine similarity of word embeddings trained on the same corpus. For example, given a question "突然听到 21___，那强劲的鼓点，那一张张脸。" (*"Suddenly I heard 21___, and the powerful drum beats reminded me of the players."*) and four answer options { *"forever"*, *"guns"*, *"jay"*, *"twins"* }, the task is to select the correct answer option *"guns"* (*"21 Guns"* is a song by the American rock band *Green Day*). We split the dataset into training, development, and testing of size 36,636, 400, 400, respectively. An-

[2]Our evaluation is based on the development set since the test set is only available to participants, and we could not find the submission teams' performance on the developmenet set.

notators manually clean and improve the quality problems by generating more confusing distractors in the dev and testing sets to guarantee that these problems are error-free and challenging.

In this experiment, for each BERT model, we follow its default hyperparameters. As shown in Table 6, the expanded model improves the multilingual BERT (38.1%) by 1.2% in accuracy. Human performance (81.4%) indicates that this is not an easy task even for human readers.

Model	Accuracy	
	Development	Test

3.6 Discussions

In this section, we first briefly investigate whether the performance boost indeed comes from the reduction of OOV and then discuss the strengths and weaknesses of the methods we investigate.

First, we argue that it is essential to alleviate the OOV issue in multilingual settings. Taking the POS tagging task as an example, we find that most errors occur at the OOV positions (Table 7 in Section 3.3). In the original BERT, the accuracy of OOV words is much lower than that of non-OOV words, and we significantly boost the accuracy of OOV words with the expanded BERT. All these results indicate that the overall improvement mostly comes from the reduction of OOV.

We also observe that the following factors may influence the performance of the expanded model. **Subwords**: When expanding the vocabulary, it is critical to add only frequent subwords. Currently, we add all unseen subwords from the 50k vocabulary (Section 3.1), which may be not an optimal choice. Adding too many subwords may prevent the model from utilizing the information from pre-trained subword embedding in BERT, especially when there is a low word-level overlap between the training and test set.

Lang	BERT		BERT_{oov}	
	non-OOV	OOV	non-OOV	OOV
fi	98.1	81.3	98.5	90.2
fr	97.0	90.2	97.2	95.6
hr	97.8	91.9	97.7	94.5
pl	98.8	84.6	99.0	93.2
pt	98.8	91.5	98.6	94.8
sl	98.6	91.6	98.7	95.1
sv	97.4	82.9	98.2	94.8
average	98.1	87.7	98.3	94.0

Table 7: POS tagging accuracy (%) for OOV tokens and non-OOV tokens on the Universal Dependencies v1.2 dataset, where the OOV/non-OOV are defined at word level with the original BERT vocabulary.

Language: We also find that languages can influence the performance of the vocabulary expansion through the following two aspects: the alignment accuracy and the closeness between a language and English. For languages that are closely related to English such as French and Dutch, it is relatively easy to align their embeddings to English as most subword units are shared (Søgaard et al., 2018; Conneau et al., 2018). In such case, the BERT embedding already contains sufficient information, and therefore adding additional subwords may hurt the performance. On the other hand, for a distant language such as Polish (Slavic family), which shares some subwords with English (Germanic family), adding subwords to BERT brings performance improvements. In the meantime, as Slavic and Germanic are two subdivisions of the Indo-European languages, we find that the embedding alignment methods per-

form reasonably well. For these languages, vocabulary expansion is usually more effective, indicated by POS tagging accuracies for Polish, Portuguese, and Slovenian (Table 2). For more distant languages like Arabic (Semitic family) that use different character sets, it is necessary to add additional subwords. However, as the grammar of such a language is very different from that of English, how to accurately align their embeddings is the main bottleneck.

Task: We see more significant performance gains on NER, POS and MT Quality Estimation, possibly because token-level understanding is more critical for these tasks, therefore alleviating OOV helps more. In comparison, for sequence level classification tasks such as machine reading comprehension (Section 3.5), OOV issue is less severe since the result is based on the entire sentence.

4 Related Work

OOV poses challenges for many tasks (Pinter et al., 2017) such as machine translation (Razmara et al., 2013; Sennrich et al., 2016) and sentiment analysis (Kaewpitakkun et al., 2014). Even for tasks such as machine reading comprehension that are less sensitive to the meanings of each word, OOV still hurts the performance (Chu et al., 2017; Zhang et al., 2018). We now discuss previous methods in two settings.

4.1 Monolingual Setting

Most previous work address the OOV problems in monolingual settings. Before more fine-grained encoding schema such as BPE (Sennrich et al., 2016) is proposed, prior work mainly focused on OOV for token-level representations (Taylor et al., 2011; Kolachina et al., 2017). Besides simply assigning random embeddings to unseen words (Dhingra et al., 2017) or using an unique symbol to replace all these words with a shared embedding (Hermann et al., 2015), a thread of research focuses on refining the OOV representations based on word-level information, such as using similar in-vocabulary words (Luong et al., 2015; Cho et al., 2015; Tafforeau et al., 2015; Li et al., 2016), mapping initial embedding to task-specific embedding (Rothe et al., 2016; Madhyastha et al., 2016), using definitions of OOV words from auxiliary data (Long et al., 2016; Bahdanau et al., 2017), and tracking contexts to build/update representations (Henaff et al., 2016; Kobayashi et al., 2017; Ji et al., 2017; Zhao et al., 2018).

Meanwhile, there have been efforts in representing words by utilizing character-level (Zhang et al., 2015; Ling et al., 2015a,b; Kim et al., 2016; Gimpel and Livescu, 2016) or subword-level representations (Sennrich et al., 2016; Bojanowski et al., 2017). To leverage the advantages in character and (sub)word level representation, some previous work combine (sub)word- and character-level representations (Santos and Zadrozny, 2014; dos Santos et al., 2015; Yu et al., 2017) or develop hybrid word/subword-character architectures (Chung et al., 2016; Luong and Manning, 2016; Pinter et al., 2017; Bahdanau et al., 2017; Matthews et al., 2018; Li et al., 2018). However, all those approaches assume monolingual setting, which is different from ours.

4.2 Multilingual Setting

Addressing OOV problems in a multilingual setting is relatively under-explored, probably because most multilingual models use separate vocabularies (Jaffe, 2017; Platanios et al., 2018). While there is no direct precedent, previous work show that incorporating multilingual contexts can improve monolingual word embeddings (Zou et al., 2013; Andrew et al., 2013; Faruqui and Dyer, 2014; Lu et al., 2015; Ruder et al., 2017).

Madhyastha and España-Bonet (2017) increase the vocabulary size for statistical machine translation (SMT). Given an OOV source word, they generate a translation list in target language, and integrate this list into SMT system. Although they also generate translation list (similar with us), their approach is still in monolingual setting with SMT. Cotterell and Heigold (2017) train char-level taggers to predict morphological taggings for high/low resource languages jointly, alleviating OOV problems to some extent. In contrast, we focus on dealing with the OOV issue at subword level in the context of pre-trained BERT model.

5 Conclusion

We investigated two methods (i.e., joint mapping and mixture mapping) inspired by monolingual solutions to alleviate the OOV issue in multilingual settings. Experimental results on several benchmarks demonstrate the effectiveness of mixture mapping and the usefulness of bilingual information. To the best of our knowledge, this is

the first work to address and discuss OOV issues at the subword level in multilingual settings. Future work includes: investigating other embedding alignment methods such as Gromov-Wasserstein alignment (Alvarez-Melis and Jaakkola, 2018) upon more languages; investigating approaches to choose the subwords to be added dynamically.

Abstract

Long sentences have been one of the major challenges in neural machine translation (NMT). Although some approaches such as the attention mechanism have partially remedied the problem, we found that the current standard NMT model, Transformer, has difficulty in translating long sentences compared to the former standard, Recurrent Neural Network (RNN)-based model. One of the key differences of these NMT models is how the model handles position information which is essential to process sequential data. In this study, we focus on the position information type of NMT models, and hypothesize that relative position is better than absolute position. To examine the hypothesis, we propose RNN-Transformer which replaces positional encoding layer of Transformer by RNN, and then compare RNN-based model and four variants of Transformer. Experiments on ASPEC English-to-Japanese and WMT2014 English-to-German translation tasks demonstrate that relative position helps translating sentences longer than those in the training data. Further experiments on length-controlled training data reveal that absolute position actually causes overfitting to the sentence length.

1 Introduction

Sequence to sequence models for neural machine translation (NMT) are now utilized for various text generation tasks including automatic summarization (Chopra et al., 2016; Nallapati et al., 2016; Rush et al., 2015) and dialogue systems (Vinyals and Le, 2015; Shang et al., 2015); the models are required to take inputs of various length. Early studies on recurrent neural network (RNN)-based model analyze the translation quality with respect to the sentence length, and show that their models improve translations for long sentences, using the long short-term memory (LSTM) (Sutskever et al., 2014) or introducing the attention mechanism (Bahdanau et al., 2015; Luong et al., 2015). However, Koehn and Knowles (2017) report that even RNN-based model with the attention mechanism performs worse than phrase-based statistical machine translation (Koehn et al., 2007) in translating very long sentences, which challenges us to develop an NMT model that is robust to long sentences or more generally, variations in input length.

Have the recent advances in NMT achieved the robustness to the variations in input length? NMT has been advancing by upgrading the model architecture: RNN-based model (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015; Luong et al., 2015) followed by convolutional neural network (CNN)-based model (Kalchbrenner et al., 2016; Gehring et al., 2017) and attention-based model (Vaswani et al., 2017) called Transformer (§ 2). Transformer is the de facto standard NMT model today for its better performance compared to the former standard RNN-based model. We thus came up with a question whether Transformer have acquired the robustness to the variations in input length.

On the length of input sentence(s), the key difference between existing NMT models is how they incorporate information on word positions in the input. RNN or CNN-based NMT captures *relative* positions which stem from sequential operation of RNN or convolution operation of CNN. On the other hand, position embeddings or positional encodings (vector representations of positions) are used to handle *absolute* positions in Transformer. Gehring et al. (2017) integrate position embeddings, which are induced together with the other model parameters, into the CNN-based model, and showed that absolute position is still beneficial for their model in addition to the relative position captured by CNN. By contrast, Transformer only em-

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 328–338
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

ploys positional encodings, which give fixed vectors to positions using sine and cosine functions.

In this study, we suspect that these differences in position information types of the models have an impact on the accuracy of translating long sentences, and investigate the impact of position information on translating long sentences to realize an NMT model that is robust to variations in input length. We reveal that RNN-based model (relative position) is better than Transformer with positional encodings (absolute position) in translating longer sentences than those in the training data (§ 5.2). Motivated from this result, we propose a simple modification to Transformer, using RNN as relative positional encoder (§ 4).

Whereas RNN and CNN-based models are inseparable from relative position inside of RNN or CNN, Transformer allows us to change the position information type. We therefore compare the RNN-based model and four variants of Transformer: vanilla Transformer, the modified Transformer using self-attention with relative positional encodings (Shaw et al., 2018), our modified Transformer with RNN instead of positional encoding layer, and a mixture of the last two models (§ 5). On ASPEC English-to-Japanese and WMT2014 English-to-German translation tasks, we show that relative information improves Transformer to be more robust to variations in input length.

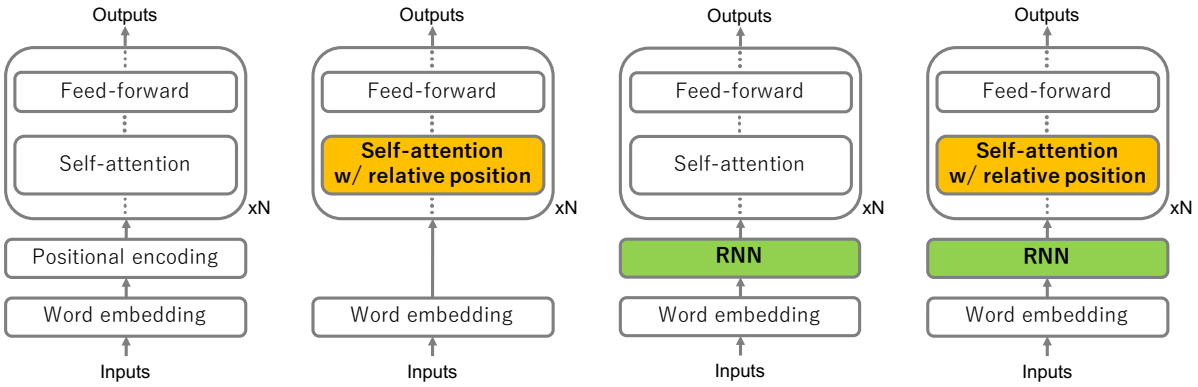
Our contribution is as follows:

- We identified a defect in Transformer. Use of absolute position makes it difficult to translate very long sentences.
- We proposed a simple method to incorporate relative position into Transformer; it gives an additive improvement to the existing model by Shaw et al. (2018) which also incorporates relative position.
- We revealed the overfitting property of Transformer to both short and long sentences.

2 Related Work

Early studies on NMT, at that time RNN-based model, analyze the translation quality in terms of sentence length (Sutskever et al., 2014; Bahdanau et al., 2015; Luong et al., 2015), and a few studies shed light on the details. Shi et al. (2016) examine why RNN-based model generates translations of the right length without special mechanism for the length, and report how LSTM regulates the output length. Koehn and Knowles (2017) reveal that RNN-based model has lower translation quality on very long sentences. Although researchers have proposed various new NMT architecture, they usually evaluate their models only in terms of the overall translation quality and rarely mention how the translation has changed (Gehring et al., 2017; Kalchbrenner et al., 2016; Vaswani et al., 2017). Only a few studies do the analysis on the translation quality in terms of sentence length (Elbayad et al., 2018; Zhang et al., 2019). The robustness of the recent NMT models on very long sentences remains to be assessed.

What we focus on in this study is the word position information which will closely relate to the decodable sentence length. Relative information has been implicitly used in the models using RNN or CNN. Gehring et al. (2017) introduce position embeddings which represent absolute position information to their CNN-based model. Sukhbaatar et al. (2015) introduce another absolute position information, positional encodings, which need no parameter training, and Vaswani et al. (2017) adopt them in their model, Transformer, which has neither RNN nor CNN.



Recently, Shaw et al. (2018) propose to incorporate relative position into Transformer by modifying the self-attention layer while removing positional encodings. Lei et al. (2018) propose a fast RNN named Simple Recurrent Units (SRU) and replace the feed-forward layers of Transformer by SRU considering that recurrent process would better capture sequential information. Although both approaches succeeded in improving BLEU score, the researchers did not report in what respect the models improved the translation.

Chen et al. (2018) propose a RNN-based model, RNMT+, which is based on stacked LSTMs and incorporates some components from Transformer such as layer normalization and multi-head attention. On the other hand, our model is based on Transformer and incorporates RNN into Transformer.

3 Preliminaries

3.1 Transformer

Transformer (Vaswani et al., 2017) is a sequence to sequence model that has an encoder to process and represent input sequence and a decoder to generate output sequence from the encoder outputs. Both the encoder and decoder have a word embedding layer, a positional encoding layer, and

(a) Transformer (Vaswani et al., 2017)

(b) Rel-Transformer (Shaw et al., 2018)

(c) RNN-Transformer Our proposed

(d) RR-Transformer (b) + Our proposed

Figure 1: The architectures of all the Transformer-based models we compare in this study; for simplicity, we show the encoder architectures here since the same modification is applied to their decoders.

stacked encoder/decoder layers. The encoder architecture is shown in Figure 1a.

Word embedding layers encode input words into continuous low-dimension vectors, followed by positional encoding layers that add position information to them. Encoder/decoder layers consist of a few sub-layers, self-attention layer, attention layer (decoder only) and feed-forward layer, with layer normalization (Ba et al., 2016) for each. Both self-attention layer and attention layer employ the same architecture, and we explain the details in § 3.3. Feed-forward layer consists of two linear transformations with a ReLU activation in between. As for the decoder, a linear transformation and a softmax function follow the stacked layers to calculate probabilities of words to output.

Figure 1 illustrates the architectures of all the Transformer-based models we compare in this study including our porposed model which will be introduced in § 4. The model in Shaw et al. (2018) modifies the self-attention layer (§ 3.3).

3.2 Word Position Information

Transformer has positional encoding layers which follow the word embedding layers and capture absolute position. The process of positional encoding layer is to add positional encodings (position vectors) to input word embeddings. The positional encodings are generated using sinusoids of varying frequencies, which is designed to allow the model to attend to relative positions from the periodicity of positional encodings (sinusoids). This is in contrast to the position embeddings (Gehring et al., 2017), a learned position vectors, which are not meant to attend to relative positions. Vaswani et al. (2017) report that both approaches produced nearly identical results in their experiments, and also mentioned that the model with positional encodings may handle longer inputs in testing than those in training, which implies that absolute position approach might have problems at this point.[1]

3.3 Self-attention with Relative Position

Some studies modify Transformer to consider relative position instead of absolute position. Shaw et al. (2018) propose an extension of self-attention mechanism which handles relative position inside in order to incorporate relative position into Transformer. We hereafter refer to their model as Rel-Transformer. In what follows, we explain the self-attention mechanism and their extension.

Self-attention is a special case of general attention mechanism, which uses three elements called query, key and value. The basic idea is to compute weighted sum of values where the weights are computed using the query and keys. Each weight represents how much attention is paid to the corresponding value. In the case of self-attention, the input set of vectors behaves as all of the three elements (query, key and value) using three different transformations. When taking a sentence as input, it is processed as a set in the self-attention.

Self-attention operation is to compute output sequence $z = (z_1, ..., z_n)$ out of input sequence $x = (x_1, ..., x_n)$, where both sequences have the same langth n and $x_i \in \mathbb{R}^{d_x}, z_i \in \mathbb{R}^{d_z}$. The output

[1] Our preliminary experiment confirmed that positional encodings perform better for longer sentences than those in the training data, while position embeddings perform slightly better for the other length.

element z_i is computed as follows.

$$z_i = \sum_{j=1}^{n} \alpha_{ij}(x_j W^V) \quad (1)$$

$$\alpha_{ij} = \frac{\exp e_{ij}}{\sum_{k=1}^{n} \exp e_{ik}} \quad (2)$$

$$e_{ij} = \frac{x_i W^Q (x_j W^K)^T}{\sqrt{d_z}}, \quad (3)$$

where $W^Q, W^K, W^V \in \mathbb{R}^{d_x \times d_z}$ are the matrices that transform input elements into querys, keys, and values, respectively.

The extension proposed by Shaw et al. (2018) adds only two terms to the original self-attention: the relative position vectors $w^K_{j-i}, w^V_{j-i} \in \mathbb{R}^{d_z}$.

$$z_i = \sum_{j=1}^{n} \alpha_{ij}(x_j W^V + w^V_{j-i}) \quad (4)$$

$$\alpha_{ij} = \frac{\exp e_{ij}}{\sum_{k=1}^{n} \exp e_{ik}} \quad (5)$$

$$e_{ij} = \frac{x_i W^Q (x_j W^K + w^K_{j-i})^T}{\sqrt{d_z}}, \quad (6)$$

Note that when using the relative position vectors, the input is processed as a directed graph instead of a set. Maximum distance k is employed to clip the relative distance within a certain distance so that the value of relative distance is limited as $-k < j - i < k$.

4 RNN as a Relative Positional Encoding

The approach by Shaw et al. (2018) is not the only way to incorporate relative position into Transformer. Lei et al. (2018) replace feed-forward layers by their proposed SRU which also incorporates relative position. Both approaches modify the encoder and decoder layers that are repeatedly stacked, which means their models handle position information multiple times. However, the original Transformer does only once at the positional encoding layer which locates shallow layer of the deep layered network.

To conduct a clear comparison of the position information types, we propose another simple method that replaces the positional encoding layer of Transformer by RNN. As the RNN has the nature to handle a sequence using relative position information, it can be used not only as a main processing unit of RNN-based model, but also as a relative positional encoder. While Lei et al. (2018) also employ RNN, they use position embeddings. Our approach is a pure replacement of position information type for Transformer.

In the original Transformer, the positional encoding layer adds the i-th position vector $pe(i) \in \mathbb{R}^{d_{wv}}$ to the i-th input word vector $wv_i \in \mathbb{R}^{d_{wv}}$ and outputs the position informed word vector $wv'_i \in \mathbb{R}^{d_{wv}}$:

$$wv'_i = wv_i + pe(i) \quad (7)$$

In our approach, we adopt RNN, specifically GRU (Cho et al., 2014) in this study, as a relative positional encoder. GRU computes its output or its i-th time hidden state $h_i \in \mathbb{R}^{d_{wv}}$ given the input word vector wv_i and the previous hidden state $h_{i-1} \in \mathbb{R}^{d_{wv}}$, and we take h_i as the position informed word vector wv'_i:

$$h_i = \mathrm{GRU}(wv_i, h_{i-1}) \quad (8)$$

$$wv'_i = h_i \quad (9)$$

Although LSTM (Hochreiter and Schmidhuber, 1997) is more often used as an RNN module in RNN-based models, we employed GRU which has less parameters. This is because, in our approach, RNN is just a positional encoder which we do not expect to work more, even though it can. We refer to our proposed model as RNN-Transformer.

We also consider the mixture of Shaw et al. (2018) and our method to investigate whether the two methods of considering relative position have additive improvements. Although both methods are intended to incorporate relative position into Transformer, they modify different parts of Transformer. By combining both, we can see either of modification suffices to incorporate relative position. We refer to this model as RR-Transformer.

5 Experiments

We conduct two experiments to evaluate our modification to Transformer and to investigate the impact of using relative position in NMT models. The first experiment is a basic translation experiment which uses all the training data. We carry out analysis on the translations generated by the NMT models in terms of sentence length, especially focusing on long sentences. In the second experiment, we control the training data by the sentence length so that the NMT models are trained only on sentences with lengths in a certain range. We also analyze the result in terms of sentence length, focusing on the short sentences.

	Train (orig.)	Dev	Test

Table 1: Number of sentence pairs in the preprocessed corpus.

5.1 Setup

Dataset and Preprocess: We perform a series of experiments on English-to-Japanese and English-to-German translation tasks. For English-to-Japanese translation task, we exploit ASPEC (Nakazawa et al., 2016), a parallel corpus compiled from abstract sections of scientific papers. For English-to-German translation task, we exploit a dataset in WMT2014, which is one of the most common dataset for translation task.

For ASPEC English-to-Japanese data, we used scripts of Moses toolkit[2](ver. 2.2.1) (Koehn et al., 2007) for English tokenization and truecasing, and KyTea[3] (ver. 0.4.2) (Neubig et al., 2011) for Japanese segmentations. Following those word-level preprocess, we further applied SentencePiece (Kudo and Richardson, 2018) to segment texts down to subword level with shared vocabulary size of 16,000. Finally we selected the first 1,500,000 sentence pairs for the poor quality of the latter part, and filtered out sentence pairs with more than 49 subwords in either of the languages.

For WMT2014 English-to-German translation task, we used preprocessed data provided from the Stanford NLP Group,[4] and used newstest2013 and newstest2014 as development and test data, respectively. We also applied SentencePiece to this data to segment into subwords with shared vocabulary size of 40,000. We filtered out the sentence pairs in the same way as the ASPEC. Table 1 shows the number of sentence pairs of preprocessed data.

Figure 2 shows the distributions of the sentences plotted against the length of input sentence. Althought ASPEC data has slightly larger peak at sentence length of 20-29 subwords, both datasets have no big difference in length distributions. The training and test data have almost identical curves.

Model: We compare the following five NMT models:

[2] http://www.statmt.org/moses/

[3] http://www.phontron.com/kytea/

[4] https://nlp.stanford.edu/projects/nmt/

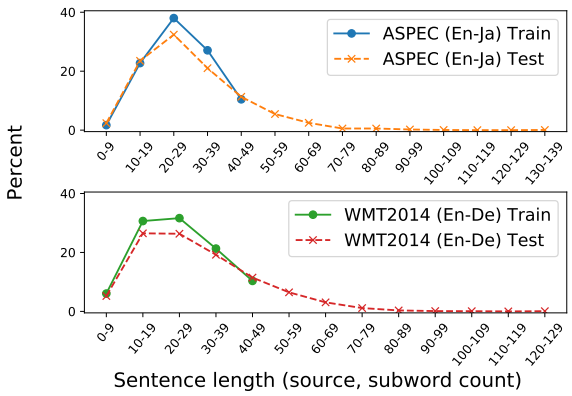

Figure 2: Sentence length ratio of preprocessed corpus.

RNN-NMT is a RNN-based NMT model with dot-attention and input-feeding (Luong et al., 2015). This model consists of four layered bi-directional LSTM for encoder and three layered uni-directional LSTM for decoder.

Transformer is a vanilla Transformer model (the base model in Vaswani et al. (2017)). This model consists of six-layered Transformer encoder and decoder.

Rel-Transformer is a modified version of Transformer by Shaw et al. (2018). Since the modifications do not increase the number of model parameter much, this model consists of the same number of encoder/decoder layers as **Transformer**, with the modified self-attention layer. We set the hyperparameter k, relative distance limit, to 16 following the base model in Shaw et al. (2018).

RNN-Transformer is another modified version of Transformer proposed in § 4. Because the replacement of the original positional encoding layer with RNN increases the number of model parameter, we employ uni-directional GRU as relative positional encoder for both encoder and decoder and reduced the number of decoder layer instead. Our RNN-Transformer model consists of six layered encoder and five layered decoder with one GRU layer for each.[5]

RR-Transformer is the mixture model of Rel-Transformer and RNN-transformer. With the same logic as Rel-Transformer, this model

[5] This configuration was chosen because it performed better than a model with five-layered encoder and six-layered decoder, and was comparable to five-layred encoder and decoder with bi-directional (instead of uni-directional) GRU for the relative position encoder in preliminary experiments.

	ASPEC (En-Ja)	WMT2014 (En-De)
RNN-NMT	70,521,476	107,409,476
Transformer	68,736,644	105,624,644
Rel-Transformer	68,787,332	105,675,332
RNN-Transformer	67,684,484	104,572,484
RR-Transformer	67,730,948	104,618,948

Table 2: Number of the model parameters.

consists of the same number of encoder and decoder layers as RNN-Transformer model, with the modified self-attention layer.

We implemented all the models using PyTorch[6] (ver. 0.4.1). Taking the base model of Transformer (Vaswani et al., 2017) which consists of six-layered encoder and decoder as a reference model, we built the other models to have almost the same number of model parameters for a fair comparison. For all models, we set word embedding dimension and model dimension (or hidden size for RNNs) to 512. For the Transformer-based models, we set feed-forward layer dimension to 2048, and the number of attention head to 8.

Table 2 shows the total number of model parameters for all the models in our implementation. The difference of the numbers by the datasets comes from the difference in vocabulary size.

Training: We used Adam optimizer (Kingma and Ba, 2015) with initial learning rate of 0.0001, and set dropout rate of 0.2 and gradient clipping value of 3.0. We adopted warm-up strategy (Vaswani et al., 2017) for fast convergence with warm-up step of 4k, and trained all the model for 300k steps. The mini-batch size was set to 128.

Evaluation: We performed greedy search for translation with the models, and evaluated the translation quality in terms of BLEU score (Papineni et al., 2002) using `multi-bleu.perl` in the Moses toolkit. We checked model's BLEU score on the development data at every 10k steps during the training, and took the best performing model for evaluation on the test data.

5.2 Long Sentence Translation

Table 3 shows the BLEU scores of the NMT models on the test data of ASPEC English-to-Japanese and WMT2014 English-to-German when using all the preprocessed training data for training. Table 4 lists the results of statistical significance test using bootstrapping of 10,000 samples. The evaluation is done on word-level, which means that we converted the outputs of NMT models from subword-level into word-level before scoring. On both datasets, Transformer outperforms RNN-NMT, and all of the three modified versions of Transformer outperform the Transformer. RNN-Transformer was comparable to Rel-Transformer, and RR-Transformer, the mixture of RNN-Transformer and Rel-Transformer, gives the best score.

	ASPEC (En-Ja)	WMT2014 (En-De) newstest2014
RNN-NMT	36.67	19.95
Transformer	38.44	21.00
Rel-Transformer	39.58	22.51
RNN-Transformer	39.17	22.35
RR-Transformer	**40.34**	**23.01**

Table 3: BLEU scores on test data.

	RNN-NMT	Trans	Rel	RNN	RR
RNN-NMT		$<<$	$<<$	$<<$	$<<$
Trans	$>>$		$<<$	$<<$	$<<$
Rel	$>>$	$>>$		$\sim$	$<$
RNN	$>>$	$>>$	$\sim$		$<<$
RR	$>>$	$>>$	$>>$	$>>$	

Table 4: Results of statistical significance test on ASPEC English-to-Japanese (lower-left) and WMT2014 English-to-German (upper-right): "$>>$" or "$<<$" means $p < 0.01$, "$>$" or "$<$" means $p < 0.05$ and "$\sim$" means $p \geq 0.05$.

In order to see the capability of translating long sentences of the models, we split the test data into different bins according to the length of input sentences, and then calculated BLEU scores on each bin. The following evaluation uses the raw subword-level outputs of the models since the sentence length is based on subwords.

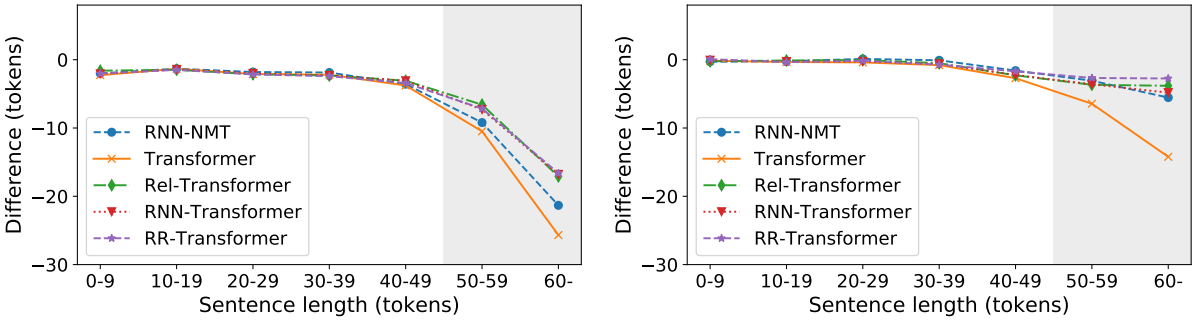

Figure 3a and 3b show the BLEU scores on the split test data of ASPEC English-to-Japanese and WMT2014 English-to-German, respectively. The BLEU score of Transformer, the only model that uses absolute position, more sharply drops than the BLEU scores of the other models at the input length of 50-59, which is outside of the length range of the training data. As for the input length of 60-, Transformer performs the worst among all the models. These results indicate that relative position works better than absolute position in translating sentences longer than those of the training data. Meanwhile, for the lengths with enough

Figure 5: Distributions of output sentence length of Transformer and RR-Transformer.

amount of training data, both position information types seem to work almost equally. On WMT2014 English-to-German, all the models except Transformer successfully keep as good performance in 50-59 and 60- bins as the other bins.

To figure out the effect of position information on the ability of the models to generate output of proper length, we look into the difference of sentence length between the model's output and the reference translation. Figure 4a and 4b show the averaged differences plotted against the input sentence length on both language pairs. We can observe that all the models tend to output shorter sentence than the reference. However, Transformer shows the largest drop at the input length of 50-59 again among all the models, which is even more than RNN-NMT. The difference between Transformer and RNN-Transformer indicates the advantage of relative position against absolute position, while the difference between the three modified Transformer-based models and RNN-NMT indicates the structural advantage of Transformer to RNN-based model in generating translations with appropriate lengths.

	min len.	max len.	# of sentences	# of tokens
Short	2	26	555,922	10,392,775

Long	34	49	740,887	29,841,519

(b) WMT2014 English-to-German

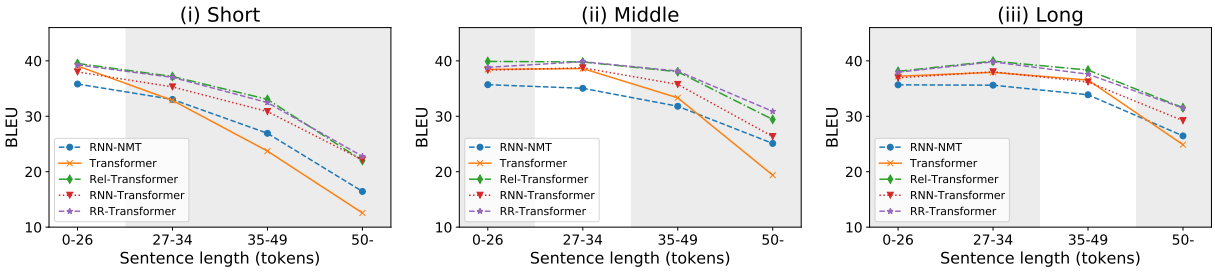
Table 5: Statistics of the split training data.

The above result that the models tend to output shorter sentences suggests that the models may have a limit in the range of output length. To confirm this possibility, we look into the distributions of the model's output length. Figure 5a and 5b show distributions of output length of Transformer and RR-Transformer for the input length of 40-49 (length within the training data) and 50-59 (length outside of the training data). For the input length of 40-49, the distributions of both models are flat and have no big difference. For the input length of 50-59, on the other hand, we can see a sharp peak in the distribution of Transformer in which most of the values distribute around 50 tokens or less. These results indicate that Transformer tends to overfit to a range of length of input sentences.

5.3 Length-Controlled Training Data

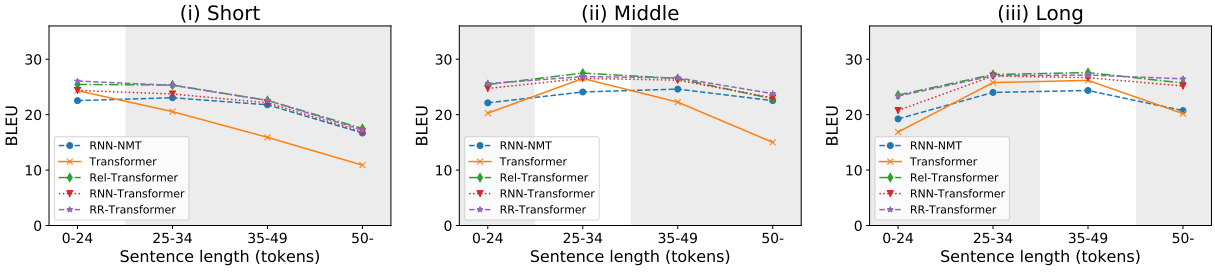
The above experiments focus on trainslation of long sentences, or, strictly speaking, sentences longer than those in the training data. With the use of absolute position, it is no surprise that the model fails to handle longer sentences since those sentences demand the model to handle the position vectors which are never seen during training.

In this section, we focus on short sentences to investigate whether Transformer overfits to the length of input sentences in the training data. Note that position vectors of small numbers are included in long sentences. If the problem is only unseen position vectors, then the model shall be able to handle short sentences because short sentences do not include any unseen position numbers.



To figure out how the NMT models behave on sentences shorter than those in the training data, we conduct another experiment in which the length of the training data is controlled. We split the training data of both ASPEC English-to-Japanese and WMT2014 English-to-German into three portions according to the length of input sentences so that each of them has almost the same number of tokens. We then trained the five NMT models on each of the three training data. We hereafter refer to these three length-controlled training data as Short, Middle and Long. The statistics of these data is summarized in Table 5a and 5b.

To see how the translation quality changes between inside and outside of the length within the training data, we split the test data with respect to the lengths of split training data. Figure 6a and 6b show the BLEU scores on all the three training data of both language pairs. Transformer shows the worst performance among the four Transformer-based models on the sentences longer than those in the training data for any controlled length. However, on the shorter sentences than those in the training data, RNN-Transformer scores almost the same as Transformer on the Middle and Long training data of ASPEC English-to-Japanese and also shows a larger drop than RNN-NMT at length of -24 on the Long training data of WMT2014 English-to-German. This implies that our proposed method to replace absolute positional encoding layer by RNN does not work well in translating shorter sentences.



We can also see that Rel-Transformer and RR-Transformer are quite competitive across all the situations. This suggests that one Transformer decoder layer and two GRUs contribute almost equally to the translation quality.

Figure 7a and 7b show the averaged difference of length between NMT model's output and the reference translation on Long training data of both datasets.[7] These figures indicate that Transformer and RNN-Transformer tend to generate inappropriately long sentences in translating much shorter sentences than those in the training data. As mentioned above, when translating short sentences, there is no unseen positions in Transformer, while there is no concrete position representation in RNN-Transformer; the above results suggest that these two models overfit to the (longer) length of input sentences. In contrast, the result of Rel-

[7] Note that Figure 7a and 7b use different x-axis scale from Figure 6a and 6b in order to show the difference clearly.

Transformer and RR-Transformer indicates that self-attention with relative position prevents this overfitting.

6 Conclusions

In this paper, we examined the relation between position information and the length of input sentences by comparing absolute position and relative position using RNN-based model and variations of Transformer models. Experiments on all the preprocessed training data revealed the crucial weakness of the original Transformer, which uses absolute position, in translating sentences longer than those of the training data. We also confirmed that incorporating relative position into Transformer helps to handle those long sentences and improves the translation quality. Another experiment on the length-controlled training data revealed that absolute position of Transformer causes overfitting to the input sentence length. To conclude, all the experiments suggest to use relative position and not to use absolute position.

Considering that the available data is not balanced in terms of the sentence length in practice, preventing the overfitting is useful for building a practical NMT system.

Abstract

In this paper, we study how word-like units are represented and activated in a recurrent neural model of visually grounded speech. The model used in our experiments is trained to project an image and its spoken description in a common representation space. We show that a recurrent model trained on spoken sentences implicitly segments its input into word-like units and reliably maps them to their correct visual referents. We introduce a methodology originating from linguistics to analyse the representation learned by neural networks – the gating paradigm – and show that the correct representation of a word is only activated if the network has access to first phoneme of the target word, suggesting that the network does not rely on a global acoustic pattern. Furthermore, we find out that not all speech frames (MFCC vectors in our case) play an equal role in the final encoded representation of a given word, but that some frames have a crucial effect on it. Finally, we suggest that word representation could be activated through a process of lexical competition.

1 Introduction

Neural models of Visually Grounded Speech (VGS) sparked interest in linguists and cognitive scientists as they are able to incorporate multiple modalities in a single network and allow the analysis of complex interactions between them. Analysing these models does not only help to understand their technological limitations, but may also yield insight on the cognitive processes at work in humans (Dupoux, 2018) who learn from contextually grounded speech utterances (either visually, haptically, socially, etc.). This is with this idea in mind that one of the first computational model of visually grounded word acquisition was introduced by Roy and Pentland (2002). More recently, Harwath et al. (2016) and Chrupała et al. (2017) were among the first to propose neural models integrating these two modalities.

While Chrupała et al. (2017) and Alishahi et al. (2017) focused on analysing speech representations learnt by speech-image neural models from a phonological and semantic point of view, the present work focuses on lexical acquisition and the way speech utterances are segmented into lexical units by a neural model.

More precisely, we aim at understanding how word-like units are processed by a VGS architecture. First, we study if such models are robust to isolated word stimuli. As such networks are trained on raw speech utterances, robustness to isolated word stimuli would indicate that a segmentation process was implicitly carried out at training time. We also explore which factors influence the most such *word recognition*. In a second step, to better understand how individual words are activated by the network, we adapt the gating paradigm initially introduced to study human word recognition (Grosjean, 1980) where our neural model is inputted with speech segments of increasing duration (*word activation*). Finally, as some linguistic models assume that the first phoneme of a target word activates all the words starting by the same phoneme, we investigate if such a pattern holds true for our neural model as well (*word competition*). As far as we know, no other study has examined patterns of word recognition, activation and competition in models of VGS.

This paper is organised as follows: section 2 presents related works and section 3 details our experimental material (data and model). Our contributions follow in section 4 (word recognition), section 5 (word activation) and section 6 (word competition). Section 7 concludes this work.

2 Related Work

In this section we explore what is known about word recognition in humans. We then review recent works related to the representation of lan-

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 339–348
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

guage in VGS models. A few words are also said about modified inputs and adversarial attacks as they are related to the analysis methodology used in part of this work.

2.1 Word Recognition in Humans

Many psycholinguistic models try to account for how words are activated and recognised from fluent speech. The process of word recognition *"requires matching the spoken input with mental representations associated with word candidates"* (Dahan and Magnuson, 2006). One of the first model trying to account for how humans recognise and extract words from fluent speech is the COHORT model by Marslen-Wilson and Welsh (1978). In this model, word recognition proceeds in 3 steps: *access*, *selection* and *integration*. *Access* denotes the process by which a set of words (a cohort) becomes activated if their onsets are consistent with the perceived spoken input. As soon as a word form becomes inconsistent with the spoken input, it is removed from the initial cohort (*selection* phase). A word is deemed recognised as soon it is the last one standing in the cohort. *Integration* consists in checking if the word's syntactic and semantic properties are consistent with the rest of the utterance. However, COHORT supposes a full match between the perceived input and the word forms and does not account for word frequency in the access phase. REVISED COHORT (Marslen-Wilson, 1987) later relaxed the constraints on the cohort formation to take into account these facts. There is no active competition *per se* between words in the COHORT model. That is, the strength of activation of a word does not depend on the value of the activation of the other words, but only on how well the internalised word form matches the perceived spoken input. TRACE (McClelland and Elman, 1986) is a connectionist model of spoken word recognition consisting of three layers of nodes, where each layer represents a particular linguistic unit (feature, phoneme and word). Layers are linked by exitatory connections (e.g. fricative feature node would activate /f/ phoneme node which would, in turn, activate words starting with this sound), and nodes within a layer are linked by inhibitory connections, thus inducing a real competition between activated words. Contrary to the COHORT model which does not allow words embedded in longer words to be activated, TRACE allows such activation. SHORTLIST (Norris, 1994) is another model which builds upon COHORT and TRACE by taking into consideration other features such as word stress.[1]

To sum up, models of spoken word recognition consider that a set of words matching to a certain extent the spoken input is simultaneously activated and these models involve at some point a form of competition between the set of activated words before reaching the stage of recognition.

2.2 Computational Models of VGS

Roy and Pentland (2002) were among the first to propose a computational model, known as CELL, that integrates both speech and vision to study child language acquisition. However, CELL required both speech and images to be pre-processed, where canonical shapes were first extracted from images and further represented as histograms; and speech was discretised into phonemes. More recently, CNN-based VGS models (Harwath et al., 2016, 2018; Kamper et al., 2019) and RNN-based VGS models (Chrupała et al., 2017) which do not require speech to be discretised into sub-units were introduced. Chrupała et al. (2017) investigated how RNN-based models encode language, and showed such models tend to encode semantic information in higher layers, while form is better encoded in lower layers. Alishahi et al. (2017) studied if such models capture phonological information and showed that some layers do capture such information more accuratly than others. Kádár et al. (2017) introduced *omission scores* to interpret the contribution of individual tokens in text-based VGS models. More recently, Havard et al. (2019) studied the behaviour of attention in RNN-based VGS models and showed that these models tend to focus on nouns and could display language-specific patterns, such as focusing on particules when prompted with Japanese. Recently, Harwath et al. (2018) showed that CNN-based models could reliably map word-like units to their visual referents, and Harwath and Glass (2019) showed such networks were sensitive to diphone transitions and that these were useful for the purpose of word recognition. However, none of the aforementioned works studied the process by which words are recognised and activated. This present work aims at bridging what is known about word activation

[1]For a review of spoken word recognition model, reader can consult Dahan and Magnuson (2006) and Weber and Scharenborg (2012)

and recognition in humans and the computations at work in VGS models.

2.3 Modified Inputs and Adversarial Attacks

As will be shown later, the gating method used in this article modifies the input stimulus to better understand the behaviour of the neural model.

We can draw a parallel with approaches recently introduced to show the vulnerability of deep networks to strategically modified samples (adversarial examples) and to detect their over-sensitivity and over-stability points. It was shown that imperceptible perturbations can fool the neural models to give false predictions. Inspired by the researches for images (Su et al., 2019), efforts on attacking neural networks for NLP applications emerged recently (see Zhang et al. (2019) for a survey). However, while a lot of references can be found for textual adversarial examples, fewer papers addressed adversarial attacks for speech (we can however mention the work of Wu et al. (2014) addressing spoofing attacks in speaker verification and of Carlini and Wagner (2018) attacking *DeepSpeech* end-to-end ASR system).

3 Experimental Settings

3.1 Model Type

Even though the methodologies developed in this work could also be applied to CNN-based VGS models, the present work will solely focus on the analysis of the representations learned by a RNN-based VGS model. Indeed, from a cognitive perspective, RNN-based models are more realistic than CNN-based models as the speech signal – or in our case, a sequence of MFCC vectors – is sequentially processed from left-to-right, whereas in CNN-based models the network processes multiple frames at the same time. This will thus allow us to explore if RNN-based models display human-like behaviour or not.

3.2 Model Architecture

The model we use for our experiment is based on that of Chrupała et al. (2017) and later modified by Havard et al. (2019). It is trained to solve an image retrieval task: given a speech query, the model should retrieve the closest matching image. The model consists of two parts: an image encoder and a speech encoder. The image encoder takes VGG-16 pre-calculated vectors as input instead of raw images. It consists of a dense layer which reduces the 4096 dimensional VGG-16 input vector into a 512 dimensional vector which is then L2 normalised. The speech encoder takes 13 Mel Frequency Cepstral Coefficients (MFCC) vectors instead of raw speech.[2] It consists of a convolutional layer (64 filters of length 6 and stride 3) followed by 5 stacked unidirectional GRU layers (Cho et al., 2014), with 512 units each. Two attention mechanisms (Bahdanau et al., 2015) are used: one after the 1^{st} recurrent layer and one after the 5^{th} recurrent layer. The final vector produced by the speech encoder corresponds to the dot product of the weighted vectors outputted by each attention mechanism. The model is trained to minimise the following triplet loss function as implemented by Chrupała et al. (2017):

$$\mathcal{L}(u,i,\alpha) = \sum_{u,i}\left(\sum_{u'}\max[0,\alpha + d(u,i) - d(u',i)] + \sum_{i'}\max[0,\alpha + d(u,i) - d(u,i')]\right) \quad (1)$$

The loss function encourages the network to minimise the cosine distance d between an image i and its corresponding spoken description u by a given margin α while maximising the distance between mismatching image/utterance pairs. For our experiments, we set $\alpha = 0.2$.

3.3 Data

The data set used for our experiments is based on MSCOCO (Lin et al., 2014). MSCOCO is a data set used to train computer vision systems, and features annotated images, each paired with 5 human written descriptions in English. MSCOCO's images where selected so that the images would contain instances of 80 possible object categories. We trained our model on the spoken extension introduced by Chrupała et al. (2017). This extension provides spoken version of the human written captions. It is worth mentioning that this extended data set features synthetic speech (female voice generated using Google's Text-To-Speech (TTS) system) and not real human speech.

[2] 12 mel frequency cepstral coefficients + log of total frame energy, vectors extracted every 10ms on a 25ms window

3.4 Model Training and Results

We trained our model for 15 epochs with Adam optimiser and an initial learning rate of 0.0002. The training set comprises 113,287 images with 5 spoken captions per image. Validation and test set comprise 5000 images each.[3] Model is evaluated in term of Recall@k (R@k) and median rank $\widetilde{r}$. That is, given a spoken query, which corresponds to a full utterance, we evaluate the model's ability to rank the unique paired image in the top k images. We obtain a $\widetilde{r}$ of 28.

Full results are shown in Table 1. Even though our results are lower than the original implementation by Chrupała et al. (2017), our model still performs far above chance level, showing it did learn how to map an image and its spoken description.

Model	R@1	R@5	R@10	$\widetilde{r}$
Synth. COCO	0.056	0.182	0.284	28

Table 1: Recall at 1, 5, and 10 results and median rank $\widetilde{r}$ on a speech-image retrieval task (test part of our datasets with 5k images). Chrupała et al. (2017) with RHN reports median rank $\widetilde{r} = 13$. Chance median rank $\widetilde{r}$ is 2500.5.

4 Word Recognition

Harwath et al. (2018) observed that CNN-based models can reliably map word-like units to their corresponding visual reference. Chrupała et al. (2017) and more recenlty Merkx et al. (2019) showed that RNN-based utterance embeddings contain information about individual words, but did not show for what type of words this behaviour holds true and if the model had learnt to map these individual words to their visual referents. Havard et al. (2019) showed that the attention mechanism of RNN-based VGS models tends to focus on the end of words that correspond to the main concept of the target image. This suggests that such models are able to isolate the target word forms from fluent speech and thus segment their inputs into sub-units. In the following experiment we test if a RNN-based VGS network can reliably map isolated word-like units to their visual referents and explore the factors that could influence such mapping.

[3]The train/dev/test correspond to those used in (Chrupała et al., 2017)

4.1 Isolated Word Mapping

We selected a set of 80 words corresponding to the name of 80 object categories in the MSCOCO data set.[4] We expect our model to be very efficient with the selected 80 words, as these are the main objects featured in MSCOCO. We generated speech signals for these 80 isolated words using Google's TTS system and then extracted MFCC features for each of the generated words. We evaluate the ability of the model to rank images containing an object instance corresponding to the target word among the first 10 images (P@10).[5] Contrary to (Chrupała et al., 2017) who uses Recall@k, we use Precision@k as there are several images that correspond to a single target word. It is to be noted that at training time, the network was only given full captions and not isolated words. Thus, if the network is able to retrieve images featuring instances of the target word, it shows that implicit segmentation was carried out at training time.

Results are shown in Figure 1. 40 words out of the 80 target words have a P@10$\geq$ 0.8. This shows that the network is able to map isolated words to their visual referent despite never having seen them in isolation and that the network implicitly segmented its input into sub-units.

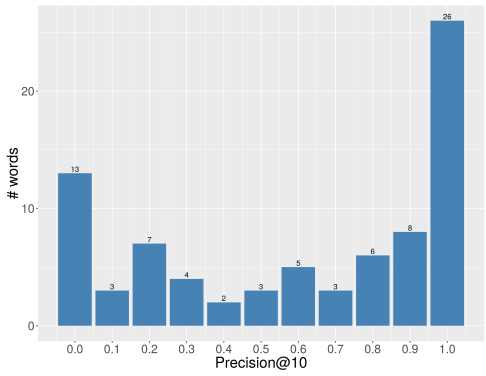

Figure 1: Precision@10 for the 80 isolated words corresponding to MSCOCO categories.

4.2 Factors Influencing Word Mapping

We explore here the factors that could come at play in the recognition of isolated words. We explore 2 types of factors: speech related factors and image related factors. For the former we consider

[4]List available at https://github.com/amikelive/coco-labels/blob/master/coco-labels-2014_2017.txt

[5]Evaluation is performed on the test set containing 5000 images

		Spearman's ρ	p-value	Effect
Images	Avg. Neighbour	-0.3906	0.0003 ***	Weak
	Avg. Size	0.3154	0.0043 **	Weak
	Avg. Freq	0.1187	0.4675	None
Text	Word Freq.	0.5514	1.148e-07 ***	Moderate
	# Syllables	-0.1211	0.2844	None

Table 2: Factors influencing word recognition performance in our model. Spearman's ρ between Precision@10 and mentioned variables as well as p-value.

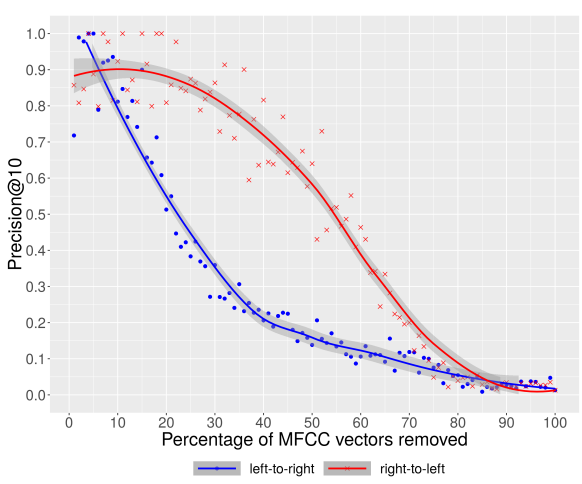
word frequency (Word Freq.) and word length (# syllables). Concerning image related factors we consider object instances frequency in the images (Avg. Freq.), average number of neighbouring object instances (Avg. Neighbour), average area of each object (Avg. Size). Results are shown in Table 2. We observe a weak negative correlation between precison and average number of neighbouring objects, thus suggesting that objects that have a low number of neighbouring objects are better recognised by the network. It also seems that bigger objects yield better precison than smaller objects as we observe a weak positive correlation. Word frequency seems to play an important role as we observe a moderate positive correlation. However, we observe no correlation between precison and the length of the target words nor with object frequency in the images. Correlation values, however, remain relatively low, suggesting some other factors could also influence word recognition.

5 Word Activation

In this section we describe how individual words are activated by the network. To do so, we perform an ablation experiment (similar to that of Grosjean (1980) which was conducted on humans) where the neural model is inputted only with a truncated version of the 80 target words (see Section 5.1). Such a method is also called *gating* in the literature.

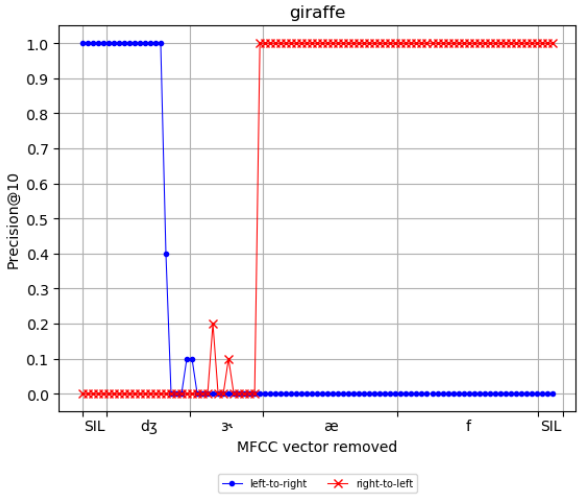
5.1 Gating

The gating paradigm *"involves the repeated presentation of a spoken stimulus (in this case, a word) such that its duration from onset is increased with each successive presentation"* (Cotton and Grosjean, 1984). In our case, it means the neural model is fed with truncated version of a target word, each truncated version comprising a larger part of the target word. Truncation is either done left-to-right (model only has access to the end of the word) or right-to-left (model only has access to the beginning of the word). Truncation is operated on the MFCC vectors computed for each individual word, meaning that MFCC vectors are iteratively removed either from the beginning of the word or the end of the word, but not from both sides at the same time. Each truncated version of the word is then fed to the speech encoder which outputs an embedding vector. As in our previous experiment, model is evaluated in terms of P@10.



COHORT model, in its initial version (Marslen-Wilson, 1987), stipulates that word onset plays a crucial role in word recognition whereas other models of spoken word recognition give less importance to word onset. This importance of exact word onset matching was later revised in later COHORT models. The aim of this experiment is to test whether word onset plays a role in word recognition for the network or not. If it is the case, we expect the network to fail recovering images of the target word if the word is truncated left-to-right.

Figure 2a shows evolution of P@10 averaged over the 80 test words. As can be seen from the graph, precision evolves differently according to which part of the word was truncated. When the target words are truncated left-to-right, precision drops quickly. However, when truncated right-to-left, precision remains high before gradually dropping. These results show that the model is robust to truncation when it is carried out right-to-left but not when it is carried out left-to-right. Figure 2b shows the evolution of P@10 for one of the target words ("giraffe"). When MFCC vectors corresponding to the first phoneme are removed (/ʤ/), precision plummets from 1 to 0. However, when MFCC vectors belonging to the end of the word are removed, precision plateaus at 1 until /ɜˑ/ is reached and then plunges to 0. This shows the model successfully retrieved giraffe images when only prompted with /ʤɜˑ/ but not when prompted with /ɜˑæf/ even though the latter comprises a longer part of the target word.



These results suggest that the model does not rely on a vague acoustic pattern to activate the semantic representation of a given concept, but needs to have access to the first phoneme in order to yield an appropriate representation.

5.2 Activated Pseudo-Words

Such ablation experiments also enables us to infer on what units the network relies to make its predictions. Indeed, Figure 3 allows us to see what

(a)

(b)

Figure 2: 2a Evolution of Precision@10 averaged over 80 test words as a function of the percentage of MFCC vector removed for each word. 2b Evolution of Precision@10 for each ablation step of the word "giraffe", with time-aligned phonemic transcription /dʒɜɹæf/ at the bottom. "SIL" signals silences. For both 2a and 2b, blue line displays scores when ablation was carried out left-to-right, meaning that at any given part on the blue curve, model has only had access to the rightmost part of the word. (e.g. /ɜɹæf/ without initial /dʒ/). Red line displays scores when ablation was carried out right-to-left, meaning that at any given part on the red curve, model has only had access to the leftmost part of the word. (e.g. /dʒɜɹ/ without final /æf/).

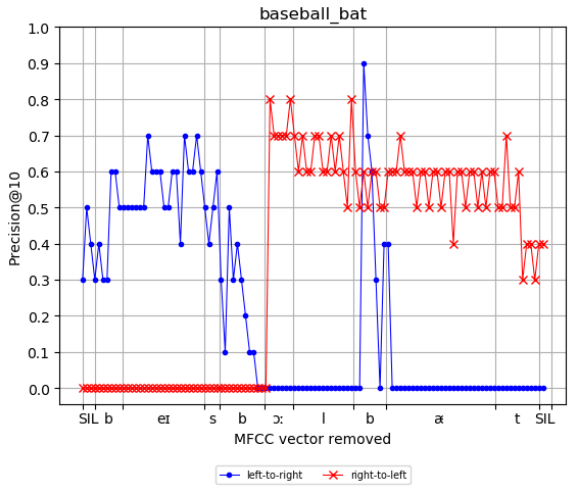


Figure 3: Evolution of P@10 for each ablation step of the word "baseball bat" with time aligned phonemic transcription /beizbɔːl#bæt/ at the bottom.

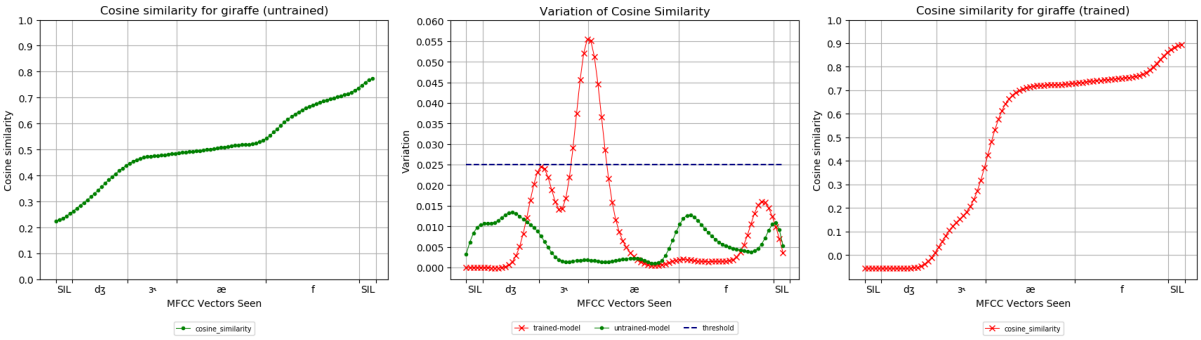


are the pseudo-words that were internalised by the network for the word "baseball bat". When truncation is done left-to-right (blue curve), we notice that at the beginning precision is quite high (≈ 0.6), then reaches 0 when only /ɔːlbæt/ is left, but suddenly increases up to 0.9 when the only part left is /bæt/. This suggests that the network mapped both "baseball bat" as a whole and "bat" as referring to the same object. We observed the same pattern for the word "fire hydrant" where both "fire hydrant" and "hydrant" are mapped to the same object.

However, Figure 2b shows that when only prompted with /dʒɜɹ/ the network manages to find pictures of giraffes. This suggests that the pseudo-words internalised by the network could be /dʒɜɹæf/ as a whole but might also be /dʒɜɹ/. We thus need to take caution when stating that the network has isolated words, as the words internalised by the network might not always match the human gold reference.

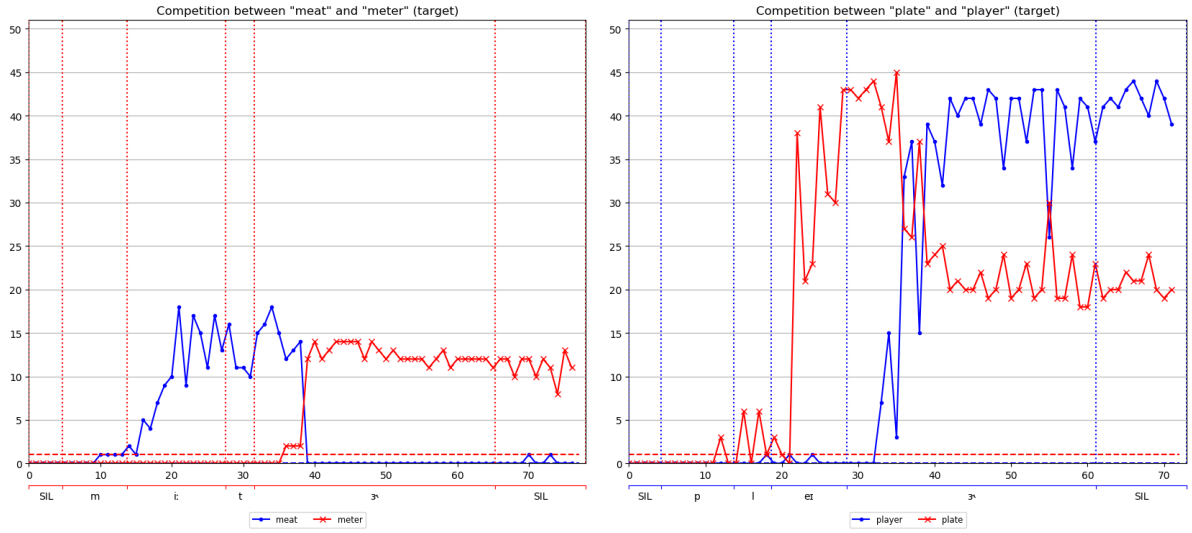
5.3 Gradual or Abrupt Activation?

Figure 2b shows that removing or adding one MFCC vector may yield large differences in the network performance. Precision decreases steeply and not steadily. This suggests that little acoustic differences yield wide differences in the final representation. Thus, in this section we analyse how representation is being constructed over time and explore if some MFCC vectors play a more important role than others in the activation of the final representation.

We progressively let the network see more and more of the MFCC vectors composing the word, iteratively feeding it with MFCC vectors starting from the beginning of the word until the network

(a) (b) (c)

Figure 4: Figure 4a shows evolution of the cosine similarity between the embeddings produced for each truncated version of the target word and the embedding for the full word using a model with randomly initialised weights. Figure 4c shows the same measure with the embeddings produced by a trained model. Figure 4b shows peaks indicating the inflection points of curve 4a (green) and 4c (red). For our experiments, we only considered inflection point to be significant if the resulting peak was higher than 0.025 (blue).



has had access to the full word. We then compute the cosine similarity between the embedding computed for each of the truncated version of the word and the embedding corresponding to the full word. The closer the cosine similarity is to 1, the more similar the two representations are. Thus, if each MFCC vector equally contributes to the final representation of the word, we expect cosine similarity to evolve linearly. However, if some MFCC vectors have a determining factor in the final representation we expect cosine similarity to evolve in steps rather than linearly. To detect steps that could occur in the evolution of cosine similarity, we approximate its derivative by computing first order difference. High steps should thus translate into peaks (e.g. Figure 4b). We compute the evolution of cosine similarity for the 80 target words encoded with the best trained model (e.g. Figure 4c) and also consider a baseline evolution by encoding the 80 target words with an untrained model (e.g. Figure 4a).[6] To avoid micro-steps of yielding peaks and thus creating noise, we smooth cosine evolution curves with a gaussian filter. We consider peaks higher than 0.025 as translating a high step in the evolution of cosine similarity.

On average, they are 1.35 peaks per word for the trained model against 0.1 peak per word for our baseline condition (untrained model), showing that cosine evolution is linear in the latter but not in the former. Thus, in our baseline condition (untrained model), each MFCC vector equally contributes to the final representation, whereas in our trained model some MFCC vectors are more decisive for the final representation than others. Indeed, some MFCC vectors trigger a high step in the cosine evolution suggesting that the embedding suddenly gets closer to its final value. Figure 4c shows the evolution of the cosine similarity for the word "giraffe". As it can be seen, cosine similarity does not tend linearly towards 1, but rather evolves in steps. Adding the MFCC vectors corresponding to the transition from /ɜɹ/ to /æ/ triggers a large difference in the embedding as the cosine similarity suddenly jumps to a higher value, showing it is getting closer to its final representation. However, cosine similarity plateaus once /æ/ is reached up until final silence, suggesting the final /æf/ plays little to no role in the final representation of the word.

6 Word Competition

As presented in Section 2.1, some linguistic models assume that the first phoneme of target word activates all the words starting by the same phoneme. The words that are activated but which do not correspond to the target words are called "competitors". As the listener perceives more and more of the target word some competitors are deactivated as they do not match what is being perceived. For example, considering the following lexicon: /beɪbi/ (baby), /beɪzɪk/ (basic), and /beɪzbɔːl/ (baseball), the first sound /b/ would activate all three words, once /beɪz/ is reached, "baby" would not be considered a competitor anymore, and once /beɪzb/ is reached the only word activated would be "baseball" as it is the only word whose beginning corresponds the perceived sounds.

[6] Thus consisting only of randomly initialised weights

(a) (b)

Figure 5: Illustration of lexical competition between 5a "meat" and "meter" (target) and 5b "plate" and "player" (target). Numbers in 1^{st} x-axis corresponds to the number of MFCC frames; 2^{nd} x-axis corresponds to time-aligned phonemic transcription of the target word; y-axis shows number of images for which at least one caption (out of 5) contains the target or competitor word. Vertical colour bars are projection of phoneme boundaries of the target word. Horizontal colour bars show chance score for each word (<2).

We test if the network displays such lexical competition patterns. To do so, we select a set of 29 word pairs according to the following criteria: i) words should at least appear 400 times or more in the captions of the training set, so that the network would have been able to learn a mapping between this word and its referent; ii) words forming a pair should at least start with the same phoneme;[7] iii) words should not be synonyms and clearly refer to a different visual object (thus excluding pairs such as "motorcycle" and "motorbike").

For each word pair, we select the longest word as target and progressively let the network see more and more of the MFCC vectors composing this word (as in Section 5.3). At each time step the network produces an embedding, which we use to rank the images from the closest matching image to the least matching image.[8] Then, for the 50 closest matching images, we check if at least one of the caption contains either the target word or the competitor. As the competitor is embedded in the longer word, we expect the network to produce an embedding close to that of the competitor at the beginning and then when the acoustic signal does not match the competitor anymore, we expect the network to be able to find only the target word.

Figure 5 shows example of competition between two word pairs. Figure 5a shows that when prompted with the beginning of the word "meter" /miːt/ the representation activated by the network is close to that of "meat" as the closest maching images's captions contain the word "meat". Representation of the word "meter" seems to be activated only when /ɜː/ is reached, and consequently triggers the total deactivation of the word "meat". Figure 5b displays a different pattern. As in the previous example, the beginning of the word "player" /pleɪ/ triggers the activation of the word "plate". When /ɜː/ is reached, the target word becomes activated and competitor "plate" starts to deactivate. However, the deactivation is not full, so that when the whole word "player" is entirely processed by the network, the word "plate" still remains highly activated. (REVISED) COHORT (Marslen-Wilson and Welsh, 1978; Marslen-Wilson, 1987) and TRACE (McClelland and Elman, 1986) both state that competing words are all activated at the same time, that is when the first phoneme is perceived. However here, the two competing words are activated sequentially but not at the same time. Also, in some cases, competing words that do not match the input anymore still remain highly activated.

[7] Phonemic transcription found in CMU Pronouncing Dictionnary was used

[8] That is, we compute the cosine distance between the embedding produced at time step t and all the images (5000) of our collection.

7 Conclusion

In this paper, we analysed the behaviour of a model of VGS and showed that a RNN-based model of VGS is able to map isolated words to their visual referents. This result is in line with previous results, such as that of Harwath and Glass (2019) which uses a CNN-based network. This shows that such models perform an implicit segmentation of the spoken input in order to extract the target words. However, the mechanism by which implicit segmentation is carried out and what cues are being used is still to be explained. We also demonstrated that not all words are equally well recognised and showed that word frequency and number of neighbouring object in an image partly explain this phenomenon.

Also, we introduced a methodology originating from linguistics to analyse the representation learned by neural networks: the gating paradigm. This enabled us to show that the beginning of a word can activate the representation of a given concept (e.g. /ʤɜ/ for "giraffe"). We explain this by the fact that the network has to handle a very small lexicon, where word forms rarely overlap and thus the network needs not see the full word to make its decision. More importantly, we showed that the network needs to have access to the first phoneme in order to activate the representation of the target word, thus showing that it does not respond to a vague acoustic pattern. Word onsets thus play a crucial role in the process of word activation and recognition for our network. Though word onsets are also important for humans, they are not as crucial as for our network. Indeed, humans are able to recover the missing information. In future work, we would like to test if sentential context has an effect in word recognition. We also demonstrated that our model is able to map multiple pseudo-words to the same referent such as humans do (Section 5.2). However, it is not clear how and when acoustics interface with meaning and this still remains an open question.

Finally, we showed that there is a form of lexical competition in the network. Indeed, small words embedded in longer words are activated. However, we showed that, contrary to humans where words sharing the same beginning are all activated at the same time, words are activated sequentially by the network. Also, some stay partially activated eventhough the input does not match that of the activated word.

Ultimately, we would like to highlight the fact that the gating paradigm could also by applied to understand the temporal dynamics of the representations learned by other speech architectures such as those used in speech recognition for instance.

EQUATE : A Benchmark Evaluation Framework for Quantitative Reasoning in Natural Language Inference

Abstract

Quantitative reasoning is a higher-order reasoning skill that any intelligent natural language understanding system can reasonably be expected to handle. We present EQUATE[1] (Evaluating Quantitative Understanding Aptitude in Textual Entailment), a new framework for quantitative reasoning in textual entailment. We benchmark the performance of 9 published NLI models on EQUATE, and find that on average, state-of-the-art methods do not achieve an absolute improvement over a majority-class baseline, suggesting that they do not implicitly learn to reason with quantities. We establish a new baseline Q-REAS that manipulates quantities symbolically. In comparison to the best performing NLI model, it achieves success on numerical reasoning tests (+24.2%), but has limited verbal reasoning capabilities (-8.1%). We hope our evaluation framework will support the development of models of quantitative reasoning in language understanding.

1 Introduction

Numbers play a vital role in our lives. We reason with numbers in day-to-day tasks ranging from handling currency to reading news articles to understanding sports results, elections and stock markets. As numbers are used to communicate information accurately, reasoning with them is an essential core competence in understanding natural language (Levinson, 2001; Frank et al., 2008; Dehaene, 2011). A benchmark task in natural language understanding is natural language inference (NLI)(or recognizing textual entailment (RTE)) (Cooper et al., 1996; Condoravdi et al., 2003; Bos and Markert, 2005; Dagan et al., 2006), wherein a model determines if a natural language hypothesis can be justifiably inferred from a given premise[2]. Making such inferences often necessitates reasoning about quantities.

RTE-QUANT
P: After the deal closes, Teva will generate sales of about $ 7 billion a year, the company said.
H: Teva earns $ 7 billion a year.
AWP-NLI
P: Each of farmer Cunningham's 6048 lambs is either black or white and there are 193 white ones.
H: 5855 of Farmer Cunningham's lambs are black.
NEWSNLI
P: Emmanuel Miller, 16, and Zachary Watson, 17, are charged as adults, police said.
H: Two teen suspects charged as adults.
REDDITNLI
P: Oxfam says richest one percent to own more than rest by 2016.
H: Richest 1% To Own More Than Half Worlds Wealth By 2016 Oxfam.

Table 1: Examples from evaluation sets in EQUATE

Consider the following example from Table 1,

P: With 99.6% of precincts counted , Dewhurst held 48% of the vote to 30% for Cruz .
H: Lt. Gov. David Dewhurst fails to get 50% of primary vote.

To conclude the hypothesis is inferable, a model must reason that since 99.6% precincts are counted, even if all remaining precincts vote for Dewhurst, he would fail to get 50% of the primary vote. Scant attention has been paid to building datasets to evaluate this reasoning ability. To address this gap, we present EQUATE (Evaluating Quantity Understanding Aptitude in Textual Entailment) (§3), which consists of five evaluation sets, each

*The first two authors contributed equally to this work.
[1]Code and data available at https://github.com/AbhilashaRavichander/EQUATE.
[2]Often, this is posed as a three-way decision where the hypothesis can be inferred to be true (entailment), false (contradiction) or cannot be determined.

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 349–361
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

featuring different facets of quantitative reasoning in textual entailment (Table 1) (including verbal reasoning with quantities, basic arithmetic computation, dealing with approximations and range comparisons.).

We evaluate the ability of existing state-of-the-art NLI models to perform quantitative reasoning (§4.1), by benchmarking 9 published models on EQUATE. Our results show that most models are incapable of quantitative reasoning, instead relying on lexical cues for prediction. Additionally, we build Q-REAS , a shallow semantic reasoning baseline for quantitative reasoning in NLI (§4.2). Q-REAS is effective on synthetic test sets which contain more quantity-based inference, but shows limited success on natural test sets which require deeper linguistic reasoning. However, the hardest cases require a complex interplay between linguistic and numerical reasoning. The EQUATE evaluation framework makes it clear where this new challenge area for textual entailment stands.

2 Related Work

NLI has attracted community-wide interest as a stringent test for natural language understanding (Cooper et al., 1996; Fyodorov; Glickman et al., 2005; Haghighi et al., 2005; Harabagiu and Hickl, 2006; Romano et al., 2006; Dagan et al., 2006; Giampiccolo et al., 2007; Zanzotto et al., 2006; Malakasiotis and Androutsopoulos, 2007; MacCartney, 2009; de2; Dagan et al., 2010; Angeli and Manning, 2014; Marelli et al., 2014). Recently, the creation of large-scale datasets (Bowman et al., 2015; wil; Khot et al., 2018) spurred the development of many neural models (Parikh et al., 2016; Nie and Bansal, 2017; Conneau et al., 2017; Balazs et al., 2017; Chen et al., 2017a; Radford et al., 2018; Devlin et al., 2018).

However, state-of-the-art models for NLI treat the task like a matching problem, which appears to work in many cases, but breaks down in others. As the field moves past current models of the matching variety to ones that embody more of the reasoning we know is part of the task, we need benchmarks that will enable us to mark progress in the field. Prior work on challenge tasks has already made headway in defining tasks for subproblems such as lexical inference with hypernymy, co-hyponymy, antonymy (Glockner et al., 2018; Naik et al., 2018). In this work, we specifically probe into quantitative reasoning.

De Marneffe et al. (2008) find that in a corpus of real-life contradiction pairs collected from Wikipedia and Google News, *29%* contradictions arise from numeric discrepancies, and in the RTE-3 (Recognizing Textual Entailment) development set, numeric contradictions make up 8.8% of contradictory pairs. Naik et al. (2018) find that model inability to do numerical reasoning causes 4% of errors made by state-of-the-art models. Sammons et al. (2010); Clark (2018) argue for a systematic knowledge-oriented approach in NLI by evaluating specific semantic analysis tasks, identifying quantitative reasoning in particular as a focus area. Bentivogli et al. (2010) propose creating specialized datasets, but feature only 6 examples with quantitative reasoning. Our work bridges this gap by providing a more comprehensive examination of quantitative reasoning in NLI.

While to the best of our knowledge, prior work has not studied quantitative reasoning in NLI, Roy (2017) propose a model for a related subtask called *quantity entailment*, which aims to determine if a given quantity can be inferred from a sentence. In contrast, our work is concerned with general-purpose textual entailment which considers if a given *sentence* can be inferred from another. Our work also relates to solving arithmetic word problems (Hosseini et al., 2014; Mitra and Baral, 2016; Zhou et al., 2015; Upadhyay et al., 2016; Huang et al., 2017; Kushman et al., 2014a; Koncel-Kedziorski et al., 2015; roy; Roy, 2017; Ling et al., 2017a). A key difference is that word problems focus on arithmetic reasoning, while the requirement for linguistic reasoning and world knowledge is limited as the text is concise, straightforward, and self-contained (Hosseini et al., 2014; Kushman et al., 2014b). Our work provides a testbed that evaluates basic arithmetic reasoning while incorporating the complexity of natural language.

Recently, Dua et al. (2019) also recognize the importance of quantitative reasoning for text understanding. They propose DROP, a reading comprehension dataset focused on a limited set of discrete operations such as counting, comparison, sorting and arithmetic. In contrast, EQUATE features diverse phenomena that occur naturally in text, including reasoning with approximation, ordinals, implicit quantities and quantifiers, requiring NLI models to reason comprehensively about the interplay between quantities and language. Ad-

ditionally, through EQUATE we suggest the inclusion of controlled synthetic tests in evaluation benchmarks. Controlled tests act as basic validation of model behaviour, isolating model ability to reason about a property of interest.

3 Quantitative Reasoning in NLI

Our interpretation of "quantitative reasoning" draws from cognitive testing and education (Stafford, 1972; Ekstrom et al., 1976), which considers it "verbal problem-solving ability". While inextricably linked to mathematics, it is an inclusive skill involving everyday language rather than a specialized lexicon. To excel at quantitative reasoning, one must interpret quantities expressed in language, perform basic calculations, judge their accuracy, and justify quantitative claims using verbal and numeric reasoning. These requirements show a reciprocity: NLI lends itself as a test bed for quantitative reasoning, which conversely, is important for NLI (Sammons et al., 2010; Clark, 2018). Motivated by this, we present the EQUATE (Evaluating Quantity Understanding Aptitude in Textual Entailment) framework.

3.1 The EQUATE Dataset

EQUATE consists of five NLI test sets featuring quantities. Three of these tests for quantitative reasoning feature language from real-world sources such as news articles and social media (§3.2; §3.3; §3.4). We focus on sentences containing quantities with numerical values, and consider an entailment pair to feature quantitative reasoning if it is at least one component of the reasoning required to determine the entailment label (but not necessarily the only reasoning component). Quantitative reasoning features quantity matching, quantity comparison, quantity conversion, arithmetic, qualitative processes, ordinality and quantifiers, quantity noun and adverb resolution[3] as well as verbal reasoning with the quantity's textual context[4]. Appendix B gives some examples for these quantitative phenomena. We further filter sentence pairs which require only temporal reasoning, since specialized knowledge is needed to reason about time. These three test sets contain pairs which conflate multiple lexical and quantitative reasoning phenomena. In order to study aspects of quantitative reasoning in isolation, EQUATE further features two controlled synthetic tests (§3.5; §3.6).

3.2 RTE-Quant

This test set is constructed from the RTE subcorpus for quantity entailment (Roy, 2017), originally drawn from the RTE2-RTE4 datasets (Dagan et al., 2006). The original sub-corpus conflates temporal and quantitative reasoning. We discarded pairs requiring temporal reasoning, obtaining a set of 166 entailment pairs.

3.3 NewsNLI

This test set is created from the CNN corpus (Hermann et al., 2015) of news articles with abstractive summaries. We identify summary points with quantities, filtering out temporal expressions. For a summary point, the two most similar sentences[5] from the article are chosen, flipping pairs where the premise begins with a first-person pronoun (eg:⟨"He had nine pears", "Bob had nine pears"⟩ becomes ⟨"Bob had nine pears", "He had nine pears"⟩). The top 50% of similar pairs are retained to avoid lexical overlap bias. We crowdsource annotations for a subset of this data from Amazon Mechanical Turk. Crowdworkers[6] are shown two sentences and asked to determine whether the second sentence is definitely true, definitely false, or not inferable given the first. We collect 5 annotations per pair, and consider pairs with lowest token overlap between premise and hypothesis and least difference in premise-hypothesis lengths when stratified by entailment label. Top 1000 samples meeting these criteria form our final set. To validate crowdsourced labels, experts are asked to annotate 100 pairs. Crowdsourced gold labels match expert gold labels in 85% cases, while individual crowdworker labels match expert gold labels in 75.8%. Disagreements are manually resolved by experts and examples not featuring quantitiative reasoning are filtered, leaving a set of 968 samples.

3.4 RedditNLI

This test set is sourced from the popular social forum \reddit[7]. Since reasoning about quanti-

[3] Such as the quantities represented in *dozen*, *twice*, *teenagers*.

[4] For example, ⟨Obama cuts tax rate to 28%, Obama wants to cut tax rate to 28% as part of overhaul⟩.

[5] According to Jaccard similarity.

[6] We require crowdworkers to have an approval rate of 95% on at least 100 tasks and pass a qualification test.

[7] According to the Reddit User Agreement, users grant Reddit the right to make their content available to other organizations or individuals.

Source	Test Set	Size	Classes	Data Source	Annotation Source	Quantitative Phenomena
Natural	RTE-Quant	166	2	RTE2-RTE4	Experts	Arithmetic, Ranges, Quantifiers
	NewsNLI	968	2	CNN	Crowdworkers	Ordinals, Quantifiers, Arithmetic, Approximation, Magnitude, Ratios
	RedditNLI	250	3	Reddit	Experts	Range, Arithmetic, Approximation, Verbal
Synthetic	Stress Test	7500	3	AQuA-RAT	Automatic	Quantifiers
	AwpNLI	722	2	Arithmetic Word Problems	Automatic	Arithmetic

Table 2: An overview of test sets included in EQUATE. RedditNLI and Stress Test are framed as 3-class (entailment, neutral, contradiction) while RTE-Quant, NewsNLI and AwpNLI are 2-class (entails=yes/no). RTE 2-4 formulate entailment as a 2-way decision. We find that few news article headlines are contradictory, thus NewsNLI is similarly framed as a 2-way decision. For algebra word problems, substituting the wrong answer in the hypothesis necessarily creates a contradiction under the event coreference assumption (De Marneffe et al., 2008), thus it is framed as a 2-way decision as well.

ties is important in domains like finance or economics, we scrape all headlines from the posts on \r\economics, considering titles that contain quantities and do not have meta-forum information. Titles appearing within three days of each other are clustered by Jaccard similarity, and the top 300 pairs are extracted. After filtering out nonsensical titles, such as concatenated stock prices, we are left with 250 sentence pairs. Similar to RTE, two expert annotators label these pairs, achieving a Cohen's kappa of 0.82. Disagreements are discussed to resolve final labels.

3.5 Stress Test

We include the numerical reasoning stress test from (Naik et al., 2018) as a synthetic sanity check. The stress test consists of 7500 entailment pairs constructed from sentences in algebra word problems (Ling et al., 2017b). Focusing on quantifiers, it requires models to compare entities from hypothesis to the premise while incorporating quantifiers, but does not require them to perform the computation from the original algebra word problem (eg: ⟨"NHAI employs 100 men to build a highway of 2 km in 50 days working 8 hours a day","NHAI employs less than 700 men to build a highway of 2 km in 50 days working 8 hours a day"⟩).

3.6 AwpNLI

To evaluate arithmetic ability of NLI models, we repurpose data from arithmetic word problems (roy). They have the following characteristic structure. First, they establish a world and optionally update its state. Then, a question is posed about the world. This structure forms the basis of our pair creation procedure. World building and update statements form the premise. A hypothesis template is generated by identifying modal/auxiliary verbs in the question, and subsequent verbs, which we call secondary verbs. We identify the agent and conjugate the secondary verb in present tense followed by the identified unit to form the final template (for example, the algebra word problem 'Gary had 73.0 dollars. He spent 55.0 dollars on a pet snake. How many dollars did Gary have left?' would generate the hypothesis template 'Agent(Gary) Verb(Has) Answer(18.0) Unit(dollars) left'). For every template, the correct guess is used to create an entailed hypothesis. Contradictory hypotheses are created by randomly sampling a wrong guess ($x \in \mathbb{Z}^+$ if correct guess is an integer, and $x \in \mathbb{R}^+$ if it is a real number) [8]. We check for grammaticality, finding only 2% ungrammatical hypotheses, which are manually corrected leaving a set of 722 pairs.

4 Models

We describe the 9 NLI models[9] used in this study, as well as our new baseline. The interested reader is invited to refer to the corresponding publications for further details.

4.1 NLI Models

1) **Majority Class (MAJ):** Simple baseline that always predicts the majority class in test set.

[8] From a uniform distribution over an interval of 10 around the correct guess (or 5 for numbers less than 5), to identify plausible wrong guesses.

[9] Accuracy of all models on MultiNLI closely matches original publications (numbers in appendix A).

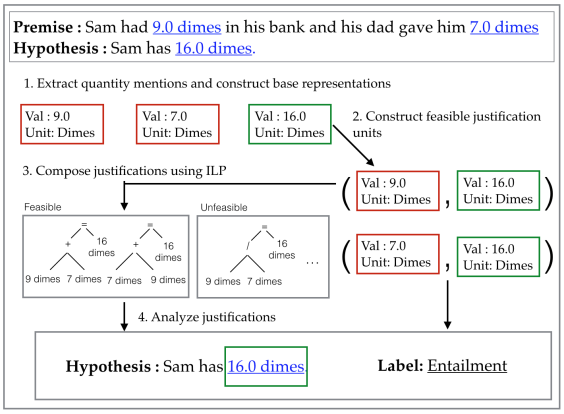

Figure 1: Overview of Q-REAS baseline.

2) **Hypothesis-Only (HYP):** FastText classifier (Mikolov et al., 2018) trained on only hypotheses (Gururangan et al., 2018).
3) **ALIGN:** A bag-of-words alignment model inspired by MacCartney (2009).[10]
4) **CBOW:** A simple bag-of-embeddings sentence representation model (wil).
5) **BiLSTM:** The simple BiLSTM model described by wil.
6) **Chen (CH):** Stacked BiLSTM-RNNs with shortcut connections and character word embeddings (Chen et al., 2017b).
7) **InferSent:** A single-layer BiLSTM-RNN model with max-pooling (Conneau et al., 2017).
8) **SSEN:** Stacked BiLSTM-RNNs with shortcut connections (Nie and Bansal, 2017).
9) **ESIM:** Sequential inference model proposed by Chen et al. (2017a) which uses BiLSTMs with an attention mechanism.
10) **OpenAI GPT:** Transformer-based language model (Vaswani et al., 2017), with finetuning on NLI (Radford et al., 2018).
11) **BERT:** Transformer-based language model (Vaswani et al., 2017), with a cloze-style and next-sentence prediction objective, and finetuning on NLI (Devlin et al., 2018).

4.2 Q-REAS Baseline System

Figure 1 describes the Q-REAS baseline for quantitative reasoning in NLI. The model manipulates quantity representations symbolically to make entailment decisions, and is intended to serve as a strong heuristic baseline for numerical reasoning on the EQUATE benchmark. This model has four stages: Quantity mentions are extracted and parsed into semantic representations called NUMSETS (§4.2.1, §4.2.2); compatible NUMSETS are extracted (§4.2.3) and composed (§4.2.4) to form *justifications*; Justifications are analyzed to determine entailment labels (§4.2.5).

[10]Model accuracy on RTE-3 test is 61.12%, comparable to the reported average model performance in the RTE competition of 62.4% .

INPUT	
P_c	Set of "compatible" single-valued premise quantities
P_r	Set of "compatible" range-valued premise quantities
H	Hypothesis quantity
O	Operator set $\{+, -, *, /, =, \cap, \cup, \setminus, \subseteq\}$
L	Length of equation to be generated
SL	Symbol list ($P_c \cup P_r \cup H \cup O$)
TL	Type list (set of types from P_c, P_r, H)
N	Length of symbol list
K	Index of first range quantity in symbol list
M	Index of first operator in symbol list
OUTPUT	
e_i	Index of symbol assigned to i^{th} position in postfix equation
VARIABLES	
x_i	Main ILP variable for position i
c_i	Indicator variable: is e_i a single value?
r_i	Indicator variable: is e_i a range?
o_i	Indicator variable: is e_i an operator?
d_i	Stack depth of e_i
t_i	Type index for e_i

Table 3: Input, output and variable definitions for the Integer Linear Programming (ILP) framework used for quantity composition

4.2.1 Quantity Segmenter

We follow Barwise and Cooper (1981) in defining quantities as having a number, unit, and an optional approximator. Quantity mentions are identified as least ancestor noun phrases from the constituency parse of the sentence containing cardinal numbers.

4.2.2 Quantity Parser

The quantity parser constructs a grounded representation for each quantity mention in the premise or hypothesis, henceforth known as a NUMSET [11]. A NUMSET is a tuple (val, unit, ent, adj, loc, verb, freq, flux)[12] with:

1. val $\in [\mathbb{R}, \mathbb{R}]$: quantity value represented as a range
2. unit $\in S$: unit noun associated with quantity
3. ent $\in S^{\phi}$: entity noun associated with unit (e.g., *donations* worth 100$)

[11]A NUMSET may be a composition of other NUMSETS .

[12]As in (Koncel-Kedziorski et al., 2015) S denotes all possible spans in the sentence, ϕ represents the empty span, and S^{ϕ}=$S \cup \phi$

Definitional Constraints	
Range restriction	$x_i < K$ or $x_i = M-1$ for $i \in [0, L-1]$ if $c_i = 1$
	$x_i \geq K$ and $x_i < M$ for $i \in [0, L-1]$ if $r_i = 1$
	$x_i \geq M$ for $i \in [0, L-1]$ if $o_i = 1$
Uniqueness	$c_i + r_i + o_i = 1$ for $i \in [0, L-1]$
Stack definition	$d_0 = 0$ (Stack depth initialization)
	$d_i = d_{i-1} - 2o_i + 1$ for $i \in [0, L-1]$ (Stack depth update)
Syntactic Constraints	
First two operands	$c_0 + r_0 = 1$ and $c_1 + r_1 = 1$
Last operator	$x_{L-1} \geq N-1$ (Last operator should be one of $\{=, \subseteq\}$)
Last operand	$x_{L-2} = M-1$ (Last operand should be hypothesis quantity)
Other operators	$x_i \leq N-2$ for $i \in [0, L-3]$ if $o_i = 1$
Other operands	$x_i < K$ for $i \in [0, L-3]$ if $c_i = 1$
	$x_i < M$ for $i \in [0, L-3]$ if $r_i = 1$
Empty stack	$d_{L-1} = 0$ (Non-empty stack indicates invalid postfix expression)
Premise usage	$x_i \neq x_j$ for $i, j \in [0, L-1]$ if $o_i \neq 1, o_j \neq 1$
Operand Access	
Right operand	$op2(x_i) = x_{i-1}$ for $i \in [0, L-1]$ such that $o_i = 1$
Left operand	$op1(x_i) = x_l$ for $i, l \in [0, L-1]$ where $o_i = 1$ and l is the largest index such that $l \leq (i-2)$ and $d_l = d_i$

Table 4: Mathematical validity constraint definitions for the ILP framework. Functions $op1()$ and $op2()$ return the left and right operands for an operator respectively. Variables defined in table 3.

Type Consistency Constraints	
Type assignment	$t_i = TL[k]$ for $i \in [0, L-1]$ if $c_i + r_i = 1$ and $type(SL_i) = k$
Two type match	$t_i = t_a = t_b$ for $i \in [0, L-1]$ such that $o_i = 1, x_i \in \{+, -, *, /, =, \cap, \cup, \setminus, \subseteq\}, a = op1(x_i), b = op2(x_i)$
One type match	$t_i \in \{t_a, t_b\}, t_a \neq t_b$ for $i \in [0, L-1]$ such that $o_i = 1, x_i = *, a = op1(x_i), b = op2(x_i)$
	$t_i = t_a \neq t_b$ for $i \in [0, L-1]$ such that $o_i = 1, x_i = /, a = op1(x_i), b = op2(x_i)$
Operator Consistency Constraints	
Arithmetic operators	$c_a = c_b = 1$ for $i \in [0, L-1]$ such that $o_i = 1, x_i \in \{+, -, *, /, =\}, a = op1(x_i), b = op2(x_i)$
Range operators	$r_a = r_b = 1$ for $i \in [0, L-1]$ such that $o_i = 1, x_i \in \{\cap, \cup, \setminus\}, a = op1(x_i), b = op2(x_i)$
	$r_b = 1$ for $i \in [0, L-1]$ such that $o_i = 1, x_i = \subseteq, b = op2(x_i)$

Table 5: Linguistic consistency constraint definitions for the ILP framework. Functions $op1()$ and $op2()$ return the left and right operands for an operator respectively. Variables defined in table 3.

4. adj $\in S^{\phi}$: adjective associated with unit if any[13],
5. loc $\subseteq S^{\phi}$: location of unit (e.g.,'in the bag')[14]
6. verb $\in S^{\phi}$: action verb associated with quantity[15].
7. freq $\subseteq S^{\phi}$: if quantity recurs[16] (e.g, 'per hour'),
8. flux $\in \{$increase to, increase from, decrease to, decrease from$\}^{\phi}$: if quantity is in a state of flux[17].

To extract **values** for a quantity, we extract cardinal numbers, recording contiguity. We normalize the number[18]. We also handle simple ratios such as quarter, half etc, and extract bounds (eg: *fewer than 10 apples* is parsed to $[-\infty, 10]$ apples.)

To extract **units**, we examine tokens adjacent to cardinal numbers in the quantity mention and identify known units. If no known units are found, we assign the token in a *numerical modifier* relationship with the cardinal number, else we assign the nearest noun to the cardinal number as the unit. A quantity is determined to be **approximate** if the word in an *adverbial modifier* relation with the cardinal number appears in a gazetteer[19]. If approximate, range is extended to (+/-)2% of the

[13]Extracted as governing verb linked to entity by an *amod* relation.

[14]Extracted as prepositional phrase attached to the quantity and containing noun phrase.

[15]Extracted as governing verb linked to entity by *dobj* or *nsubj* relation.

Table 6: Accuracies(%) of 9 NLI Models on five tests for quantitiative reasoning in entailment. M and D represent *models* and *datasets* respectively. Δ captures improvement over majority-class baseline for a dataset. Column Nat.Avg. reports the average accuracy(%) of each model across 3 evaluation sets constructed from natural sources (RTE-Quant, NewsNLI, RedditNLI), whereas Synth.Avg. reports the average accuracy(%) on 2 synthetic evaluation sets (Stress Test, AwpNLI). Column Avg. represents the average accuracy(%) of each model across all 5 evaluation sets in EQUATE.

current value.

4.2.3 Quantity Pruner

The pruner constructs "compatible" premise-hypothesis NUMSET pairs. Consider the pair "Insurgents killed *7 U.S. soldiers*, set off a car bomb that killed *four Iraqi policemen*" and "*7 US soldiers* were killed, and *at least 10 Iraqis* died". Our parser extracts NUMSETS corresponding to *"four Iraqi policemen"* and *"7 US soldiers"* from premise and hypothesis respectively. But these NUMSETS should not be compared as they involve different units. The pruner discards such incompatible pairs. Heuristics to identify unit-compatible NUMSET pairs include three cases- 1) direct string match, 2) synonymy/hypernymy relations from WordNet, 3) one unit is a nationality/ job[20] and the other unit is synonymous with person (Roy, 2017).

4.2.4 Quantity Composition

The composition module detects whether a hypothesis NUMSET is justified by composing "compatible" premise NUMSETS . For example, consider the pair "I had *3 apples* but gave *one* to my brother" and "I have *two apples*". Here, the premise NUMSETS P_1 ("*3 apples*") and P_2 ("*one apple*") must be composed to deduce that the hypothesis NUMSET H_1 ("*2 apples*") is justified. Our framework accomplishes this by generating postfix arithmetic equations[21] from premise NUMSETS , that justify the hypothesis NUMSET [22]. In this example, the expression $< P_1, P_2, -, H_1, =>$ will be generated.

The set of possible equations is exponential in number of NUMSETS , making exhaustive generation intractable. But a large number of equations are invalid as they violate constraints such as unit consistency. Thus, our framework uses integer linear programming (ILP) to constrain the equation space. It is inspired by prior work on algebra word problems (Koncel-Kedziorski et al., 2015), with some key differences:

1. **Arithmetic equations:** We focus on arithmetic equations instead of algebraic ones.
2. **Range arithmetic:** Quantitative reasoning involves ranges, which are handled by representing then as endpoint-inclusive intervals and adding the four operators ($\cup, \cap, \setminus, \subseteq$)
3. **Hypothesis quantity-driven:** We optimize an ILP model for each hypothesis NUMSET because a sentence pair is marked "entailment" iff every hypothesis quantity is justified.

Table 3 describes ILP variables. We impose the following types of constraints:
1. Definitional Constraints: Ensure that ILP variables take on valid values by constraining initialization, range, and update.
2. Syntactic Constraints: Assure syntactic validity of generated postfix expressions by limiting

[20]Lists of jobs, nationalities scraped from Wikipedia.

[21]Note that arithmetic equations differ from algebraic equations in that they do *not* contain unknown variables

[22]Direct comparisons are incorporated by adding "=" as an operator.

operator-operand ordering.

3. Operand Access: Simulate stack-based evaluation correctly by choosing correct operator-operand assignments.

4. Type Consistency: Ensure that all operations are type-compatible.

5. Operator Consistency: Force range operators to have range operands and mathematical operators to have single-valued operands.

Definitional, syntactic, and operand access constraints ensure mathematical validity while type and operator consistency constraints add linguistic consistency. Constraint formulations are provided in Tables 4 and 5. We limit tree depth to 3 and retrieve a maximum of 50 solutions per hypothesis NUMSET , then solve to determine whether the equation is mathematically correct. We discard equations that use invalid operations (division by 0) or add unnecessary complexity (multiplication/ division by 1). The remaining equations are considered plausible justifications .

4.2.5 Global Reasoner

The global reasoner predicts the final entailment label as shown in Algorithm 1[23], on the assumption that every NUMSET in the hypothesis *has* to be justified [24] for entailment.

Algorithm 1 PredictEntailmentLabel(P, H, C, E)

Input: Premise quantities P, Hypothesis quantities H, Compatible pairs C, Equations E
Output: Entailment label $l \in$ { e, c, n }

if $C = \emptyset$ **then return** n
$J \leftarrow \emptyset$
$L \leftarrow []$
for $q_h \in H$ **do**
    $J_h \leftarrow \{q_p \mid q_p \in P, (q_p, q_h) \in C\}$
    $J \leftarrow J \cup \{(q_h, J_h)\}$
    $L \leftarrow L + [false]$
for $(q_h, J_h) \in J$ **do**
    if $J_h = \emptyset$ **then return** n
    for $q_p \in J_h$ **do**
        $s \leftarrow$ MaxSimilarityClass(q_p, q_h)
        if $s = e$ **then**
            if ValueMatch(q_p, q_h) **then**
                $L[q_h] = true$
            if !ValueMatch(q_p, q_h) **then**
                $L[q_h] = false$
        if $s = c$ **then**
            if ValueMatch(q_p, q_h) **then**
                $L[q_h] = c$
for $q_h \in H$ **do**
    $E_q \leftarrow \{e_i \in E \mid hyp(e_i) = q_h\}$
    if $E_q \neq \emptyset$ **then**
        $L[q_h] = true$
if $c \in L$ **then return** c
if count($L, true$) = len(L) **then return** e
return n

5 Results and Discussion

Table 6 presents results on EQUATE. All models, except Q-REAS are trained on MultiNLI. Q-REAS utilizes WordNet and lists from Wikipedia. We observe that neural models, particularly OpenAI GPT excel at verbal aspects of quantitative reasoning (RTE-Quant, NewsNLI), whereas Q-REAS excels at numerical aspects (Stress Test, AwpNLI).

5.1 Neural Models on NewsNLI:

To tease apart contributory effects of numerical and verbal reasoning in natural data, we experiment with NewsNLI. We extract all entailed pairs where a quantity appears in both premise and hypothesis, and perturb the quantity in the hypothesis generating contradictory pairs. For example, the pair ⟨'In addition to 79 fatalities , some 170 passengers were injured.'⟩ 'The crash took the lives of 79 people and injured some 170', 'entailment' is changed to ⟨'In addition to 79 fatalities , some 170 passengers were injured.', 'The crash took the lives of 80 people and injured some 170', 'contradiction'⟩, assuming scalar implicature and event coreference. Our perturbed test set contains 218 pairs. On this set, GPT[25] achieves an accuracy of 51.18%, as compared to 72.04% on the unperturbed set, suggesting the model relies on verbal cues rather than numerical reasoning. In comparison, Q-REAS achieves an accuracy of 98.1% on the perturbed set, compared to 75.36% on the unperturbed set, highlighting

[23] MaxSimilarityClass() takes two quantities and returns a probability distribution over entailment labels based on unit match. Similarly, ValueMatch() detects whether two quantities match in value (this function can also handle ranges).

[24] This is a necessary but not sufficient condition for entailment. Consider the example, ⟨'Sam believed Joan had 5 apples', 'Joan had 5 apples'⟩. The hypothesis quantities of 5 apples is justified but is not a sufficient condition for entailment.

[25] the best-performing neural model on EQUATE.

reliance on quantities rather than verbal information. Closer examination reveals that OpenAI switches to predicting the 'neutral' category for perturbed samples instead of entailment, accounting for 42.7% of its errors, possibly symptomatic of lexical bias issues (Naik et al., 2018).

5.2 What Quantitative Phenomena Are Hard?

We sample 100 errors made by Q-REAS on each test in EQUATE, to identify phenomena not addressed by simple quantity comparison. Our analysis of causes for error suggest avenues for future research:

1. **Multi-step numerical-verbal reasoning:** Models do not perform well on examples requiring interleaved verbal and quantitative reasoning, especially multi-step deduction. Consider the pair ⟨"Two people were injured in the attack", "Two people perpetrated the attack"⟩. Quantities "two people" and "two people" are unit-compatible, but must not be compared. Another example is the NewsNLI entailment pair in Table 1. This pair requires us to identify that 16 and 17 refer to Emmanuel and Zachary's ages (quantitative), deduce that this implies they are teenagers (verbal) and finally count them (quantitative) to get the hypothesis quantity "two teens". Numbers and language are intricately interleaved and developing a reasoner capable of handling such complex interplay is challenging.

2. **Lexical inference:** Lack of real world knowledge causes errors in identifying quantities and valid comparisons. Errors include mapping abbreviations to correct units ("m" to "meters"), detecting part-whole coreference ("seats" can be used to refer to "buses"), and resolving hypernymy/hyponymy ("young men" to "boys").

3. **Inferring underspecified quantities:** Quantity attributes can be implicitly specified, requiring inference to generate a complete representation. Consider "A mortar attack killed four people and injured 80". A system must infer that the quantity "80" refers to people. On RTE-Quant, 20% of such cases stem from zero anaphora, a hard problem in coreference resolution.

4. **Arithmetic comparison limitations:** These examples require composition between incompatible quantities. For example, consider ⟨"There were 3 birds and 6 nests", "There were 3 more nests than birds"⟩. To correctly label this pair "3 birds" and "6 nests" must be composed.

6 Conclusion

In this work, we present EQUATE, an evaluation framework to estimate the ability of models to reason quantitatively in textual entailment. We observe that existing neural approaches rely heavily on the lexical matching aspect of the task to succeed rather than reasoning about quantities. We implement a strong symbolic baseline Q-REAS that achieves success at numerical reasoning, but lacks sophisticated verbal reasoning capabilities. The EQUATE resource presents an opportunity for the community to develop powerful hybrid neuro-symbolic architectures, combining the strengths of neural models with specialized reasoners such as Q-REAS . We hope our insights lead to the development of models that can more precisely reason about the important, frequent, but understudied, phenomena of quantities in natural language.

Linguistic Analysis Improves Neural Metaphor Detection

Abstract

In the field of metaphor detection, deep learning systems are the ubiquitous and achieve strong performance on many tasks. However, due to the complicated procedures for manually identifying metaphors, the datasets available are relatively small and fraught with complications. We show that using syntactic features and lexical resources can automatically provide additional high-quality training data for metaphoric language, and this data can cover gaps and inconsistencies in metaphor annotation, improving state-of-the-art word-level metaphor identification. This novel application of automatically improving training data improves classification across numerous tasks, and reconfirms the necessity of high-quality data for deep learning frameworks.

1 Introduction

Humans use metaphors to conceptualize abstract and often difficult concepts by employing knowledge of more concrete domains. They are prevalent in speech and text, and allow us to communicate more effectively and more imaginatively. The fact that they are commonplace and easily understood by humans makes appropriate interpretation of them essential for high quality natural language processing applications.

The primary linguistic and cognitive theory of metaphor is conceptual metaphor theory (Lakoff and Johnson, 1980; Lakoff, 1993), which theorizes that metaphors are primarily a mental activity, and the language is merely a side effect of these "conceptual" metaphors. From this, it is posited that metaphors are agnostic with regard to syntactic structure: a conceptual mapping can be expressed through whatever syntax the speaker desires. This is apparent from evidence that many metaphoric predications have the same syntactic properties as their literal counterparts. Goldberg (1995) observes that metaphorical ditransitive sentences like "It gave me a headache" do not differ syntactically from literal ditransitive sentences like "She gave me the account." Accordingly, to find syntactic hallmarks of metaphorical meaning we do not look generally for particular syntactic constructions, but rather for mismatches of various kinds between specific verbs' ordinary syntactic behavior and their behavior under metaphoric interpretation.

Perhaps the primary source of verbal syntactic variability is the set of argument-structure constructions identified by Goldberg (1995). One such construction is Caused Motion (CM), illustrated by the sentence "They pushed it down the hall". CM can augment the array of semantic roles supplied by the verb, as in "They laughed me out of the room". Augmentation often entails a metaphoric construal: here the verb "laugh", otherwise a single-argument verb, is paired with both a theme argument (the direct object) and a PP location argument, and the resulting predication expresses metaphorical rather than literal motion (Hwang, 2014).

Despite this connection between verbal syntax and metaphoric properties, most computational approaches to metaphor eschew syntax for more semantic features. While these have proven effective, metaphor detection remains a difficult task. This could be due to many factors, but a primary reason is the lack of adequate training data. Annotation of metaphor has proven to be extremely difficult, as is evident by the variety of schemes used to attempt to achieve consistent annotation.[1] This has led to a lack of "big data" for training models, as well as inconsistencies and gaps in the data that is available.

In this work, we show that syntactic properties

[1]For a review of systems, see Veale et al. (2016)

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 362–371
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

can be used to improve training data, which is beneficial to metaphor processing systems. Deep learning models require sufficient quality data, which is lacking for many metaphorical expressions. We automatically fill gaps in metaphor training data by exploiting syntax in two ways: first, we use the syntactically-motivated lexical resource VerbNet to identify additional data through metaphoric and literal sense identification, and second, we use syntactic properties of certain lexemes, which allow us to identify relevant sentences via dependency parses. These methods yield training data that improves performance for metaphor classification across a variety of tasks.

2 Related Work

While most computational metaphor processing methods rely heavily on lexical semantics, many previous approaches also employ syntactic structures to varying degrees. Most prior work involving argument structure is based on the idea of selectional preferences: certain verbs prefer certain arguments when used literally, and others when used metaphorically. This idea is captured by determining what kinds of arguments fill syntactic and semantic roles for specific verbs.

The CorMet system (Mason, 2004) employs this paradigm, and is similar to ours in their collection of key verbs and analysis of syntactic arguments and semantic roles. They automatically collect documents for particular domains based on key words, and identify selectional preferences based on the WordNet hierarchy for verbs in these particular domains. For example, they find that *assault* typically takes direct objects of the type *fortification* in the *MILITARY* domain. This allows them to make inferences about when selectional preferences are adhered to, and they can then identify mappings between different domains. While their task is fundamentally different, their usage of syntactic frames to identify relevant arguments is very similar to our work. However, rather than identify preferences, we are using syntactic frames to identify whether the verbs are possibly used metaphorically. Our methods require less adherence to semantic properties, which they retrieve from WordNet. Our methods are also inherently somewhat more noisy: while there is evidence that syntactic frames can be indicative of metaphoric properties, these properties are rarely observed deterministically.

Gedigian et al. (2006) use FrameNet and PropBank annotation to collect data, focusing on the FrameNet frames *MOTION* and *CURE*. They use PropBank argument annotations as features, resulting in metaphoric classification accuracy on these domains of over 95%, although this is only slightly above the most frequent class baseline (92%). They collect data from lexical resources and then annotate it for metaphoricity, which is similar to our approach of analyzing the resources and word senses for metaphors.

Shutova et al. (2013) also employs selectional preferences based on argument structure, identifying verb-subject and verb-direct object pairs in corpora. They begin with a seed set of metaphoric pairs, similar to our methods of collecting instances based on syntactic information. They use these seed pairs to identify new metaphors, similar to our usage of syntactic patterns to identify training data. Their methods are based on the selectional preferences of verbs, and thus are less concerned with the variety of syntactic patterns metaphors can participate in. We will identify much more complex syntactic patterns, and we then use the data for training metaphor systems rather than identifying selectional preferences.

Stowe et al. (2018) use syntactic structures directly for feature-based machine learning methods. They highlight the distribution of various syntactic patterns in corpora, and extract features based on dependency parses to improve classifier performance. While their results outperform lexical baselines, they still lag behind other metaphor detection systems, with F1 scores of 53.1 for verbs and 50.5 for nouns on the Vrije Universtat Amsterdam Metaphor Corpus (VUAMC) (Steen et al., 2010). We improve on their work by employing deep learning architecture while still attempting to leverage syntactic information. As many deep learning algorithms (including the recurrent neural networks used here) natively capture long-distance dependencies, direct inclusion of syntactic features is likely not productive. By capturing additional data, we can take advantage of linguistic analysis to improve deep learning-based metaphor detection.

With regard to datasets and tasks, metaphor processing has suffered from a lack of consistent evaluation methods. The metaphor shared task provided a standard evaluation procedure that has greatly helped with system comparison (Leong

et al., 2018). They use the VUAMC, providing a train/test split that has been used to regularize the evaluation of metaphor identification systems. For both sections of the task (identifying all metaphoric words and identifying verbs), four of the top five systems use some form of long short-term memory network (LSTM). The system of Wu et al. (2018) performed best on both tasks (F1 of .651 on all parts of speech, and .672 for verbs) using a combination of a convolutional neural network (CNN) and bidirectional LSTM.

Since the shared task, a variety of other approaches have been developed using similar deep learning techniques. Most recently, the work of Gao et al. (2018) achieved state-of-the-art performance on the shared task data as well as a variety of other datasets, including the TroFi (Birke and Sarkar, 2006) and Mohammad et al. (2016) datasets, using Bi-LSTM models coupled with GloVe (Pennington et al., 2014) and ELMo (Peters et al., 2018) embeddings. For the VUAMC shared task, they report F1 scores of .726 for all parts of speech and .697 for verbs. For the Mohammad et al. dataset, they report an average F1 score of .791, and for the Trofi they report an F1 score of .72, slightly lower than the current state of the art (.75 of Köper et al. (2017)).

Despite recent advances in evaluation and algorithm performance, the task still remains difficult, with the highest F1 scores nearing only .73 on the VUAMC data. This is likely due to the relatively small dataset size (app. 200,000 words), which is in part caused by difficulties in annotation. We aim to overcome some of this difficulty by automatically extracting additional training data with lexical and syntactic methods.

3 Methods

We aim to improve training data for metaphor processing by performing linguistic analysis on difficult verbs to uncover the syntactic properties that can potentially influence their metaphoricity. Our work is focused on verbs: they form the foundation of many metaphoric expressions, and evidence from construction grammar and frame semantics has shown that syntactic properties can often influence the types of metaphors that are produced (Sullivan, 2013). We show that identification of anomalous syntactic structures can provide evidence towards metaphoricity, and can be leveraged to automatically extract training data that improves classification performance.

This is done through two paths: first, we explore the lexical semantic resource VerbNet, an ontology of English verbs that contains rich syntactic and semantic information. From VerbNet we explore verb senses that can potentially be deterministically metaphoric or literal, and extract training data from existing VerbNet annotation. Second, we analyze syntactic patterns from Wikipedia data. We identify patterns that indicate metaphoric or literal senses of verbs, and then extract additional data based on these patterns.

3.1 Finding Difficult Verbs

First, we need to select verbs to analyze. Our goal is to find verbs that are likely difficult for classifiers, as well as those that are frequent enough to have a significant impact. This is accomplished through two avenues: first, we examine all the verbs in the training data, and analyze those that have the most even class balance between literal and metaphoric uses. We refer to these verbs as our most "ambiguous" verbs. For our preliminary experiments, we selected the ten most ambiguous verbs which occurred at least ten times in the training data.

Second, we employed the metaphor detection system of Gao et al. (2018). We trained the system on the provided VUAMC shared task training data and ran it on their validation set. We then analyzed which verbs were most frequently misclassified in the validation data, to determine where additional data would be most effective. We chose to use the VUAMC data for this task due to its size and status as the standard for metaphor identification. As with the most ambiguous verbs, we selected the ten verbs with the lowest F1 score that occurred at least ten times in the data for analysis. The verbs chosen through these analyses are shown in Table 1. In theory, expanding the number of verbs analyzed would yield more data and improve performance, but as an experimental baseline ten verbs is sufficient for analysis and classifier improvement.

For each of these verbs, we performed two kinds of analysis. First, we explored their metaphoric and literal usage in VerbNet. Second, we examined their syntactic properties for metaphoric and literal patterns.

3.2 VerbNet

VerbNet is a lexical resource that currently categorizes 6,791 verbs into 329 verb classes based

Most Ambiguous Verbs				Most Misclassified Verbs

Table 1: Difficult Verbs from the VUAMC data: on the left, the verbs with the most even split between literal and metaphoric. On the right, verbs in the validation set that were most misclassified. Restricted to verbs where count ≥ 10.

on their syntactic and semantic behavior (Kipper-Schuler, 2005).[2] These verb classes are based on the work of Levin (1993), who shows that for many verbs their semantics can be determined by the syntactic alternations they participate in, arguing that "the behavior of a verb, particularly with respect to the expression and interpretation of its arguments, is to a large degree determined by its meaning." (pg 1)

VerbNet is primarily composed of verb "classes": these classes are a hierarchically structuring of verb senses based on their syntactic and semantic behavior. Each class contains a list of verb senses, the syntactic frames that these verbs can participate in, a first-order semantic predicate representation for the class's meaning, and the thematic roles the verb takes as arguments. These thematic roles, which are fairly coarse-grained roles such as Agent, Theme, and Patient, are often marked with selectional restrictions. For example, many classes have Agents that are marked as +ANIMATE, indicating the Agent of the verb must be an animate entity.

VerbNet has practical applications for word sense disambiguation and semantic role labelling, and numerous annotation projects have been done to tag data with the correct VerbNet senses. Our goal is to identify which particular VerbNet senses are typically metaphoric or literal, and extract sentences tagged with these VerbNet senses.

For each verb, we examined the VerbNet classes in which it appears. We looked at VerbNet annotation, the example sentences, the selectional preferences on the class's thematic roles, and the semantic predicates. From this we assessed whether the sense of the verb in each class was typically metaphoric or literal. Consider the verb "grow". It is present in two particular VerbNet classes: **GROW-26.2** and **CALIBRATABLE_COS-45.6**. The **GROW-26.2** class has an animate Agent role, and produces a concrete Product out of a concrete Material:

1. A private farmer in Poland is free to buy and sell land, hire help, and decide what to **grow**.

2. It's the kind of fruit that **grew** freely and that you could help yourself to.

We note from the semantics and annotated examples, we expect this sense of grow to typically be literal. However, in the **CALIBRATABLE_COS-45.6** class, it contains a Value role that moves along a scale by a certain Extent. These examples all appear to be metaphoric, evoking the MORE IS UP mapping[3]:

1. Exports in the first eight months **grew** only 9%.

2. Non-interest expenses **grew** 16% to $496 million.

This allows us to extract new training data using these classes. We use a repository of manually annotated VerbNet senses, containing approximately 150,000 annotated verbs (Palmer et al.,

[2] https://verbs.colorado.edu/verbnet/

[3] Examples from the VerbNet annotation data from Palmer et al. (2017)

2017). We found all annotated instances of "grow" in the **GROW-26.2** class, and considered them to be literal, and all instances of "grow" from **CALIBRATABLE_COS-45.6** were considered metaphoric. This process was completed for all of the verbs in Table 1. This analysis only includes the particular verb in question. We believe "grow" in the **GROW-26.2** class is typically literal, and "grow" in the **CALIBRATABLE_COS-45.6** class is typically metaphoric, but this does not necessarily extend to other verbs in these classes. We will discuss the possibility of expanding this analysis to include all verbs for particular classes in Section 6.

Note that we only consider the verbs in these instances: we have no knowledge of the metaphoricity of the verbs' arguments. For each verb, we extracted up to 100 annotations for each sense that we determined to be largely metaphoric or literal.

3.3 Syntactic Patterns

As a second path for finding additional data, we explore the syntactic properties of metaphoric expressions. While metaphors are traditionally seen as cognitive, and relatively unaffected by surface syntactic realizations, there is recent evidence based in construction grammar that syntactic structures can influence the source and target domain elements of metaphoric expressions (Sullivan, 2013; David and Matlock, 2018; David, 2017). We expand on this idea: we believe that not only can syntactic structures indicate source and target elements, but they can also indicate metaphoricity.

We see this in English with verbs like hemorrhage, which is almost always used metaphorically when it is used transitively[4]:

- GM was supporting this event even as they were **hemorrhaging cash**.
- For 30 straight years, American organized labor has been **hemorrhaging members**.

When used intransitively, hemorrhage is almost always literal:

- Cerebral AVMs often have no symptoms until they rupture and **hemorrhage**.
- Michael **hemorrhaged** and sustained a massive stroke to the left side of his brain.

[4]Examples from SketchEngine (Kilgarriff et al., 2014) http://www.sketchengine.eu/

This is likely due to the fact that literal use of "hemorrhage" contains an understood argument, blood, which is the most natural object of the verb. If the use is intended in a less literal way, which requires on over syntactic object, the null "blood" object needs to be overridden. While not all verbs have this direct relation between argument number and metaphoricity, we believe that the type and number of syntactic arguments of a verb can be indicative of unmarked usage, and may be utilized as a method for automatically extracting training data for metaphor classification. This analysis doesn't reflect linguistic facts: it is possible to construct sentences in which the intransitive use of "hemorrhage" is metaphoric ("after the stock market crashed, the company hemorrhaged"), as well as transitive usages that are literal ("after the surgery, the patient hemorrhaged blood"). However, we find that in the majority of cases, metaphoricity aligns with the argument structure, and these contrived examples are exceedingly rare.

For each verb in our list, we analyzed all the sentences from the VUAMC training data as well as 50 additional sentences from Wikipedia that contained the verb, and attempted to discover syntactic patterns that are indicative of metaphoricity. We examined argument structure, active vs passive voice, prepositional complements, aspect, idiomatic combinations and other surface syntactic properties. We created a short list of the most likely candidates for literal and metaphoric syntactic patterns. We then extracted up to 100 sentences from Wikipedia that matched these syntactic patterns.

A brief overview of the syntactic patterns and VerbNet class analysis is shown in Table 2; the full extraction rules, code, and data will be released upon publication.

Note that for many cases, it was difficult to determine what was literal and what was metaphoric. Highly polysemous verbs like "get" in particular are problematic: they contain many different meanings and usages that can often be annotated inconsistently, so strong metaphoric or literal patterns were impossible to identify.

As with the "hemorrhage" examples above, these patterns are not deterministic. The syntactic structures analyzed aren't always metaphoric or literal, but they are consistent enough to be useful for extracting additional training data. For each verb we attempted to extract up to 100 samples

Table 3: Total samples extracted from VerbNet classes and syntactic patterns, along with the percentage of extracted samples that are metaphoric.

for each VerbNet sense and each syntactic pattern. This is to prevent the extracted data becoming saturated with extremely common senses or patterns. Many senses and patterns are rare, and fewer than 100 instances were collected. A summary of the extracted data by verb is shown in Table 3.

In total, we extracted 3,985 samples from VerbNet annotation and 3,736 samples from Wikipedia based on syntactic samples for our analyzed verbs. Each sample is an entire sentence containing the verb in question, for which we can provide automatic annotation based on our VerbNet and syntactic analyses. We can treat this as distantly supervised data: we have beliefs about the metaphoric and literal labels for the verbs in each sentence extracted, but these aren't always deterministic: errors in syntactic pattern matching, anomalous examples, and other factors introduce inaccuracies in these samples.

4 Tasks

In order to show the efficacy of our extracted data, we add this data to the standard datasets and evaluate performance on a variety of metaphor processing tasks. For a relevant comparison to contemporary research, we evaluate our results using the baseline system of Gao et al. on five different tasks. As per their work, we experiment with two different models: a sequence based model (dubbed "SEQ") that performs best when all parts of speech contain metaphor tags, and a "classification" model ("CLS"), which tags individual verbs as metaphoric or not.

4.1 Sequential Model (SEQ)

The sequential model takes as input sentences from VUAMC data, each with a binary metaphor tag. They represent each word as the concatenation of a 300 dimension GloVe embeddings with an ELMo vector. These are then input to a bidirectional LSTM. These sequential models are particularly useful for encoding relations among distant words, and have proven effective on a large number of tasks for which each word in a sentence has a tag.

4.2 Classification Model (CLS)

The classification model represents each verb in the VUAMC data as its own instance, maintaining the sentential context, and these each retain their annotation as either metaphoric or not. As with the

sequential model, they are input to a bidirecitonal LSTM using GloVe and ELMo vectors. They also include an index embedding and attention layer to encode the location of the target word.[5]

These models are used over a variety of datasets: the dataset from Mohammad et al. (2016), the Trofi dataset (Birke and Sarkar, 2006), and the VUA metaphor corpus which is the basis for the metaphor shared task (Steen et al., 2010). They use a section of the Mohammad et al. dataset dubbed "MOH-X", consisting of 636 example sentences from 214 verbs taken from WordNet, annotated as metaphoric or literal. The Trofi dataset contains 3,737 sentences from 50 different verbs which were automatically clustered into metaphoric or literal clusters. The sequence tagger shows best performance when all words in the sentence are metaphoric, as is the case with the VUAMC data. The classification model performs best when only a single word is metaphoric, as in the MOH-X and Trofi datasets. While the VUAMC is the basis of our analysis, we will also examine how adding additional impacts results on the MOH-X and Trofi datasets; their setup as classification tasks more accurately mirrors the additional data, as there is only one potentially metaphoric word per sample.

4.3 Architecture

We replicate the architectures of Gao et al., using the same experimental set-up. For the classification model, we can include our extra data as-is, with metaphor annotations based on our analysis. For the sequential model, we consider only the verb analyzed as metaphoric, leaving the rest of the words tagged as literal. In order to judge performance, we run three experimental setups: one with the additional VerbNet samples, one with the additional samples generated via syntactic patterns, and one with both. We experimented with tuning hyperparameters (learning rate, dropout, and the size of the hidden layer), but found no significant improvements over their experimental setup. We did make one modification: we increased the amount of training epochs in proportion to the amount of training data added. This allows for the model to be sufficiently trained over all the data.

The VUAMC data has been split into training and test sections for the shared task, and these sections are also used by Gao et al. We will adopt this split. For the MOH-X and Trofi datasets, they run 10-fold cross validation and report the mean F1 score. Due to the variable nature of neural models and the relatively small dataset size, we include experiments to calculate the statistical significance of our methods. We split these datasets into 75% training, 25% test, mirroring the VUAMC data, and ran classification 10 times. We then calculated the means and standard deviations. We also ran bootstrap estimation for all tasks, reevaluating using random replacement over 10^6 iterations (Efron, 1979; Berg-Kirkpatrick et al., 2012). We consider improvement significant when the mean and standard deviation from both methods yield p values of less than .01.

5 Results

The results from our additions on the original tasks are shown in Figure 1, and the improvements over the baseline for each method are outlined in Table 4. For each task, we display the results of the original Gao baseline, along with the addition of VerbNet samples, syntactic pattern-based samples, and both. For each of these, we show the mean and standard deviation from running the task 10 times.

We find that adding VerbNet samples, syntactic patterns, and both datasets all always produces a significant improvement over the baseline. Adding this additional data outperforms the Gao et al. sequence tagging algorithm on the VUA shared task data for both verbs and all parts of speech. We also see improvements in the classification model, and on the Trofi dataset. It is important to note that the extreme variability in the results for these smaller datasets. We found our improvements on the Trofi dataset to be significant, while the MOH-X results were not significant. This is likely due to the size of the dataset: the MOH-X data contains only 636 samples, leading to high variance in performance. Further evaluation is necessary to determine the consistent effect of this data.

For verb sequence tagging, the VerbNet data yielded the best performance, while for all parts of speech the additional syntactic data performed best. This may be because the VerbNet data comes specifically from VerbNet annotation, relying strictly on VerbNet senses. VerbNet is grounded in syntactic alternations, but individually VerbNet senses occasionally encode metaphor

[5]Full details and code for each of these models can be found at https://github.com/gao-g/metaphor-in-context/

without direct relation to the verb's arguments. The syntactic data directly relies on patterns which include other parts of speech: arguments, prepositions, and idiomatic expressions. These extra components of the analysis may make the data more broadly applicable to all parts of speech, driving the improvement in the sequence tagging of all words.

Adding both distantly supervised datasets improved performance over adding either individually only for the classification-based tasks, where only one word per sentence has a tag (the Trofi and VUAMC verb classification tasks). Only on the Trofi dataset was the improvement from adding both datasets significantly higher than the improvement from adding the best individual dataset. For the sequence-based tagging of the VUAMC, adding both yielded negligible improvements. As adding both datasets was effective for classification tasks, we believe the difficulty in combining both datasets in the sequence models is due to excessive noise from the non-target words of the samples. We default to marking every word other than the target verb in the sentence as literal, so the additional data is understandably less informative for sequence tagging problems. It is likely that the combination of VerbNet data and syntactic pattern-based data caused additional noise: the two datasets may in places be contradictory, particularly with regard to these non-target elements.

6 Conclusions

We show that using external data found through syntactic structures and lexical resources can be used to improve deep learning methods for metaphoric classification. This is due to regular syntactic patterns of metaphoric usage, and the idea that the semantics of verbs can be dependent on the syntactic patterns that it participates in. For future improvements, there are other resources available that could be leveraged in the same way. PropBank (Palmer et al., 2005), FrameNet (Baker

et al., 1998), and WordNet (Fellbaum, 2010) all offer some syntactic and/or semantic information, and data annotated with these resources could prove another valuable source of additional samples.

We also only examine some basic syntactic patterns for a small number of verbs, and this was done manually. Improved methods for automatically detecting relevant syntactic patterns as well as further effort in manual identification of syntactic properties of metaphoric samples could increase the amount of data extracted. Further linguistic analysis of constructions that either require or prohibit metaphoric interpretations could improve both automatic metaphor processing and our broader understanding of linguistic metaphors. Additionally, we only look at specific verbs within VerbNet classes. All verbs within VerbNet classes share syntactic and semantic properties, so it is likely that we can extend our verb-level analysis to a broader class-level analysis. A straightforward extension of this work would be to analyze VerbNet classes as being metaphoric or literal, and extracting data for all verbs within a given class.

Finally, while they have proven invaluable for the standardization of metaphor processing, there are still gaps and inconsistencies in our metaphor datasets. Extracting additional training data based on syntactic patterns likely was effective in this case in part due to the idiosyncrasies of the previous datasets, which may over-annotate possible metaphors. This procedure yields a large number of conventional metaphors, which lack novelty, are very frequent, and are perhaps more amenable to being discovered via syntactic patterns. More data annotated for metaphor is essential to improve deep learning methods for metaphor processing, and while we are attempting to overcome these gaps with outside resources, further quality metaphor annotation would prove especially valuable to the field.

Abstract

Cross-lingual transfer learning has become an important weapon to battle the unavailability of annotated resources for low-resource languages. One of the fundamental techniques to transfer across languages is learning *language-agnostic* representations, in the form of word embeddings or contextual encodings. In this work, we propose to leverage unannotated sentences from auxiliary languages to help learning language-agnostic representations. Specifically, we explore adversarial training for learning contextual encoders that produce invariant representations across languages to facilitate cross-lingual transfer. We conduct experiments on cross-lingual dependency parsing where we train a dependency parser on a source language and transfer it to a wide range of target languages. Experiments on 28 target languages demonstrate that adversarial training significantly improves the overall transfer performances under several different settings. We conduct a careful analysis to evaluate the language-agnostic representations resulted from adversarial training.

1 Introduction

Cross-lingual transfer, where a model learned from one language is transferred to another, has become an important technique to improve the quality and coverage of natural language processing (NLP) tools for languages in the world. This technique has been widely applied in many applications, including part-of-speech (POS) tagging (Kim et al., 2017), dependency parsing (Ma and Xia, 2014), named entity recognition (Xie et al., 2018), entity linking (Sil et al., 2018), coreference resolution (Kundu et al., 2018), and question answering (Joty et al., 2017). Noteworthy improvements are achieved on low resource language applications due to cross-lingual transfer learning.

In this paper, we study cross-lingual transfer for dependency parsing. A dependency parser consists of (1) an encoder that transforms an input text sequence into latent representations and (2) a decoding algorithm that generates the corresponding parse tree. In cross-lingual transfer, most recent approaches assume that the inputs from different languages are aligned into the same embedding space via multilingual word embeddings or multilingual contextualized word vectors, such that the parser trained on a source language can be transferred to target languages. However, when training a parser on the source language, the encoder not only learns to embed a sentence but it also carries language-specific properties, such as word order typology. Therefore, the parser suffers when it is transferred to a language with different language properties. Motivated by this, we study how to train an encoder for generating language-agnostic representations that can be transferred across a wide variety of languages.

We propose to utilize *unlabeled* sentences of one or more auxiliary languages to train an encoder that learns language-agnostic contextual representations of sentences to facilitate cross-lingual transfer. To utilize the unlabeled auxiliary language corpora, we adopt adversarial training (Goodfellow et al., 2014) of the encoder and a classifier that predicts the language identity of an input sentence from its encoded representation produced by the encoder. The adversarial training encourages the encoder to produce language invariant representations such that the language classifier fails to predict the correct language identity. As the encoder is jointly trained with a loss for the primary task on the source language and adversarial loss on all languages, we hypothesize that it will learn to capture task-specific features as well as generic structural patterns applicable to many languages, and thus have better transferrability.

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 372–382
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

To verify the proposed approach, we conduct experiments on neural dependency parsers trained on English (source language) and directly transfer them to 28 target languages, with or without the assistance of unlabeled data from auxiliary languages. We chose dependency parsing as the primary task since it is one of the core NLP applications and the development of Universal Dependencies (Nivre et al., 2016) provides consistent annotations across languages, allowing us to investigate transfer learning in a wide range of languages. Thorough experiments and analyses are conducted to address the following research questions:

- Does encoder trained with adversarial training generate language-agnostic representations?
- Does language-agnostic representations improve cross-language transfer?

Experimental results show that the proposed approach consistently outperform a strong baseline parser (Ahmad et al., 2019), with a significant margin in two family of languages. In addition, we conduct experiments to consolidate our findings with different types of input representations and encoders. Our experiment code is publicly available to facilitate future research.[1]

2 Training Language-agnostic Encoders

We train the encoder of a dependency parser in an *adversarial* fashion to guide it to avoid capturing language-specific information. In particular, we introduce a language identification task where a classifier predicts the language identity (id) of an input sentence from its encoded representation. Then the encoder is trained such that the classifier fails to predict the language id while the parser decoder predicts the parse tree accurately from the encoded representation. We hypothesize that such an encoder would have better cross-lingual transferability. The overall architecture of our model is illustrated in Figure 1. In the following, we present the details of the model and training method.

2.1 Architecture

Our model consists of three basic components, (1) a general encoder, (2) a decoder for parsing, and (3) a classifier for language identification. The encoder learns to generate contextualized representations for the input sentence (a word sequence)

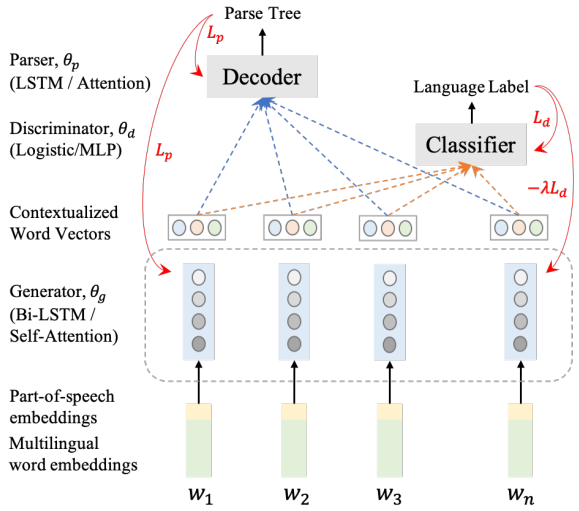

Figure 1: An overview of our experimental model consists of three basic components: (1) Encoder, (2) (Parsing) Decoder, and (3) (Language) Classifier. We also show how parsing and adversarial losses (L_p and L_d) are back propagated for parameter updates.

which are fed to the decoder and the classifier to predict the dependency structure and the language identity (id) of that sentence.

The encoder and the decoder jointly form the parsing model and we consider two alternatives[2] from (Ahmad et al., 2019): "SelfAtt-Graph" and "RNN-Stack". The "SelfAtt-Graph" parser consists of a modified self-attentional encoder (Shaw et al., 2018) and a graph-based deep bi-affine decoder (Dozat and Manning, 2017), while the "RNN-Stack" parser is composed of a Recurrent Neural Network (RNN) based encoder and a stack-pointer decoder (Ma et al., 2018).

We stack a classifier (a linear classifier or a multi-layer Perceptron (MLP)) on top of the encoder to perform the language identification task. The identification task can be framed as either a word- or sentence-level classification task. For the sentence-level classification, we apply average pooling[3] on the contextual word representations generated by the encoder to form a fixed-length representation of the input sequence, which is fed to the classifier. For the word-level classification, we perform language classification for each token individually.

[1] https://github.com/wasiahmad/cross_lingual_parsing

[2] Ahmad et al. (2019) studied order-sensitive and order-free models and their performances in cross-lingual transfer. In this work, we adopt two typical ones and study the effects of adversarial training on them.

[3] We also experimented with max-pooling and weighted pooling but average pooling resulted in stable performance.

Algorithm 1 Training procedure.

Parameters to be trained: Encoder (θ_g), Decoder (θ_p), and Classifier (θ_d)
X^a = Annotated source language data
X^b = Unlabeled auxiliary language data
I = Number of warm-up iterations
k = Number of learning steps for the discriminator (D) at each iteration
λ = Coefficient of $\mathcal{L}_d$
α_1, α_1 = learning rate; B = Batch size

Require:

for $j = 0, \cdots, I$ **do**
  Update $\theta_g := \theta_g - \alpha_1 \nabla_{\theta_g} \mathcal{L}_p$
  Update $\theta_p := \theta_p - \alpha_1 \nabla_{\theta_p} \mathcal{L}_p$
for $j = I, \cdots, num_iter$ **do**
  for k steps **do**
    $(x_a^i)_{i=1}^{B/2} \leftarrow$ Sample a batch from X^a
    $(x_b^i)_{i=1}^{B/2} \leftarrow$ Sample a batch from X^b
    Update $\theta_d := \theta_d - \alpha_2 \nabla_{\theta_d} \mathcal{L}_d$
  Total loss $\mathcal{L} := \mathcal{L}_p - \lambda \mathcal{L}_d$
  Update $\theta_g := \theta_g - \alpha_1 \nabla_{\theta_g} \mathcal{L}$
  Update $\theta_p := \theta_p - \alpha_1 \nabla_{\theta_p} \mathcal{L}$

In this work, following the terminology in adversarial learning literature, we interchangeably call the encoder as the generator, G and the classifier as the discriminator, D.

2.2 Training

Algorithm 1 describes the training procedure. We have two types of loss functions: $\mathcal{L}_p$ for the parsing task and $\mathcal{L}_d$ for the language identification task. For the former, we update the encoder and the decoder as in the regular training of a parser. For the latter, we adopt adversarial training to update the encoder and the classifier. We present the detailed training schemes in the following.

2.2.1 Parsing

To train the parser, we adopt both cross-entropy objectives for these two types of parsers as in (Dozat and Manning, 2017; Ma et al., 2018). The encoder and the decoder are jointly trained to optimize the probability of the dependency trees (y) given sentences (x):

$$\mathcal{L}_p = -\log p(y|x).$$

The probability of a tree can be further factorized into the products of the probabilities of each token's (m) head decision ($h(m)$) for the graph-based parser, or the probabilities of each transition step decision (t_i) for the transition-based parser:

$$\text{Graph:} \quad \mathcal{L}_p = -\sum_m \log p(h(m)|x, m),$$
$$\text{Transition:} \quad \mathcal{L}_p = -\sum_i \log p(t_i|x, t_{<i}).$$

2.2.2 Language Identification

Our objective is to train the contextual encoder in a dependency parsing model such that it encodes language specific features as little as possible, which may help cross-lingual transfer. To achieve our goal, we utilize adversarial training by employing unlabeled auxiliary language corpora.

Setup We adopt the basic generative adversarial network (GAN) for the adversarial training. We assume that X^a and X^b be the corpora of the source and auxiliary language sentences, respectively. The discriminator acts as a binary classifier and is adopted to distinguish the source and auxiliary languages. For the training of the discriminator, weights are updated according to the original classification loss:

$$\mathcal{L}_d = \mathbb{E}_{x \sim X^a}[\log\ D(G(x)) + \mathbb{E}_{x \sim X^b}[\log\ (1 - D(G(x))].$$

For the training of dependency parsing, the generator, G collaborates with the parser but acts as an adversary with respect to the discriminator. Therefore, the generator weights (θ_g) are updated by minimizing the loss function,

$$\mathcal{L} = \mathcal{L}_p - \lambda \mathcal{L}_d,$$

where λ is used to scale the discriminator loss ($\mathcal{L}_d$). In this way, the generator is guided to build language-agnostic representations in order to fool the discriminator while being helpful for the parsing task. Meanwhile, the parser can be guided to rely more on the language-agnostic features.

Alternatives We also consider two alternative techniques for the adversarial training: Gradient Reversal (GR) (Ganin et al., 2016) and Wasserstein GAN (WGAN) (Arjovsky et al., 2017). As opposed to GAN based training, in GR setup, the discriminator acts as a multiclass classifier that predicts language identity of the input sentence, and we use multi-class cross-entropy loss. We also study Wasserstein GAN (WGAN), which is proposed by Arjovsky et al. (2017) to improve the stability of GAN based learning. Its loss function is shown as follows.

$$\mathcal{L}_d = \mathbb{E}_{x \sim X^a}[D(G(x)] - \mathbb{E}_{x \sim X^b}[D(G(x)],$$

here, the annotations are similar to those in the GAN setting.

3 Experiments and Analysis

In this section, we discuss our experiments and analysis on cross-lingual dependency parsing transfer from a variety of perspectives and show the advantages of adversarial training.

Settings. In our experiments, we study single-source parsing transfer, where a parsing model is trained on one source language and directly applied to the target languages. We conduct experiments on the Universal Dependencies (UD) Treebanks (v2.2) (Nivre et al., 2018) using 29 languages, as shown in Table 1. We use the publicly available implementation[4] of the "SelfAtt-Graph" and "RNN-Stack" parsers.[5] Ahmad et al. (2019) show that the "SelfAtt-Graph" parser captures less language-specific information and performs better than the 'RNN-Stack" parser for distant target languages. Therefore, we use the "SelfAtt-Graph" parser in most of our experiments. Besides, the multilingual variant of BERT (mBERT) (Devlin et al., 2019) has shown to perform well in cross-lingual tasks (Wu and Dredze, 2019) and outperform the models trained on multilingual word embeddings by a large margin. Therefore, we consider conducting experiments with both multilingual word embeddings and mBERT. We use aligned multilingual word embeddings (Smith et al., 2017; Bojanowski et al., 2017) with 300 dimensionss or contextualized word representations provided by multilingual BERT[6] (Devlin et al., 2019) with 768 dimensions as the word representations. In addition, we use the Gold universal POS tags to form the input representations.[7] We freeze the word representations during training to avoid the risk of disarranging the multilingual representation alignments.

We select six auxiliary languages[8] (French, Portuguese, Spanish, Russian, German, and Latin) for unsupervised language adaptation via adversarial training. We tune the scaling parameter λ in the range of $[0.1, 0.01, 0.001]$ on the source language validation set and report the test performance with the best value. For gradient reversal (GR) and GAN based adversarial objectives, we use Adam (Kingma and Ba, 2015) to optimize the discriminator parameters, and for WGAN, we use RMSProp (Tieleman and Hinton, 2012). The learning rate is set to 0.001 and 0.00005 for Adam and RMSProp, respectively. We train the parsing models for 400 and 500 epochs with multilingual BERT and multilingual word embeddings respectively. We tune the parameter I (as shown in Algorithm 1) in the range of $[50, 100, 150]$.

Language Test. The goal of training the contextual encoder adversarially with unlabeled data from auxiliary languages is to encourage the encoder to capture more language-agnostic representations and less language-dependent features. To test whether the contextual encoders retain language information after adversarial training, we train a multi-layer Perceptron (MLP) with softmax on top of the *fixed* contextual encoders to perform a 7-way classification task.[9] If a contextual encoder performs better in the language test, it indicates that the encoder retains language specific information.

3.1 Results and Analysis

Table 2 presents the main transfer results of the "SelfAtt-Graph" parser when training on only English (en, baseline), English with French (en-fr), and English with Russian (en-ru). The re-

[4]https://github.com/uclanlp/CrossLingualDepParser

[5]We adopt the same hyper-parameters, experiment settings and evaluation metrics as those in (Ahmad et al., 2019).

[6]https://github.com/huggingface/pytorch-transformers

[7]We concatenate the word and POS representations. In our future work, we will conduct transfer learning for both POS tagging and dependency parsing.

[8]We want to cover languages from different families and with varying distances from the source language (English).

[9]With the source (English) and six auxiliary languages.

Table 2: Cross-lingual transfer performances (UAS%/LAS%, excluding punctuation) of the SelfAtt-Graph parser (Ahmad et al., 2019) on the test sets. In column 1, languages are sorted by the word-ordering distance to English. (en-fr) and (en-ru) denotes the source-auxiliary language pairs. '†' indicates that the adversarially trained model results are statistically significantly better (by permutation test, $p < 0.05$) than the model trained only on the source language (en). Results show that the utilization of unlabeled auxiliary language corpora improves cross-lingual transfer performance significantly.

sults demonstrate that the adversarial training with the auxiliary language identification task benefits cross-lingual transfer with a small performance drop on the source language. When multi-lingual embedding is employed, the performance significantly improves, in terms of UAS of 0.48 and 0.61 over the 29 languages when French and Russian are used as the auxiliary language, respectively. When richer multilingual representation technique like mBERT is employed, adversarial training can still improve cross-lingual transfer performances (0.21 and 0.54 UAS over the 29 languages by using French and Russian, respectively).

Next, we apply adversarial training on the "RNN-Stack" parser and show the results in Table 3. Similar to the "SelfAtt-Graph"parser, the "RNN-Stack" parser resulted in significant improvements in cross-lingual transfer from unsupervised language adaptation. We discuss our detailed experimental analysis in the following.

3.1.1 Impact of Adversarial Training

To understand the impact of different adversarial training types and objectives, we apply adversarial training on both word- and sentence-level with gradient reversal (GR), GAN, and WGAN objectives. We provide the average cross-lingual transfer performances in Table 4 for different adversarial training setups. Among the adversarial training objectives, we observe that in most cases, the GAN objective results in better performances than the GR and WGAN objectives. Our finding is in contrast to Adel et al. (2018) where GR was reported to be the better objective. To further investigate, we perform the language test on the encoders trained via these two objectives. We find that the GR-based trained encoders

perform consistently better than the GAN based ones on the language identification task, showing that via GAN-based training, the encoders become more language-agnostic. In a comparison between GAN and WGAN, we notice that GAN-based training consistently performs better.

Comparing word- and sentence-level adversarial training, we observe that predicting language identity at the word-level is slightly more useful for the "SelfAtt-Graph" model, while the sentence-level adversarial training results in better performances for the "RNN-Stack" model. There is no clear dominant strategy.

In addition, we study the effect of using a linear classifier or a multi-layer Perceptron (MLP) as the discriminator and find that the interaction between the encoder and the linear classifier resulted in improvements.[10]

3.1.2 Adversarial v.s. Multi-task Training

In section 3.1.1, we study the effect of learning language-agnostic representation by using auxiliary language with adversarial training. An alternative way to leverage auxiliary language corpora is by encoding language-specific information in the representation via multi-task learning. In the multi-task learning (MTL) setup, the model observes the same amount of data (both labeled and unlabeled) as the adversarially trained (AT) model. The only difference between the MTL and AT models is that in the MTL models, the contextual encoders are encouraged to capture language-dependent features while in the AT models, they are trained to encode language-agnostic features.

The experiment results using multi-task learning in comparison with the adversarial training are presented in Table 5. Interestingly, although the MTL objective sounds contradiction to adversarial learning, it has a positive effect on the cross-lingual parsing, as the representations are learned with certain additional information from new (unlabeled) data. Using MTL, we sometimes observe improvements over the baseline parser, as indicated with the † sign, while the AT models consistently perform better than both the baseline and the MTL model (as shown in Columns 2–5 in Table 5). The comparisons on parsing performances do not reveal whether the contextual encoders learn to encode language-agnostic or dependent features.

Therefore, we perform language test with the MTL and AT (GAN based) encoders, and the results are shown in Table 5, Columns 6–7. The results indicate that the MTL encoders consistently perform better than the AT encoders, which verifies our hypothesis that adversarial training motivates the contextual encoders to encode language-agnostic features.

3.1.3 Impact of Auxiliary Languages

To analyze the effects of the auxiliary languages in cross-language transfer via adversarial training, we perform experiments by pairing up[11] the source language (English) with six different lan-

[10] This is a known issue in GAN training as the discriminator becomes too strong, it fails to provide useful signals to the generator. In our case, MLP as the discriminator predicts the language labels with higher accuracy and thus fails.

[11] We also conduct experiments on multiple languages as the auxiliary language. For GAN and WGAN-based training, we concatenate the corpora of multiple languages and treat them as one auxiliary language. In these set of experiments, we do not observe any apparent improvements.

Table 6: Average cross-lingual transfer performances (UAS%/LAS%, w/o punctuation) on the test sets using SelfAtt-Graph parser when different languages play the role of the auxiliary language in adversarial training.

guages (spanning Germanic, Romance, Slavic, and Latin language families) as the auxiliary language. The average cross-lingual transfer performances are presented in Table 6 and the results suggest that Russian (ru) and German (de) are better candidates for auxiliary languages.

We then dive deeper into the effects of auxiliary languages trying to understand whether auxiliary languages particularly benefit target languages that are closer to them[12] or from the same family. Intuitively, we would assume when the auxiliary language has a smaller average distance to all the target languages, the cross-lingual transfer performance would be better. However, from the results in Table 6, we do not see such a pattern. For example, Portuguese (pt) has the smallest average distance to other languages among the auxiliary languages we tested, but it is not among the better auxiliary languages.

We further zoom in the cross-lingual transfer improvements for each language families as shown in Table 7. We hypothesis that the auxiliary languages to be more helpful for the target languages in the same family. The experimental results moderately correlate with our expectation. Specifically, the Germanic family benefits the most from employing German (de) as the auxiliary language; similarly Slavic family with Russian (ru) as the auxiliary language (although German as the auxiliary language brings similar improvements). The Romance family is an exception because it benefits the least from using French (fr) as the auxiliary language. This may due to the fact that French is too closed to English, thus is less suitable to be used as an auxiliary language.

4 Related Work

Unsupervised Cross-lingual Parsing. Unsupervised cross-lingual transfer for dependency parsing has been studied over the past few years (Agić et al., 2014; Ma and Xia, 2014; Xiao and Guo, 2014; Tiedemann, 2015; Guo et al., 2015; Aufrant et al., 2015; Rasooli and Collins, 2015; Duong et al., 2015; Schlichtkrull and Søgaard, 2017; Ahmad et al., 2019; Rasooli and Collins, 2019; He et al., 2019). Here, "unsupervised transfer" refers to the setting where a parsing model trained only on the source language is directly

[12]The language distances are computed based on word order characteristics as suggested in Ahmad et al. (2019).

Table 7: Average cross-lingual performance difference between the SelfAtt-Graph parser trained on the source (en) and an auxiliary (x) language and the SelfAtt-Graph parser trained only on English (en) language (UAS%/LAS%, excluding punctuation). We use multilingual BERT in this set of experiments.

transferred to the target languages. In this work, we relax the setting by allowing unlabeled data from one or more auxiliary (helper) languages other than the source language. This setting has been explored in a few prior works. Cohen et al. (2011) learn a generative target language parser with unannotated target data as a linear interpolation of the source language parsers. Täckström et al. (2013) adopt unlabeled target language data and a learning method that can incorporate diverse knowledge sources through ambiguous labeling for transfer parsing. In comparison, we leverage unlabeled auxiliary language data to learn language-agnostic contextual representations to improve cross-lingual transfer.

Multilingual Representation Learning. The basic of the unsupervised cross-lingual parsing is that we can align the representations of different languages into the same space, at least at the word level. The recent development of bilingual or multilingual word embeddings provide us with such shared representations. We refer the readers to the surveys of Ruder et al. (2017) and Glavaš et al. (2019) for details. The main idea is that we can train a model on top of the source language embeddings which are aligned to the same space as the target language embeddings and thus all the model parameters can be directly shared across languages. During transfer to a target language, we simply replace the source language embeddings with the target language embeddings. This idea is further extended to learn multilingual contextualized word representations, for example, multilingual BERT (Devlin et al., 2019), have been shown very effective for many cross-lingual transfer tasks (Wu and Dredze, 2019). In this work, we show that further improvements can be achieved by adaptating the contextual encoders via unlabeled auxiliary languages even when the encoders are trained on top of multilingual BERT.

Adversarial Training. The concept of adversarial training via Generative Adversarial Networks (GANs) (Goodfellow et al., 2014; Szegedy et al., 2014; Goodfellow et al., 2015) was initially introduced in computer vision for image classification and received enormous success in improving model's robustness on input images with perturbations. Later many variants of GANs (Arjovsky et al., 2017; Gulrajani et al., 2017) were proposed to improve its' training stability. In NLP, adversarial training was first utilized for domain adaptation (Ganin et al., 2016). Since then adversarial training has started to receive an increasing interest in the NLP community and applied to many NLP applications including part-of-speech (POS) tagging (Gui et al., 2017; Yasunaga et al., 2018), dependency parsing (Sato et al., 2017), relation extraction (Wu et al., 2017), text classification (Miyato et al., 2017; Liu et al., 2017; Chen and Cardie, 2018), dialogue generation (Li et al., 2017).

In the context of cross-lingual NLP tasks, many recent works adopted adversarial training, such as in sequence tagging (Adel et al., 2018), text classification (Xu and Yang, 2017; Chen et al., 2018), word embedding induction (Zhang et al., 2017; Lample et al., 2018), relation classification (Zou et al., 2018), opinion mining (Wang and Pan, 2018), and question-question similarity reranking (Joty et al., 2017). However, existing approaches only consider using the *target* language as the auxiliary language. It is unclear whether the language invariant representations learned by previously proposed methods can perform well on a

wide variety of *unseen* languages. To the best of our knowledge, we are the first to study the effects of language-agnostic representations on a broad spectrum of languages.

5 Conclusion

In this paper, we study learning language invariant contextual encoders for cross-lingual transfer. Specifically, we leverage unlabeled sentences from auxiliary languages and adversarial training to induce language-agnostic encoders to improve the performances of the cross-lingual dependency parsing. Experiments and analysis using English as the source language and six foreign languages as the auxiliary languages not only show improvements on cross-lingual dependency parsing, but also demonstrates that contextual encoders successfully learns not to capture language-dependent features through adversarial training. In the future, we plan to investigate the effectiveness of adversarial training for multi-source transfer to parsing and other cross-lingual NLP applications.

Abstract

Recognising dialogue acts (DA) is important for many natural language processing tasks such as dialogue generation and intention recognition. In this paper, we propose a dual-attention hierarchical recurrent neural network for DA classification. Our model is partially inspired by the observation that conversational utterances are normally associated with both a DA and a topic, where the former captures the social act and the latter describes the subject matter. However, such a dependency between DAs and topics has not been utilised by most existing systems for DA classification. With a novel dual task-specific attention mechanism, our model is able, for utterances, to capture information about both DAs and topics, as well as information about the interactions between them. Experimental results show that by modelling topic as an auxiliary task, our model can significantly improve DA classification, yielding better or comparable performance to the state-of-the-art method on three public datasets.

1 Introduction

Dialogue Acts (DA) are semantic labels of utterances, which are crucial to understanding communication: much of a speaker's intent is expressed, explicitly or implicitly, via social actions (e.g., questions or requests) associated with utterances (Searle, 1969). Recognising DA labels is important for many natural language processing tasks. For instance, in dialogue systems, knowing the DA label of an utterance supports its interpretation as well as the generation of an appropriate response (Searle, 1969; Chen et al., 2018). In the security domain, being able to detect intention in conversational texts can effectively support the recognition of sensitive information exchanged in emails or other communication channels, which is critical to timely security intervention (Verma et al., 2012).

A wide range of techniques have been investigated for DA classification. Early works on DA classification are mostly based on general machine learning techniques, framing the problem either as multi-class classification (e.g., using SVMs (Liu, 2006) and dynamic Bayesian networks (Dielmann and Renals, 2008)) or a structured prediction task (e.g., using Conditional Random Fields (Kim et al., 2010; Chen et al., 2018; Raheja and Tetreault, 2019, CRF)). Recent studies to the problem of DA classification have seen an increasing uptake of deep learning techniques, where promising results have been obtained. Deep learning approaches typically model the dependency between adjacent utterances (Ji et al., 2016; Lee and Dernoncourt, 2016). Some researchers further account for dependencies among both consecutive utterances and consecutive DAs, i.e., both are considered factors that influence natural dialogue (Kumar et al., 2018; Chen et al., 2018). There is also work exploring different deep learning architectures (e.g., hierarchical CNN or RNN/LSTM) for incorporating context information for DA classification (Liu et al., 2017).

It has been observed that conversational utterances are normally associated with both a DA and a topic, where the former captures the social act (e.g., promising) and the latter describes the subject matter (Wallace et al., 2013). It is also recognised that the types of DA associated with a conversation are likely to be influenced by the topic of the conversation (Searle, 1969; Wallace et al., 2013). For instance, conversations relating to topics about *customer service* might be more frequently associated with DAs of type Wh-question (e.g., *Why my mobile is not working?*) and a complaining statement (Bhuiyan et al., 2018); whereas meetings covering administrative

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 383–392
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

topics about resource allocation are likely to exhibit significantly more defending statements and floor grabbers (e.g., *Well I mean - is the handheld really any better?*) (Wrede and Shriberg, 2003). However, such a reasonable source of information, surprisingly, has not been explored in the deep learning literature for DA classification. We assume that modelling the topics of utterances as additional contextual information may effectively support DA classification.

In this paper, we propose a dual-attention hierarchical recurrent neural network with a CRF (DAH-CRF) for DA classification. Our model is able to account for rich context information with the developed dual-attention mechanism, which, in addition to accounting for the dependencies between utterances, can further capture, for utterances, information about both topics and DAs. Topic is a useful source of context information which has not previously been explored in existing deep learning models for DA classification. Second, compared to the flat structure employed by existing models (Khanpour et al., 2016; Ji et al., 2016), our hierarchical recurrent neural network can represent the input at the character, word, utterance, and conversation levels, preserving the natural hierarchical structure of a conversation. To capture the topic information of conversations, we propose a simple automatic utterance-level topic labelling mechanism based on LDA (Blei et al., 2003), which avoids expensive human annotation and improves the generalisability of our model.

We evaluate our model against several strong baselines (Wallace et al., 2013; Ji et al., 2016; Kumar et al., 2018; Chen et al., 2018; Raheja and Tetreault, 2019) on the task of DA classification. Extensive experiments conducted on three public datasets (i.e., Switchboard Dialog Act Corpus (SWDA), DailyDialog (DyDA), and the Meeting Recorder Dialogue Act corpus (MRDA)) show that by modelling the topic information of utterances as an auxiliary task, our model can significantly improve DA classification for all datasets compared to a base model without modelling topic information. Our model also yields better or comparable performance to state-of-the-art deep learning method (Raheja and Tetreault, 2019) in classification accuracy.

To summarise, the contributions of our paper are three-fold: (1) we propose to leverage topic information of utterances, a useful source of contextual information which has not previously been explored in existing deep learning models for DA classification; (2) we propose a dual-attention hierarchical recurrent neural network with a CRF which respects the natural hierarchical structure of a conversation, and is able to incorporate rich context information for DA classification, achieving better or comparable performance to the state-of-the-art; (3) we develop a simple topic labelling mechanism, showing that using the automatically acquired topic information for utterances can effectively improve DA classification.

2 Related Work

Broadly speaking, methods for DA classification can be divided into two categories: multi-class classification (e.g., SVMs (Liu, 2006) and dynamic Bayesian networks (Dielmann and Renals, 2008)) and structured prediction tasks including HMM (Stolcke et al., 2000) and CRF (Kim et al., 2010). Recently, deep learning has been widely applied in many NLP tasks, including DA classification. Kalchbrenner and Blunsom (2013) proposed to model a DA sequence with a RNN where sentence representations were constructed by means of a convolutional neural network (CNN). Lee and Dernoncourt (2016) tackled DA classification with a model built upon RNNs and CNNs. Specifically, their model can leverage the information of preceding texts, which can effectively help improve the DA classification accuracy. A latent variable recurrent neural network was developed for jointly modelling sequences of words and discourse relations between adjacent sentences (Ji et al., 2016). In their work, the shallow discourse structure is represented as a latent variable and the contextual information from preceding utterances are modelled with a RNN.

Kumar et al. (2018) proposed a hierarchical Bi-LSTM model with a CRF for DA classification, where the inter-utterance and intra-utterance information are encoded by a hierarchical Bi-LSTM and the dependency between DA labels is captured by a CRF. Chen et al. (2018) developed a CRF-Attentive Structured Network (CRF-ASN) for DA classification. They applied structured attention network to the CRF layer in order to model contextual utterances and corresponding DAs together. Raheja and Tetreault (2019) achieved the state-of-the-art performance on the SWDA dataset by employing a self-attention mechanism, a CRF

layer and character-level embeddings.

In addition to modelling dependency between utterances, various contexts have also been explored for improving DA classification or joint modelling DA under multi-task learning. For instance, Wallace et al. (2013) proposed a generative joint sequential model to classify both DA and topics of patient-doctor conversations. Their model is similar to the factorial LDA model (Paul and Dredze, 2012), which generalises LDA to assign each token a K-dimensional vector of latent variables. We would like to emphasise that the model of Wallace et al. (2013), only assumed that each utterance is generated conditioned on the previous and current topic/DA pairs. In contrast, our model is able to model the dependencies of all preceding utterances of a conversation, and hence can better capture the effect between DAs and topics.

3 Methodology

Given a training corpus $\mathcal{D} = \langle (C_n, Y_n, Z_n) \rangle_{n=1}^{N}$, where $C_n = \langle u_t^n \rangle_{t=1}^{T}$ is a conversation containing a sequence of T utterances, $Y_n = \langle y_t^n \rangle_{t=1}^{T}$ and $Z_n = \langle z_t^n \rangle_{t=1}^{T}$ are the corresponding labels of DA and topics for C_n, respectively. Each utterance $u_t = \langle w_t^i \rangle_{i=1}^{K}$ of C_n is a sequence of K words. Our goal is to learn a model from $\mathcal{D}$, such that, given an unseen conversation C_u, the model can predict the DA labels of the utterances of C_u.

Figure 1 gives an overview of the proposed Dual-Attention Hierarchical recurrent neural network with a CRF (DAH-CRF). A shared utterance encoder encodes each word w_t^i of an utterance u_t into a vector $\mathbf{h}_t^i$. The DA attention and topic attention mechanisms capture DA and topic information as well as the interactions between them. The outputs of the dual-attention are then encoded in the conversation-level sequence taggers (i.e., $\mathbf{g}_t$ and $\mathbf{s}_t$), based on the corresponding utterance representations (i.e., $\mathbf{l}_t$ and $\mathbf{v}_t$). Finally, the target labels (i.e., y_t and z_t) are predicted in the CRF layer.

3.1 Shared Utterance Encoder

In our model, we adopt a shared utterance encoder to encode the input utterances. Such a design is based on the rationale that the shared encoder can transfer parameters between two tasks and reduce the risk of overfitting (Ruder, 2017). Specifically, the shared utterance encoder is implemented using the bidirectional gated recurrent unit (Cho et al., 2014, BiGRU), which encodes each utterance $u_t = \langle w_t^i \rangle_{i=1}^{K}$ of a conversation C_n as a series of hidden states $\langle \mathbf{h}_t^i \rangle_{i=1}^{K}$. Here, i indicates the timestamp of a sequence, and we define $\mathbf{h}_t^i$ as follows

$$\mathbf{h}_t^i = \overrightarrow{\mathbf{h}}_t^i \oplus \overleftarrow{\mathbf{h}}_t^i \tag{1}$$

where $\oplus$ is an operation for concatenating two vectors, and $\overrightarrow{\mathbf{h}}_t^i$ and $\overleftarrow{\mathbf{h}}_t^i$ are the i-th hidden state of the forward gated recurrent unit (Cho et al., 2014, GRU) and backward GRU for w_t^i, respectively. Formally, the forward GRU $\overrightarrow{\mathbf{h}}_t^i$ is computed as follows

$$\overrightarrow{\mathbf{h}}_t^i = \mathrm{GRU}(\overrightarrow{\mathbf{h}}_t^{i-1}, \mathbf{e}_t^i) \tag{2}$$

where $\mathbf{e}_t^i$ is the concatenation of the word embedding and the character embedding of word w_t^i. Finally, the backward GRU encodes u_t from the reverse direction (i.e. $w_t^K \rightarrow w_t^1$) and generates $\langle \overleftarrow{\mathbf{h}}_t^i \rangle_{i=1}^{K}$ following the same formulation as the forward GRU.

3.2 Task-specific Attention

Recall that one of the key challenges of our model is to capture for each utterance, information about both DAs and topics, as well as information about the interactions between them. We address this challenge by incorporating into our model a novel task-specific dual-attention mechanism, which accounts for both DA and topic information extracted from utterances. In addition, DAs and topics are semantically relevant to different words in an utterance. With the proposed attention mechanism, our model can also assign different weights to the words of an utterance by learning the degree of importance of the words to the DA or topic labelling task, i.e., promoting the words which are important to the task and reducing the noise introduced by less important words.

For each utterance u_t, the DA attention calculates a weight vector $\langle \alpha_t^i \rangle_{i=1}^{K}$ for $\langle \mathbf{h}_t^i \rangle_{i=1}^{K}$, the hidden states of u_t. u_t can then be represented as an attention vector $\mathbf{l}_t$ computed as follows

$$\mathbf{l}_t = \sum_{i=1}^{K} \alpha_t^i \mathbf{h}_t^i \tag{3}$$

In contrast to the traditional attention mechanism (Bahdanau et al., 2015), which only depends on one set of hidden vectors from the Seq2Seq decoder, the DA attention of our model relies on two sets of hidden vectors, i.e., $\mathbf{g}_{t-1}$ of

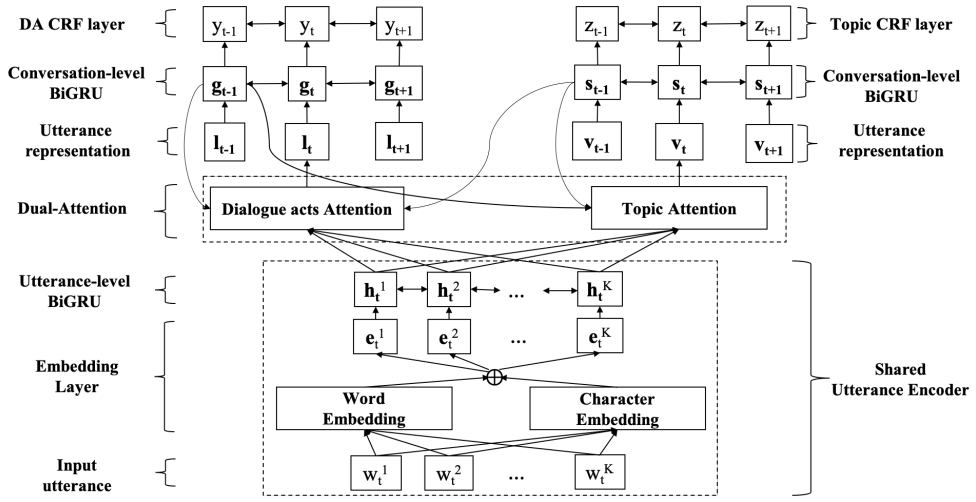

Figure 1: Overview of the dual-attention hierarchical recurrent neural network with a CRF.

the conversation-level DA tagger and $\mathbf{s}_{t-1}$ of the conversation-level topic tagger, where dual attention mechanism can capture, for utterances, information about both DAs and topics as well as the interaction between them. Specifically, the weights $\langle \alpha_t^i \rangle_{i=1}^K$ for the DA attention are calculated as follows:

$$\alpha_t^i = \text{softmax}(o_t^i) \tag{4}$$

$$o_t^i = \mathbf{w}_a^\top \tanh\left(\mathbf{W}^{(\text{act})}(\mathbf{s}_{t-1} \oplus \mathbf{g}_{t-1} \oplus \mathbf{h}_t^i) + \mathbf{b}^{(\text{act})}\right) \tag{5}$$

The topic attention layer has a similar architecture to the DA attention layer, which takes as input both $\mathbf{s}_{t-1}$ and $\mathbf{g}_{t-1}$. The weight vector $\langle \beta_t^i \rangle_{i=1}^K$ for the topic attention output $\mathbf{v}_t$ can be calculated similar to Eq. 3 and Eq. 4. Note that $\mathbf{w}_a$, $\mathbf{W}^{(\text{act})}$, and $\mathbf{b}^{(\text{act})}$ are vectors of parameters that need to be learned during training.

3.3 Conversational Sequence Tagger

CRF sequence tagger for DA. The conversational CRF sequence tagger for DA predicts the next DA y_t conditioned on the conversational hidden state $\mathbf{g}_t$ and adjacent DAs (c.f. Figure 1). Formally, this conditional probability of the whole conversation can be formulated as

$$p\left(y_{1:T}|C;\theta\right) = \frac{\prod_{t=1}^T \Psi\left(y_{t-1}, y_t, \mathbf{g}_t;\theta\right)}{\sum_Y \prod_{t=1}^T \Psi\left(y_{t-1}, y_t, \mathbf{g}_t;\theta\right)} \tag{6}$$

$$\begin{aligned}\Psi\left(y_{t-1}, y_t, \mathbf{g}_t;\theta\right) &= \Psi_{emi}\left(y_t, \mathbf{g}_t\right)\Psi_{tran}\left(y_{t-1}, y_t\right) \\ &= \mathbf{g}_t\left[y_t\right]\mathbf{P}_{y_t, y_{t-1}}\end{aligned} \tag{7}$$

Here the feature function $\Psi(\cdot)$ includes two score potentials: emission and transition. The emission potential Ψ_{emi} regards utterance representation $\mathbf{g}_t$ as the unary feature. The transition potential Ψ_{tran} is a pairwise feature constructed from a $T \times T$ state transition matrix $\mathbf{P}$, where T is the number of DA classes, and $\mathbf{P}_{y_t, y_{t-1}}$ is the probability of transiting from state y_{t-1} to y_t. $C = \langle u_t \rangle_{t=1}^T$ is the sequence of all utterances seen so far, θ is the parameters of the CRF layer. $\mathbf{g}_t$ is calculated in a BiGRU similar to Eq. 1 and Eq. 2:

$$\mathbf{g}_t = \overrightarrow{\mathbf{g}}_t \oplus \overleftarrow{\mathbf{g}}_t \tag{8}$$

$$\overrightarrow{\mathbf{g}}_t = \text{GRU}(\overrightarrow{\mathbf{g}}_{t-1}, \mathbf{l}_t) \tag{9}$$

CRF sequence tagger for topic. The conversational CRF sequence tagger for topic is designed to predict topic z_t conditioned on $\mathbf{v}_t$ and adjacent topics, which can be calculated similar to the formulation of the CRF tagger for DA.

Training the model. Let Θ be all the model parameters that need to be estimated for DAH-CRF. Θ then is estimated based on $\mathcal{D} = \langle (C_n, Y_n, Z_n) \rangle_{n=1}^N$ (i.e., a corpus with N conversations) by maximising the following objective function

$$\begin{aligned}\mathcal{L} = \sum_{n=1}^N [&\log\left(p\left(y_{1:T}^n|C_n;\Theta\right)\right) \\ &+\alpha \log\left(p\left(z_{1:T}^n|C_n;\Theta\right)\right)]\end{aligned} \tag{10}$$

The hyper-parameter α controls the contribution of the conversational topic tagger towards the objective function. In our experiments, $\alpha = 0.5$ is determined using the validation datasets. During

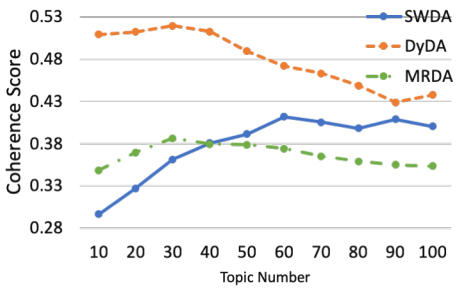

Figure 2: Coherence score of LDA on three datasets.

the test, the optimal DA or topic sequence is calculated using the Viterbi algorithm (Viterbi, 1967).

$$Y' = \arg \max_{y_{1:T} \in Y} p(y_{1:T}|C, \Theta) \quad (11)$$

3.4 Automatically Acquiring Topic Labels

To avoid expensive human annotation and to improve the generalisability of our model, we propose to label the topic of each utterance of the datasets using LDA (Blei et al., 2003). While perplexity has been widely used for model selection for LDA (Lin, 2011; He et al., 2012), we employ a topic coherence measure proposed by (Röder et al., 2015) to determine the optimal topic number for each dataset, which combines the indirect cosine measure with the normalised pointwise mutual information (Bouma, 2009, NPMI) and the Boolean sliding window. Empirically, we found the latter yields much better topic clusters than perplexity for supporting DA classification.

We treat each conversation as a document and train topic models using Gensim with topic number settings ranging from 10 to 100 (using an increment step of 10). Gibbs sampling is used to estimate the model posterior and for each model we run 1,000 iterations. For each trained model, we calculate the averaged coherence score of the extracted topics using Gensim[1], an implementation following (Röder et al., 2015). Figure 2 shows the topic coherence score for each topic number setting for all datasets, from which we determine that the optimal topic number setting for SWDA, DyDA, and MRDA are 60, 30, and 30, respectively.

Based on the optimal models (i.e., a trained LDA model using the optimal topic number setting), we assign topic labels to the datasets with two different strategies, i.e., conversation-level labelling ($conv$) and utterance-level labelling (utt).

[1]https://radimrehurek.com/gensim/models/coherencemodel.html

Dataset	$\|C\|$	$\|T\|$	$\|V\|$	Training	Validation	Testing
SWDA	42	66	20K	1003/193K	112/23K	19/5K
DyDA	4	10	22K	11K/92.7K	1K/8.5K	1K/8.2K
MRDA	5	-	15K	51/77.9K	11/15.8K	11/15.5K

Table 1: $|C|$ is the number of DA classes, $|T|$ is the number of manually labelled conversation-level topic classes, $|V|$ is the vocabulary size. Training, Validation and Testing indicate the number of conversations/utterances in the respective splits.

For conversation-level labelling, we assign the topic label with the highest marginal probability to the conversation based on the corresponding per-document topic proportion estimated by LDA. Every utterance of the conversation then shares the same topic label of the conversation. For utterance-level labelling, there is an additional step to perform inference on every utterance based on corresponding optimal model (e.g., for every utterance of SWDA, we do inference using the LDA trained on SWDA with 60 topics), and assign the topic label with the highest marginal probability to the utterance. Therefore, the topic labels of the utterances of the same conversation could be different for utterance-level labelling.

4 Experimental Settings

4.1 Datasets

We evaluate the performance of our model on three public DA datasets with different characteristics, namely, Switchboard Dialog Act Corpus (Jurafsky, 1997, SWDA), Dailydialog (Li et al., 2017, DyDA), and the Meeting Recorder Dialogue Act corpus (Shriberg et al., 2004, MRDA).

SWDA[2] consists of 1,155 two-sided telephone conversations manually labelled with 66 conversation-level topics (e.g., *taxes*, *music*, etc.) and 42 utterance-level DAs (e.g., *statement-opinion*, *statement-non-opinion*, *wh-question*).

DyDA[3] contains 13,118 human-written daily conversations, manually labelled with 10 conversation-level topics (e.g., *tourism*, *politics*, *finance*) as well as four utterance-level DA classes, i.e., *inform*, *question*, *directive* and *commissive*. The former two classes are information transfer acts, while the latter two are action discussion acts.

MRDA[4] contains 75 meeting conversations anno-

[2]https://web.stanford.edu/~jurafsky/ws97/manual.august1.html

[3]http://yanran.li/dailydialog

[4]http://www1.icsi.berkeley.edu/~ees/dadb/

tated with 5 DAs, i.e., Statement (S), Question (Q), Floorgrabber (F), Backchannel (B), and Disruption (D). The average number of utterances per conversation is 1,496. There are no manually annotated topic labels available for this dataset.

4.2 Implementation Details

For all experimental datasets, the top 85% highest frequency words were indexed. For SWDA and MRDA, we split training/validation/testing datasets following (Stolcke et al., 2000; Lee and Dernoncourt, 2016). For DyDA, we used the standard split from the original dataset (Li et al., 2017). The statistics of the experimental datasets are summarised in Table 1. We represented input data with 300-dimensional Glove word embeddings (Pennington et al., 2014) and 50-dimensional character embeddings (Ma and Hovy, 2016). We set the dimension of the hidden layers (i.e., $\mathbf{h}_t^i$, $\mathbf{g}_t$ and $\mathbf{s}_t$) to 256 and applied a dropout layer to both the shared encoder and the sequence tagger at a rate of 0.2. The Adam optimiser (Kingma and Ba, 2015) was used for training with an initial learning rate of 0.001 and a weight decay of 0.0001. Each utterance in a mini-batch was padded to the maximum length for that batch, and the maximum batch-size allowed was 50.

4.3 Baselines

We compare the proposed DAH-CRF model incorporating utterance-level topic labels extracted by LDA (denoted as DAH-CRF+LDA$_{utt}$) against five strong baselines and two variants of our own models:

JAS[5]: A generative joint, additive, sequential model of topics and speech acts in patient-doctor communication (Wallace et al., 2013);

DRLM-Cond[6]: A latent variable recurrent neural network for DA classification (Ji et al., 2016);

Bi-LSTM-CRF[7]: A hierarchical Bi-LSTM with a CRF to classify DAs (Kumar et al., 2018);

CRF-ASN: An attentive structured network with a CRF for DA classification (Chen et al., 2018);

SelfAtt-CRF: A hierarchical Bi-GRU with self-attention and CRF (Raheja and Tetreault, 2019);

DAH-CRF+MANUAL$_{conv}$: Use the manually annotated conversation-level topic labels (i.e., each utterance of the conversation shares the same topic) for DAH-CRF model training rather than the topic labels automatically acquired from LDA;

DAH-CRF+LDA$_{conv}$: Use conversation-level topic labels automatically acquired from LDA for DAH-CRF model training.

Note that only JAS (a non-deep-learning model) has attempted to model both DAs and topics, whereas all the deep learning baselines do not model topic information as a source of context for DA classification. All the baselines mentioned above use the same test dataset as our models for all experimental datasets.

5 Experimental Results

5.1 Dialogue Acts Classification

Table 2 shows the DA classification accuracy of our models and the baselines on three experimental datasets. We fine-tuned the model parameters for JAS, DRLM-Cond and Bi-LSTM-CRF in order to make the comparison as fair as possible. The implementation of CRF-ASN and SelfAtt-CRF are not available so we can only report their results for SWDA and MRDA based on the original papers (Chen et al., 2018; Raheja and Tetreault, 2019).

It can be observed that by jointly modelling DA and topics, DAH-CRF+LDA$_{utt}$ outperforms the two best baseline models SelfAtt-CRF and CRF-ASN around 1% on the MRDA dataset. Our model also gives similar performance to SelfAtt-CRF, the baseline which achieved the state-of-the-art performance on the SWDA dataset (i.e., 82.3% vs. 82.9%). While both manually annotated and automatically acquired topic labels are effective, we see that DAH-CRF+LDA$_{utt}$ outperforms both DAH-CRF+MANUAL$_{conv}$ and DAH-CRF+LDA$_{conv}$, i.e., with over 1.6% gain on DyDA and over 1.4% on SWDA (significant; paired t-test $p < .01$). It is also ob-

Model	SWDA	MRDA	DyDA

SAH-CRF	78.4	89.6	84.1
DAH + LDA$_{utt}$	79.5	91.1	86.0
DAH-CRF + LDA$_{utt}$ (without Dual-Att)	81.0	91.3	86.3
DAH-CRF + LDA$_{utt}$	82.3	92.2	88.1

Table 3: Ablation studies of DA classification.

served that DAH-CRF+MANUAL$_{conv}$ and DAH-CRF+LDA$_{conv}$ perform very similar to each other.

5.2 Ablation Study Results

We conducted ablation studies (see Table 3) in order to evaluate the contribution of the components of our DAH-CRF+LDA$_{utt}$ model, and more importantly, the effectiveness of leveraging topic information for supporting DA classification.

DAH-CRF+LDA$_{utt}$ (without Dual-Att) removes the dual-attention component from DAH-CRF+LDA$_{utt}$, and DAH+LDA$_{utt}$ removes the CRF from DAH-CRF+LDA$_{utt}$ but retaining the dual-attention component. SAH is a Single-Attention Hierarchical RNN model without a CRF, i.e., a simplified version of DAH+LDA$_{utt}$ that only models DAs with topical information omitted. As can be seen in Table 3, DAH+LDA$_{utt}$ achieves over 3% averaged gain on all datasets when compared to SAH, which clearly shows that leveraging topic information can effectively support DA classification. It is also observed that both the dual-attention mechanism and the CRF component are beneficial, but are more effective on the SWDA and DyDA datasets than MRDA.

In summary, while all the analysed model components are beneficial, the biggest gain is obtained by jointly modelling DAs and topics.

5.3 Analysing the Effectiveness of Joint Modelling Dialogue Act and Topic

In this section, we provide detailed analysis on why DAH-CRF+LDA$_{utt}$ can yield better performance than SAH-CRF by jointly modelling DAs and topics. Due to the page limit, our discussion focuses on SWDA and DyDA datasets.

Figure 4 shows the normalized confusion matrix derived from 10 DA classes of SWDA for both SAH-CRF and DAH-CRF+LDA$_{utt}$ models. It can be observed that DAH-CRF+LDA$_{utt}$ yields improvement on recall for many DA classes compared to SAH-CRF, e.g., 23.8% improvement

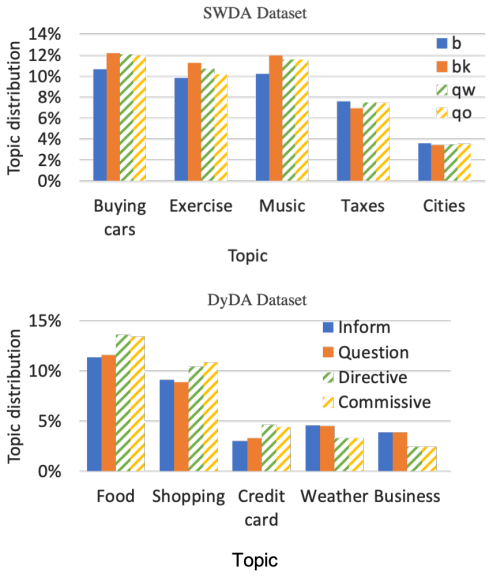

Figure 3: We highlight the prominent topics for some example DAs. The topic distribution of a topic k under a DA label d is calculated by averaging the marginal probability of topic k for all utterances with the DA label d.

on *bk* and 11.7% on *sv*. For *bk* (`Response Acknowledge`) which has the highest improvement level, we see that the improvement largely comes from the reduction of misclassifing *bk* to *b* (`Acknowledge Backchannel`). The key difference between *bk* and *b* is that an utterance labelled with *bk* has to be produced within a question-answer context, whereas *b* is a "continuer" simply representing a response to the speaker (Jurafsky, 1997). It is not surprising that SAH-CRF makes poor prediction on the utterances of these two DAs: they share many syntactic cues, e.g., indicator words such 'okay', 'oh', and 'uh-huh', which can easily confuse the model. When comparing the topic distribution of the utterances under the *bk* and *b* categories (cf. Figure 3), we found topics relating to personal leisure (e.g., buying cars, music, and exercise) are much more prominent in *bk* than *b*. By leveraging the topic information, DAH-CRF+LDA$_{utt}$ can better handle the confusion cases and hence improve the prediction for *bk* significantly.

There are also cases where DAH-CRF+LDA$_{utt}$ performs worse than SAH-CRF. Take the DA pair of *qo* (`Open Question`) and *qw* (`wh-questions`) as an example. *qo* refers to questions like '*How about you?*' and its variations (e.g., '*What do you think?*'), whereas *qw* represents wh-questions which are much

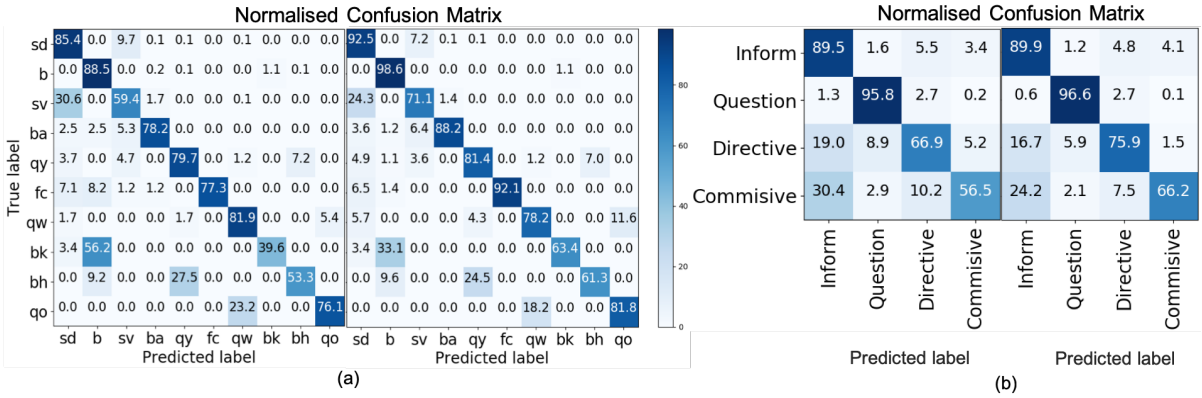

Figure 4: The normalized confusion matrix of DAs using SAH-CRF (left) and DAH-CRF+LDA$_{utt}$ (right) on SWDA (a) and DyDA (b).

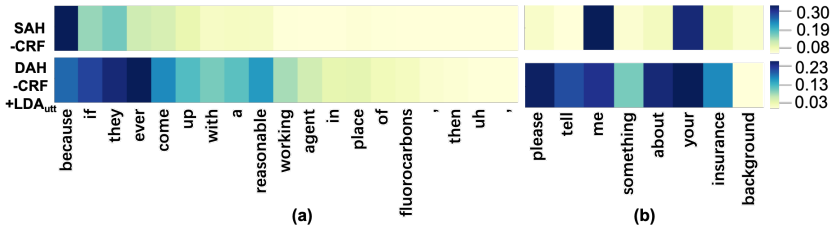

Figure 5: DA Attention visualisation using SAH-CRF and DAH-CRF+LDA$_{utt}$ on (a) SWDA and (b) DyDA datasets. The true labels of the utterances above are *sd* (*statement-non-opinion*) and *Directive*, respectively. SAH-CRF misclassified the DA as *sv* (*statement-opinion*) and *Inform* whereas DAH-CRF+LDA$_{utt}$ gives correct prediction for both cases.

more specific in general (e.g. '*What other long range goals do you have?*'). SAH-CRF gives quite decent performance in distinguishing *qw* and *qo* classes. This is somewhat reasonable, as linguistically the utterances of these two classes are quite different, i.e., the *qw* utterance expresses very specific question and is relatively lengthy, whereas *qo* utterances tends to be very brief. We see that DAH-CRF+LDA$_{utt}$ performs worse than SAH-CRF: a greater number of *qw* utterances are misclassified by DAH-CRF+LDA$_{utt}$ as *qo*. This might be attributed to the fact that topic distributions of *qw* and *qo* are similar to each other (see Figure 3), i.e., incorporating the topic information into DAH-CRF may cause these two DAs to be less distinguishable for the model.

We also conducted a similar analysis on the DyDA dataset. As can be seen from the confusion matrices shown in Figure 4, DAH-CRF+LDA$_{utt}$ gives improvement over SAH-CRF for all the four DA classes of DyDA. In particular, `Directives` and `Commissive` achieve higher improvement margin compared to the other two classes, where the improvement are largely attributed to less number of instances of the `Directives` and `Commissive` classes being mis-classified into `Inform` and `Questions`. Examining the topic distributions in Figure 3 reveals that `Directives` and `Commissive` classes are more relevant to the topics such as *food*, *shopping*, and *credit card*. In contrast, the topics of `Inform` and `Questions` classes are more about *business*, and *weather*.

Finally, Figure 5 shows the DA attention visualisation examples of SAH-CRF and DAH-CRF+LDA$_{utt}$ for an utterance from SWDA and DyDA. For SWDA, it can be seen that SAH-CRF gives very high weight to the word "because" and de-emphasizes other words. However, DAH-CRF+LDA$_{utt}$ can capture more important words (e.g., "if", "reasonable", etc.) and correctly predicts the DA label as *sd*. For DyDA, SAH-CRF only focuses on "me" and "your", but DAH-CRF+LDA$_{utt}$ captures more words relevant to `Directive`, such as "please", "tell", etc. To summarise, DAH-CRF+LDA$_{utt}$ can capture more significant words related to the corresponding DA, by modelling both DAs and topic information with

the dual-attention mechanism.

6 Conclusion

In this paper, we developed a dual-attention hierarchical recurrent neural network with a CRF for DA classification. With the proposed task-specific dual-attention mechanism, our model is able to capture information about both DAs and topics, as well as information about the interactions between them. Moreover, our model is generalised by leveraging an unsupervised model to automatically acquire topic labels. Experimental results based on three public datasets show that modelling utterance-level topic information as an auxiliary task can effectively improve DA classification, and that our model is able to achieve better or comparable performance to the state-of-the-art deep learning methods for DA classification.

We envisage that our idea of modelling topic information for improving DA classification can be adapted to other DNN models, e.g., to encode topic labels into word embeddings and then concatenate with the utterance-level or conversation-level hidden vectors of our baselines, e.g. SelfAtt-CRF. It will also be interesting to explicitly take into account speaker's role in the future.

Abstract

Reflective listening—demonstrating that you have heard your conversational partner—is key to effective communication. Expert human communicators often *mimic and rephrase* their conversational partner, e.g., when responding to sentimental stories or to questions they don't know the answer to. We introduce a new task and an associated dataset wherein dialogue agents similarly mimic and rephrase a user's request to communicate sympathy (*I'm sorry to hear that*) or lack of knowledge (*I do not know that*). We study what makes a rephrasal response good against a set of qualitative metrics. We then evaluate three models for generating responses: a syntax-aware rule-based system, a seq2seq LSTM neural models with attention (S2SA), and the same neural model augmented with a copy mechanism (S2SA+C). In a human evaluation, we find that S2SA+C and the rule-based system are comparable and approach human-generated response quality. In addition, experiences with a live deployment of S2SA+C in a customer support setting suggest that this generation task is a practical contribution to real world conversational agents.

1 Introduction

Humans in conversation naturally engage in reflective (or active) listening, where they indicate they have heard and understood their partner by repeating or rephrasing what they have said. This strategy has its roots in Rogerian psychology (Rogers, 1951) as a counseling technique meant to build trust and empathy. Dialog agents benefit from the same strategy to keep conversations pleasant, especially when the agent cannot help.

Reflective listening can be formalized into two aspects: (1) *mimicking and rephrasing* the conversational partner's utterance, and (2) incorporating an expressive speech act (Searle, 1976) appropriate for the utterance. For example, in Table 1 (b) we incorporate the speech act *I don't know* on top of the mimicked utterance *when the swimming pool is open*.

Prompt: *Hmm... I'm curious as to whether the swimming pool is open after 7pm?*
✓ a. I do not know that
✓ b. I don't know when the swimming pool is open.
✓ c. I don't know as to whether the swimming pool is open after 7pm.
✗ d. I don't know if you are curious as to whether the swimming pool is open after 7pm.
✗ e. I don't know Hmm... I'm curious as to whether the swimming pool is open after 7pm?

Table 1: Possible responses to indicate the dialog agent doesn't know the answer to a question (the prompt). The last two responses (d,e) are incorrect while the first three (a,b,c) are all acceptable with varying levels of specificity. The best response (b) is the one that is neither too vague (a) nor too verbose and repetitive (c).

In this paper, we propose a new task of generating mimic rephrasals for a given speech act. Table 1 illustrates the task with an example prompt and possible range of responses. The task is non-trivial to handle as naively putting the two parts together will result in responses that are either ungrammatical (e) or do not select the appropriate clause to rephrase (d). In our example, the first three responses all correctly convey the "I don't know" message. However, the blanket response (a) is overly vague and does not convey any understanding. Response (c) is specific but overly verbose and robotic. The best response is (b) since it contains enough details to signal understanding while remaining concise.

To get this best response, the agent must ig-

nore user flourishes (*"Hmm... I'm curious"*), identify the relevant portions of the prompt, correctly rephrase keywords (replace "I" with "you"), and coordinate arguments (using *"when"*).

By simulating reflective listening, we believe that mimic rephrasals will allow goal-oriented dialog systems to still respond naturally to open-ended input from users. In that vein, there has been renewed interest in open-ended dialog systems using neural models. However, Li et al. (2016a) have noted that naïve neural models tend to generate repetitive and dull responses such as "I don't know". While several attempts have been made to control various aspects of generation and hence produce more diverse output (Li et al., 2018; Hu et al., 2017; Logeswaran et al., 2018), we instead focus on expressing a single speech act (e.g., "I don't know"), but grounding it in diverse open-ended settings to simulate reflective listening.

In this paper, we examine what makes for a *good* response for a given speech act. We create two datasets IDONTKNOW and EMOTIVE focusing on two speech acts demonstrating reflective listening, respectively stating that we do not know an answer and expressing sympathy. We analyze the quality of responses along different dimensions such as fluency (is the response grammatical?), appropriateness (is the response on topic?), specificity, repetitiveness, and conciseness. We also compare responses from rule-based and neural models to gain insight into the strengths/weaknesses of different models at this task. We demonstrate that the rule-based model is repetitive but performs well for simple cases, while a sequence-to-sequence model with attention (Bahdanau et al., 2015) and a copying mechanism (Gu et al., 2016) has more varied responses and compares favorably. We release our dataset, code, and experiments to the community. [1]

2 Task: Mimic Rephrasals

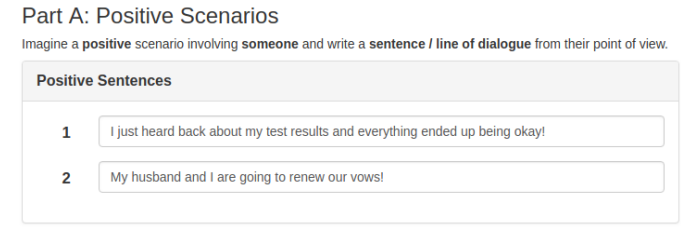
In this section, we introduce the task of *Mimic Rephrasal* more formally. We use the term *speech act* to describe the information we want to convey to our conversational partner. For example, a lack of knowledge, sympathy, etc. We define a *prompt* as an utterance by a conversational partner that should trigger some form of speech act. For example, "where is my car?" could be a prompt for the speech act conveying a lack of knowledge. Note that detection of these prompts and classification into the appropriate speech act—while important for a real-world system—is outside the scope of this task.

The task is as follows: given a prompt and the target speech act, generate a *mimic rephrasal* of that prompt which conveys the speech act. We explore the two use-cases of rephrasing lack of knowledge (IDONTKNOW) and sympathy (EMOTIVE).

The important goal of the task to generate a response that makes the user feel that they have been heard and understood. Directly measuring this is difficult. Instead, we propose five metrics to characterize the quality of mimic rephrasals:

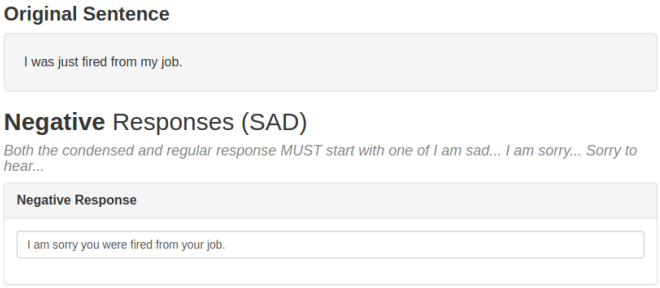
- **appropriateness** Did the response include the topic of interest in the rephrasal?
- **fluency** Is the response grammatical?
- **specificity** How much detail from the input prompt is captured?
- **conciseness** Is the response to the point?
- **repetitiveness** Is the response repetitive?

Looking at Table 1: (d) is not *appropriate* and (e) has low *fluency*. (a) to (c) are both *appropriate* and *fluent* with varying *specificity* (from low to high) and *conciseness* (from high to low). Intuitively, there is a tradeoff between specificity and repetitiveness: it should neither be too vague nor too repetitive.



3 Dataset

Section 3.1 describes our process for collecting data, to document our dataset creation and to describe how to collect data for other speech acts—e.g., expressing gratitude, soliciting confirmation of intents, etc. The subsequent section (Section 3.2) describes some statistics of the two datasets in this paper: EMOTIVE and IDONTKNOW.



3.1 Data collection

Our data collection pipeline has two phases. In the first phase, workers were asked to come up with a *prompt* or scenario. For example, a question to ask the dialog agent, or a sentiment laden scenario. During this phase, workers were asked to be as creative as possible, to explore a variety of sentence structures and lengths in the way they phrase their prompts, and diversity in the topics covered. In the second phase, we asked another set of workers to generate multiple *responses* each to the prompt.

[1] https://github.com/square/MimicAndRephrase/

(a) Interface when generating prompts

(b) Interface when generating mimic rephrasals

Figure 1: Our data collection pipeline. First, crowdworkers are asked to generate a given *prompt* or scenario (a). Then, a different worker is asked to generate the *mimic rephrasal* of the prompt generated by the first worker (b).

IDontKnow
Prompt: I am legally resident in Northern Ireland, where can I apply for an Irish visa **Mimic Rephrasal**: I do not know where you can apply for an Irish visa
P: When I register a domain, do I receive a website and a web hosting space **MR**: I do not know if you receive a website and a web hosting space when you register a domain
P: I'm having difficulty signing up. Whom can I contact **MR**: I do not know who you can contact about your difficulty signing up
Emotive
P: The sisters were able to reunite after 20 years **MR**: I am happy to hear the sisters were able to reunite after all this time
P: The future looks brighter than I ever imagined **MR**: I 'm happy that your future looks bright to you
P: My phone fell into the toilet and it's ruined now. **MR**: I am sad that your phone is ruined because it fell into the toilet

Table 2: Examples of mimic rephrasals in the IDontKnow and Emotive datasets collected in this paper. Each example has a *prompt* (the utterance from the conversational partner), and a *mimic rephrasal*: the utterance that should be returned by the dialog agent.

We found that splitting the task up into these two steps—generating prompts and then responses—improved the quality of our collected sentence pairs.

The interface used by Mechanical Turk workers is shown in Figure 1. Workers are first asked to generate a number of prompts (scenarios) in Figure 1 (a). Once these prompts are collected, a different set of workers were asked to generate responses to the prompts, completing our dataset (see Figure 1 (b)). Workers were paid \$0.10 per sentence in the prompt generation task, and \$0.07 per sentence in the response generation task.

3.2 Dataset statistics

We use the method described in Section 3.1 to collect two datasets IDontKnow and Emotive. Both datasets are split into train/dev/test splits with a ratio of 70/15/15%.

IDontKnow is a dataset for indicating that we don't know the answer to a question, or cannot execute a request. **Emotive** is a dataset for expressing sympathy for the topic of the prompt, with a balanced distribution of positive and negative sentiment. Examples for the two datasets can be found in Table 2, and statistics are given in Table 3. The modest size of the training set (10 189) means that a good fraction of the test set contains out of vocabulary words: the 1 377 test examples contain 512 words not seen during training, motivating our use of a copy mechanism.

We report statistics both on the full mimic rephrasal (MR), as well as for just the *Mimic* por-

	IDK	EMOTIVE
Dataset size		
Training pairs	6435	3887
Development pairs	1377	834
Test pairs	1377	828
Sentence length		
Prompt mean token count	11.7	11.0
Mimic mean token count	8.8	9.1
MR mean token count	12.9	10.2
Train Vocabulary		
Prompt vocabulary size	5703	4060
MR vocabulary size	5136	3200
Prompt/MR Jaccard Sim	0.83	0.61

Table 3: Statistics about the IDONTKNOW and EMOTIVE datasets. *Mimic* is here taken to be the mimicked utterance, without the preceding "I am happy/sorry/etc." or "I don't know". *MR* is the complete mimic rephrased response.

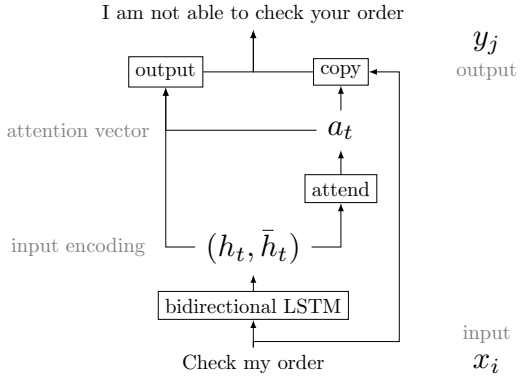


Figure 2: An outline of the sequence to sequence model with attention and a copying mechanism. The input phrase is *"Check my order"* with a correct output of *"I am not able to check your order"*.

tion of the mimic rephrasal. For example, for the MR "I do not know where you can apply for an Irish visa", the *Mimic* portion would be "where you can apply for an Irish visa." While the average MR is slightly longer than the original prompt, the Mimic portion averages 2.9 tokens (25%) shorter than the prompt. In addition, the high Jaccard similarity between the prompt and mimic portion suggests the task involves selecting key portions of the original sentence. [2]

4 Methods

In this section we describe three models for the task described above. These include a rule based baseline constructed with deterministic syntactic transformations as well as trained neural models.

4.1 Rule based baseline

As a naïve baseline, we use a set of hand-written syntactic rephrasing rules using Stanford CoreNLP (Manning et al., 2014). For example, for the IDONTKNOW dataset we developed 8 rules that match a Semgrex (Chambers et al., 2007) pattern to an associated dependency graph manipulation algorithm. For example, the rule based system matches the phrase *"What is the difference between the debt and the deficit?"* to a general type of pattern where the verb (in this case *"is"*) needs to be extracted from the dependency graph and reattached at the end to produce *"I do not know what the difference between the debt and the deficit is."* The EMOTIVE rule based system extracts the root clause from the constituency parse of the sentence and adds enclosing phrasing ("Sorry to hear that..."). Both systems also use simple string manipulation to replace pronouns and correct casing. We note that the rules were developed by iterating on the training data. In the appendix, we include a histogram of how often each rule was fired in the IDONTKNOW rule based system.

Although this is a strong baseline, it has some weaknesses. Writing and maintaining the rule set is difficult and time consuming. The Semgrex patterns and accompanying transformations are non-trivial and requires expert time to develop and maintain. Additionally, it is difficult to deterministically decide which portions of the prompt to keep or drop in the rephrasal. For instance, *"I found out someone has been stealing from me"* should drop the *found out* and respond with: *"Sorry to hear that someone has been stealing from you"*.

4.2 Neural Models

To address these issues, we develop a series of neural models for the task. Formally, let $\mathbf{x} = x_1, \ldots, x_n$ be the source sentence, and $\mathbf{y} = y_1, \ldots, y_m$ be the generated sequence of output tokens. We define a seq2seq model similar to existing neural MT models (Cho et al., 2014) for generating $\mathbf{y}$ given an input $\mathbf{x}$, as well as a model augmented with a copy mechanism.

Input embedding. All models use concatenated ELMo (Peters et al., 2018) and GloVE (Pennington et al., 2014) embedding for the input embeddings. The model architectures used for the EMOTIVE and IDONTKNOW datasets are identical with one

[2] Jaccard similarity is computed as the intersection over union of lemmatized non-stopword tokens between the prompt and Mimic portion.

exception. For the EMOTIVE task, an extra bit is appended to the word embeddings to specify whether the input has a positive or negative sentiment. [3]

Baseline neural model. Our baseline neural model is a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) with attention (Bahdanau et al., 2015). Formally, the *encoder* outputs a set of hidden states for each token given by $\{\bar{h}_1, \ldots, \bar{h}_n\} = LSTM\{m(x_1, \ldots, x_n)\}$ for word embeddings $m(x)$. The decoder is also an LSTM with hidden state initialized to the sum of the final hidden states of the forward and backward LSTMs contained in the bidirectional LSTM encoder. For encoder hidden state $\bar{h}_s$ and decoder hidden state h_t, the attention score $a_t(s)$ is defined as

$$a_t(s) = \frac{\exp(\text{score}(h_t, \bar{h}_s))}{\sum_{s'} \exp(\text{score}(h_t, \bar{h}_{s'}))}$$

where $\text{score}(h_t, \bar{h}_s) = \boldsymbol{v}_a^T \cdot \tanh(W_a[h_t; \bar{h}_s])$ and $\boldsymbol{v}_a$ and W_a are learnable parameters.

Decoding uses a modified beam search (see Section 4.3),[4] and the model is trained on the following cross entropy loss function:

$$J = \sum_{i=1}^{m} -\log p_v(y_i = y_i^* | y_{<i}, x)$$

where y_i^* is the expected output token given in the training data and $\log p_v(y_i = y_i^* | y_{<i}, x)$ is a distribution over the models vocabulary computed from the logits outputted by the model.

Neural model with copying. The most effective neural model we implemented augments the baseline neural model with a copying mechanism (Gu et al., 2016). This allows the model to generalize better to unseen vocabulary, and more strongly enforces the core tenant of the task: that we should be *mimicking* the prompt. An overview of the model is shown in Figure 2.

The key difference from the baseline neural model is that we now generate output tokens using a combined softmax over the model's vocabulary and the tokens in the input:

$$\log p(y_i = y_i^* | y_{<i}, x) = \log p_v(y_i = y_i^* | y_{<i}, x) + \sum_{\{j | x_j = y_i^*\}} \log p_c(y_i = \text{copy}(x_j) | y_{<i}, x),$$

where $\log p_v(\cdot)$ is the same as before, and $\log p_c(\cdot)$ is a distribution over the words in the input. For further details we defer the reader to (Gu et al., 2016). Similar to the baseline model, we decode the model using a modified beam search and train it using a cross-entropy loss.

4.3 Modified Beam Search

We use a modified version of beam search (Huang et al., 2017) when generating output tokens to favor longer responses. The modified beam search first calculates the average ratio of output tokens to input tokens from the dev set, k. We then compute the average logit value of an individual output token, $r(y_i)$, over all outputs produced on the dev set input, r_{avg}. A modified perplexity, $\tilde{sc}(\mathbf{y}, \mathbf{x})$, is used to determine which beams to prune, where $\mathbf{x}$ is a series of input tokens and $\mathbf{y}$ is a proposed series of output tokens (a beam):

$$\tilde{sc}(\mathbf{y}, \mathbf{x}) = sc(\mathbf{y}) + r_{avg} \cdot \min\{\text{len}(\mathbf{y}), k \cdot \text{len}(\mathbf{x})\}$$

where $sc(\mathbf{y}) = \sum_{i=1}^{\text{len}(\mathbf{y})} r(y_i)$ is the standard perplexity for the generated output.

Additionally, we found that for a given output $\bar{\mathbf{y}}$, the score $\tilde{sc}(\bar{\mathbf{y}}, \mathbf{x})$ provides a good measure of generation quality and is useful when filtering out poor or unacceptable output.

4.4 Training

All models were implemented and trained using PyTorch (Paszke et al., 2017). The Adam (Kingma and Ba, 2014) optimizer was used for all gradient based optimization.

We used a randomized hyperparameter grid search to determine the learning rate, number of layers, dropout, and the dimensions of the hidden layers. We used a learning rate of 0.000718 for all optimization. A dropout value of 0.1 is used for all models. All LSTMs are bidirectional with a single layer. Both sequence to sequence models for the IDONTKNOW task use a hidden size of 524 within the LSTM, a hidden size of 100 for the attention layer, a hidden size of 638 for the copy layer, and a dropout value of 0.1. Both sequence to sequence models for the EMOTIVE task use a hidden size of 600 within the LSTM, a hidden size of 200 for the attention layer, a hidden size of 650 for the copy layer, and a dropout value of 0.1.

5 Experiments

We study what makes a good response by correlating human judgments of goodness (based on a

[3] We note that the rule-based system simply used different rules for different settings of this bit.

[4] Initial experiments show that this modified beam search worked better

Model	IDontKnow Dev	IDontKnow Test	Emotive Dev	Emotive Test
BLEU				
Rule-based	78.9	79.4	**47.0**	**46.6**
S2SA	63.3	63.1	32.9	34.2
S2SA+C	**79.9**	**79.7**	44.6	46.3
METEOR				
Rule-based	84.6	85.3	**54.4**	**54.1**
S2SA	74.1	73.6	37.1	38.1
S2SA+C	**88.4**	**88.5**	51.5	52.8

Table 4: BLEU and METEOR scores evaluated on the Dev and Test sets. The S2SA+C performs the best on IDontKnow and the rule-based performs the best on Emotive.

5-point Likert scale) to the set of qualitative metrics we defined in Section 2. The average score is 4.2 for IDontKnow and 3.7 for Emotive. We also evaluated the performance of different models on these datasets using: (1) an automated BLEU and METEOR evaluation, (2) an A/B study comparing the model output with the gold response, and (3) the qualitative metrics. We conclude with a qualitative error analysis and some observations from a live deployment of the neural rephrasal model.

We compare the responses generated by three models: (1) the **Rule-based** baseline; (2) **S2SA**: neural model consisting of a seq2seq model with attention, and (3) **S2SA+C**: neural seq2seq model with attention and copying.

5.1 Results

BLEU/METEOR Following prior work on text generation, we use BLEU (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005) to compare the performance of our model.[5] From the results shown in Table 4, the neural model with copying (**S2SA+C**) are the rule-based baseline have comparable performance, with both significantly outperforming the baseline neural model (**S2SA**).

A/B Test We perform a human evaluation of our model outputs by creating an A/B test where evaluators specify a preference for either the model output, or the gold human response (see Figure 3). A perfect score on this evaluation would be 50%, indicating that the model and human response are indistinguishable. We ran this test on 305 examples selected from the test set. For each example which was not identical to the gold output, five Turk Workers were asked to choose which response they preferred. Table 5 shows the result of the study, showing that the copy mechanism outperforms both the rule-based baseline and the **S2SA** model for IDontKnow. For Emotive, the rule-based baseline is preferred.

[5]Specifically, we used NLTK (Loper and Bird, 2002) to compute both BLEU and METEOR scores with one human reference for each example. The BLEU score is weighted equally between 1-grams, 2-grams, 3-grams, and 4-grams

Model	IDontKnow P%	IDontKnow (I%)	Emotive P%	Emotive (I%)
Rule-based	38.0	(28.9)	**39.7**	(0.25)
S2SA	16.4	(11.5)	12.1	(0.25)
S2SA+C	**46.7**	(44.3)	35.9	(1.0)

Table 5: The percent of model responses that were (P)referred over the human responses in the A/B test portion of the user study on 305 IDontKnow examples and 400 Emotive examples. When the model's response was identical to the human's, we assume it is preferred 50% of the time: the percentage of these examples is reported in the (I) column.

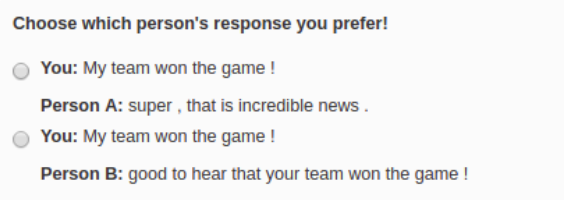

Figure 3: Example question in A/B test. The prompt asks the crowdworker to choose between the human response and the model output. In this example, one would prefer the Person B's response because it is more specific and exhibits reflective listening.

Qualitative Metrics To gain insight into the types of errors the different models are making, we elicited human assessment of three of the metrics defined in Section 2:

1. **Appropriateness** Evaluators make a binary choice as to whether the response included the correct part of the prompt.
2. **Fluency** Evaluators assess the grammatical correctness of the response by selecting on a 3 point Likert scale ranging from "not fluent" to "somewhat fluent" to "fluent". Scores are normalized to 1.
3. **Specificity** We present evaluators with a response and ask them to pick the original prompt from 4 choices (the original prompt, two distractors, and "none/multiple applies"). The distractors are chosen from the nearest neighbors of the prompt using an averaged

S2SA+C	**0.41**	**0.41**	0.00	0.02	-0.00

Table 7: Correlations between diagnostic metrics and human quality judgments for responses in the two datasets, with **bold** indicating statistically significant correlations. For all model responses, we use the A/B test preferences as a measure of quality judgment. For the human responses, we use a 5-pt Likert scale of the "goodness" of response as a quality judgment.

GloVE sentence embedding.

We also used the following automatic metrics as proxies for the remaining qualitative metrics:

1. **Conciseness** The length of the response normalized to the length of the prompt (smaller is more concise).
2. **Repetitiveness** We use METEOR (Banerjee and Lavie, 2005) to measure the overlap between prompt and response.

Table 6 shows the results of the human judgment on 400 generated responses for the test set. The **rule-based** model does well on the EMOTIVE dataset. The **S2SA** model is overall worst on most metrics, except conciseness. On the other hand, the **S2SA+C** model performs best on appropriateness and fluency for the IDONTKNOW dataset, and compares favorably with the rule-based model for other metrics. We note that the **S2SA+C** model most closely matches the amount of specificity, conciseness, and repetitiveness in the human responses. Examples of human responses with their corresponding metrics is provided in the appendix, along with additional responses from the models and error analysis.

5.2 Analysis

Next, we look at the correlation of our qualitative metrics to overall human quality judgments. Results of this analysis are in Table 7 and we provide additional visualizations in the appendix. The human response goodness score correlated positively with appropriateness, fluency, and to some extent with repetitiveness. On the other hand it correlated negatively with conciseness (i.e., shorter responses are preferred), while correlation with specificity was less pronounced. This seems to indicate that good responses are characterized by being appropriate and fluent, while having an appropriate level of detail (indicated by some amount of repetitiveness balanced with conciseness). We see a similar trend for the model responses: appropriateness and fluency are the most important attributes for when a model's response is preferred over the human's.

To get a better qualitative understanding of the model's performance, we studied the responses generated by our models (see Table 8 for examples). For simple sentences, the IDONTKNOW **rule-based** responses are reasonable. However, for more complex sentences, it becomes challenging to identify relevant subclauses or to handle non-trivial constructions like conditional clauses (see aquarium example). As a result, the EMOTIVE **rule-based** responses, while grammatical, tend to be overly verbose.

Both **S2SA** and **S2SA+C** are good at producing relatively fluent sentences, and performing the correct pronoun replacements ("you" with "we" and "I"). **S2SA** responses are often off-topic and inappropriate, with the model generating words that related to the topic but prone to drift (e.g., the teapot example). Since we train on a very small dataset, many words in the prompt are not seen during training. While the input word embedding can help during encoding, the decoder is nonetheless unable to generate words it has not seen during training.

The two biggest errors **S2SA+C** makes are incorrectly identifying the relevant parts of the question

	IDONTKNOW	EMOTIVE
Prompt	If I win my case, what am I entitled to	I dropped the jar and it shattered everywhere
Human	I do not know what you are entitled to	I am sorry to hear the jar broke
Rule-based	I do not know what you are entitled to	I am sorry you dropped the jar and it shattered everywhere
S2SA	I do not know what you are required to	i am sorry to hear about the ice
S2SA+C	I do not know what you are entitled to	i am sorry you dropped the jar
Prompt	At what temperature should I heat my water in a Staub teapot	The dentist told me that my insurance did n't cover dental
Human	I do not know what temperature you should heat your water to in a Staub teapot	I am sorry your insurance does n't cover dental
Rule-based	I do not know at what temperature you should heat your water in a Staub teapot	I am sad the dentist told you that your insurance did n't cover dental
S2SA	i am not able to tell you what long it you should handle your tea in a tsunami machine	sorry to hear that you ca n't afford your insurance insurance insurance insurance
S2SA+C	i do not know at what you should heat your water in a staub teapot	sorry to hear that the dentist did n't cover dental
Prompt	Are the animals at your aquarium humanely treated	Did I tell you that I won $ 500 at bingo
Human	I do not know if the animals at our aquarium are humanely treated	I am glad you won it
Rule-based	I do not know of the are animals at my aquarium humanely treated	I'm happy did you tell me that you won $ 500 at bingo
S2SA	i do not know if the animals are at our zoo are allowed	i am happy you won the lottery
S2SA+C	i do not know if the animals are at our aquarium are treated treated	i am happy that you won $ 500 at bingo

Table 8: Example responses from the different models, with errors highlighted in red. Note that the **S2SA** model tend to introduce random terms and **S2SA+C** model will retain numbers such as $ 500.

(e.g., the response *"I do not know what reporter's transcript deposit are"* to the question *"What are Reporter's Transcript Deposit Costs?"*) and grammatical errors when rephrasing (e.g., the response *"I do not know when the free trial is end."* to the question *"When does the free trial end?"*).

5.3 Observations from a Live Deployment

We deployed the **S2SA+C** model as part of a live chatbot for customer service that helped answer customer queries and perform simple tasks like tracking their packages.[6] As context, customers would ask the chatbot questions (e.g., "how do I ship pets?" or "I want to change the delivery address for my package") which were matched against a knowledge base containing frequently asked questions. If a question similarity model was unable to find a match, we tried to communicate to the user that we could not answer their request. Prior to this work, the chatbot would respond with a generic backoff message: "I'm sorry I didn't understand something you said" which resulted in users repeatedly rewording their request even if their request was genuinely outside of the chatbot's knowledge base, and ultimately expressing frustration with the chatbot.

We incorporated mimic rephrasals into our system by responding with the output generated by the S2SA+C model trained on the IDONTKNOW dataset if its score, $\tilde{sc}(\mathbf{y}, \mathbf{x})$, was higher than a fixed threshold, and using the previous backoff response if not. We observed that when the model replied with a mimic rephrasal, users usually responded with gratitude, e.g. "Thanks for letting me know!", and either continued by asking a different question or leaving the conversation. Presented with the mimic response, users rarely wasted time rewording a request that was out of the scope of what the chatbot could handle.

6 Related Work

Verbal mimicry is used in conversation to build social rapport (Rogers, 1951; Rautalinko and Lisper, 2004). This observation has been leveraged even in the early development of conversational agents, for example in systems such as Eliza (Weizenbaum, 1966), which engaged users by picking up keywords and repeating open ended questions back to the patient, or PARRY (Colby et al., 1972), which follows a similar strategy to rephrase utterances to

[6]The live deployment was run at Eloquent Labs prior to their acquisition by Square Inc.

indicate anger or fear. Our work applies mimicry in the task-oriented setting and studies how and when generated mimic rephrasals are preferred over human responses.

More recently, sequence to sequence models have been used for open domain chatbots (Sordoni et al., 2015; Shang et al., 2015; Vinyals and Le, 2015; Wen et al., 2015; Serban et al., 2016). However, these models suffered from generic responses and turns that are semantically inconsistent and incoherent. To address these issues, Li et al. (2016a) introduced a maximum mutual information objective to encourage diversity. Consistency in dialog agents has been well studied in Kobsa and Wahlster (1989) *inter-alia*, and for neural methods by Li et al. (2016b). Rashkin et al. (2019) also recognized the need to acknowledge others' feelings in a conversation and introduced a dataset for benchmarking emphathetic dialog models.

Sequence-to-sequence models with copying was introduced in Gu et al. (2016). Such models have also been shown to be effective at semantic parsing (Jia and Liang, 2016), summarization (See et al., 2017; Cao et al., 2018), and task oriented dialog (Eric and Manning, 2017).

Our task can in many ways be considered a controlled generation task. Other work in this area includes generating text conditioned on a sentiment to express (Li et al., 2018), or controlled generation (Hu et al., 2017) by editing attributes (Shen et al., 2017; Logeswaran et al., 2018; Lample et al., 2019). These works can successfully change the tone and intent of an utterance, but tend to frequently rewrite enough of the content that the method is less effective for practical dialog applications. Ke et al. (2018) examined how to generate dialog responses with different sentence function (e.g., imperative, interrogative, etc.), which similarly allows for more distant rewriting than is optimal for our task. Finally, our task exhibits many of the challenges observed by Bilu et al. (2015) in the context of negating claims.

Other work in generation addresses tasks such as rephrasals for generating paraphrases (Prakash et al., 2016; Gupta et al., 2018), sentence simplification (Narayan et al., 2017), and query rewriting for question answering (Dong et al., 2017).

7 Conclusions

We proposed a new task and associated datasets for *mimicking and rephrasing* a speaker's prompt to communicate a given intent. We showed that both rule-based based and neural seq2seq models both approach human level performance. Additionally, we share observations from a real world deployment of the model to highlight how solving these tasks can potentially improve the end-user experience. We hope this will inspire future work in dialog agents, making these agents more fluent and personable.

Automated Pyramid Summarization Evaluation

Yanjun Gao[1], **Chen Sun**[2], and **Rebecca J. Passonneau**[1]

[2]chensunx@gmail.com

Abstract

Pyramid evaluation was developed to assess the content of paragraph length summaries of source texts. A pyramid lists the distinct units of content found in several reference summaries, weights content units by how many reference summaries they occur in, and produces three scores based on the weighted content of new summaries. We present an automated method that is more efficient, more transparent, and more complete than previous automated pyramid methods. It is tested on a new dataset of student summaries, and historical NIST data from extractive summarizers.

1 Introduction

During the 70's and 80's, educational pychologists studied human summarization skills, and their development throughout secondary school and beyond. Three separate skills are acquired in the following order: selection of **important** information, **abstraction** through vocabulary generalization and sentence fusion, and **integration** with background knowledge (van Dijk and Kintsch, 1977; Brown and Day, 1983). A recent comparison of summaries from human experts versus extractive summarizers on forty-six topics from the TAC 2010 summarization challenge used automatic caseframe analysis, and found essentially these same properties in the human summaries, and not in the extractive ones (Cheung and Penn, 2013). Abstractive summarizers, however, are beginning to replicate the first two of these behaviors, as illustrated in many published examples based on encoder-decoder and pointer-generator neural architectures (Nallapati et al., 2016; See et al., 2017; Hsu et al., 2018; Guo et al., 2018). Summarization evaluation relies almost exclusively on ROUGE (Lin, 2004), an automated tool that cannot directly assess importance of summary content, or novel wording for the same information. We present an automated method to assess the importance of summary content, independent of wording, based on a widely used manual evaluation called pyramid (Nenkova et al., 2007).

Aligned PyrEval (W=5) and Manual (W=4) SCU

Figure 1: Alignment of a single PyrEval SCU of weight 5 to a manual SCU of weight 4 from a dataset of student summaries. The manual and automated SCUs express the same content, and their weights differ only by one. For each of five reference summaries (RSUM1-RSUM5), exact matches of words between the PyrEval and manual contributor are in bold, text in plain font (RSUM2, RSUM4) appears only in the manual version, and text in italics appears only in the PyrEval version. Paraphrases of the same content from RSUM4 were identified by human annotators (plain font) and PyrEval (italics). Also shown is a matching segment from a student summary, where the student used synonyms of some of the words in the reference summaries.

The pyramid method and ROUGE both use multiple summaries written by humans as references to assess new summaries. The manual pyramid method requires human annotators to identify Summary Content Units (SCUs) by grouping phrases from different reference summaries into

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 404–418
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

the same SCU if they express the same propositional content. Figure 1 illustrates an SCU from a manual pyramid applied to college student summaries of articles on cryptocurrency, with contributions from four of the five reference summaries (RSUM1-RSUM4). It is aligned to a nearly identical SCU constructed by PyrEval, with a contribution from the fifth reference (RSUM5). Previous work has shown that these kinds of discrepancies occur between human annotators, and have little effect on interannotator agreement or rankings of summarizers (Passonneau, 2010). The importance of an SCU increases with the number of reference summaries that express it, as indicated by its weight. If an evaluation summary expresses the same content as an SCU, its score is increased by the SCU weight (details below). ROUGE allows the user to select among numerous ways to measure ngram overlap of a new summary to the references, e.g., for different ngram sizes with or without skips, and with or without stemming. ROUGE does not, however, consider the relative importance of content, or account for synonyms of words that appear in the reference summaries.

We present PyrEval,[1] which outperforms previous work on automated pyramid in accuracy and efficiency. It produces human-readable pyramids, and prints matches between SCUs and evaluation summaries, which can support feedback for educational applications. PyrEval performs well on a new dataset of student summaries, where we applied the pyramid annotation. We also present results for TAC 2010 automated summaries, one of the more recent years where NIST applied pyramid evaluation. While ROUGE-2 more accurately identifies system differences than PyrEval, its performance is more sensitive to different topics.

2 Pyramid Content Analysis

The challenge in evaluation of summary content is that different equally good human summaries have only partial content overlap. van Halteren and Teufel (2003) annotated factoids (similar to FOL propositions, and to SCUs) for fifty summaries of a Dutch news article, and found a Zipfian distribution of factoid frequency: a small number of factoids represent 80% of the content in summaries, but a very long tail of rare content accounts for 20%. Pyramid annotation of ten summaries for a few DUC 2003 topics had a similar a Zipfian distribution (Nenkova and Passonneau, 2004).

Pyramid has had extensive reliability testing. A sensitivity analysis showed four reference summaries were sufficient for score reliability, and with probability of misranking errors below 0.01% (Nenkova and Passonneau, 2004; Nenkova et al., 2007). Interannotator agreement using Krippendorff's alpha on ten pyramids ranged from 0.61 to 0.89, and averaged 0.78 on matching new summaries to pyramids for 16 systems on 3 topics each (Passonneau, 2010). Comparison of two manual pyramid evaluations from distinct annotators showed that different pyramids for the same topic yield the same system rankings, even though SCUs from different pyramids typically do not align exactly (Passonneau, 2010).

The default size of a phrase that contributes to an SCU is a simple clause, but if it is clear from the context that a summary essentially expresses the same content expressed in other reference summaries, it is said to contribute to the same SCU, and the annotator must select at least a few contributing words. SCU weights reflect how many of $\mathcal{N}$ reference summaries express the SCU content. As such, SCUs are constrained to have no more than one contributor phrase from each reference summary. If a summary repeats the same information, the repetition will increment the count of total SCUs within one summary, but cannot be a distinct contributor. For example, the paraphrases from RSUM4 shown in Figure 1 add two to the total SCU size of the summary, but can only be used once to increment an SCU weight. Simple clauses in an evaluation summary that do not match pyramid SCUs add to the summary's SCU count, but have zero weight.

3 Related Work

Summarization is an important component of strategy instruction in reading and writing skills (Graham and Perin, 2007), but is used less than it could be due to the demands of manual grading and feedback. However, integration of NLP with rubric-based assessment has received increasing attention. Gerard et al. (2016) and Gerard and Linn (2016) applied automated assessment using rubrics to successfully identify students who need the most help, and facilitate and meaningful classroom interactions. Agejev and Šnajder (2017) used ROUGE and BLEU to identify col-

[1] Available at https://github.com/serenayj/PyrEval

lege students' L2 skills. Santamaría Lancho et al. (2018) used G-Rubric, an LSA-based tool, to help instructors grade short text answers to open-ended questions. Passonneau et al. (2018) found a high correlation of an automated pyramid with a manual rubric on a small set of summaries; see last paragraph of this section.

ROUGE is the most prevalent method to assess automated summarization. In 39 long papers on summarization in ACL conferences from 2013 through 2018 (mostly abstractive), 87% used ROUGE-1, ROUGE-2 or other variants such as LCS (longest common subsequence). A few used POURPRE (question answering) (Lin and Demner-Fushman, 2006), or METEOR (MT) (Denkowski and Lavie, 2014) to investigate scores based on weighted content or synonomy. POURPRE relies on string matching against reference units called answer facts, weighting matches by inverse document frequency. METEOR aligns words between reference and candidate, and can use relaxed word matching, such as WordNet synonymy. Despite its dominant use in previous work, Graham (2015) noted that the large range of ROUGE variants causes inconvenience and instability in evaluating performance. Graham's results from testing the 192 variants on DUC2004 data suggest that the ROUGE variants that correlate best with human evaluations are not often used.

PyrEval differs from other automated pyramid tools in its focus on accurately isolating and weighting the distinct SCUs in the reference summaries. Three previous semi-automated pyramid tools used dynamic programming to score summaries, given a manual pyramid (Harnly et al., 2005; Passonneau et al., 2013, 2018). The first of these used unigram overlap to compare summaries to a pyramid. Absolute scores were much lower than ground truth, but average system rankings across multiple tasks were accurate. A subsequent extension that used cosine similarity of latent vector representations of ngrams and SCUs, based on (Guo and Diab, 2012), had much better performance (Passonneau et al., 2013). This was extended further through use of a weighted set cover algorithm for scoring (Passonneau et al., 2018). PEAK was the first fully automated approach to construct a pyramid and score summaries (Yang et al., 2016). It uses OpenIE to extract subject-predicate-object triples from references, then constructs a hypergraph with triples as hyperedges. Semantic similarity between nodes from distinct hyperedges is measured using ADW's random walks over WordNet (Pilehvar et al., 2013), to assign weights to triples. On a small set of summaries used here in Table 1, PEAK raw scores had a high correlation with a manual summary rubric. PEAK was also tested on a single DUC 2006 topic, where the input text was first manually altered. Because PEAK is slow, Peyrard and Eckle-Kohler (2017) reimplemented it's use of the Hungarian algorithm to optimize their summarizer. Because PEAK produces many noisy copies of the same SCU, its output cannot be used to justify scores based on the unique matches or misses of a student summary to SCUs. Its score normalizations are inaccurate, and the un-normalized scores are impractical for general-purpose evaluation.

4 PyrEval System

To construct a pyramid, humans identify contributor segments[2] and group them into SCUs. Evaluating a summary is a simpler process of matching phrases to existing SCUs. PyrEval performs analogous steps, as shown in Figure 2. It first decomposes sentences of reference summaries (RSUM) into segments (DECOMP PARSE) and converts them into semantic vectors (LATENT SEM). It then applies EDUA to group the segment vectors into SCUs. EDUA (see below) is a novel restricted set partition algorithm that maximizes the semantic similarity within SCUs, subject to SCU constraints. Evaluation summaries (ESUM) are preprocessed in a similar fashion to convert them to segments represented as vectors. As in (Passonneau et al., 2018), PyrEval applies WMIN (Sakai et al., 2003) to find the optimal set of matches with pyramid SCUs. The remainder of this section describes each step.

4.1 Sentence Decomposition

The decomposition parser takes as input a phrase structure parse and dependency parse for each sentence, using Stanford CoreNLP (Manning et al., 2014). Every tensed verb phrase (VP) from the phrase structure parse initializes a new segment. The head verbs of tensed VPs are aligned to the dependency parse, and their dependent subjects are then attached to the segments. Words other than

[2]These can be discontinuous substrings, and can reuse words from other contributors, e.g., subjects of VP conjuncts.

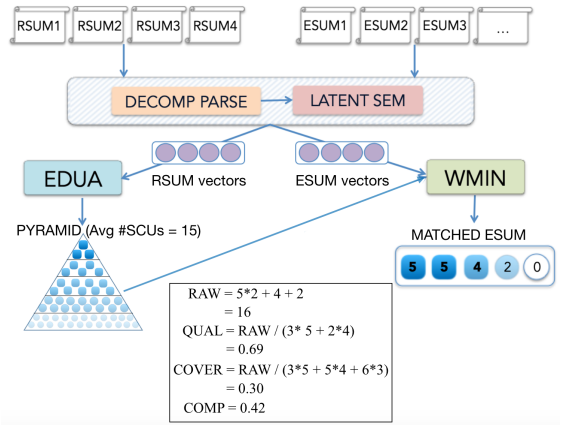

Figure 2: PyrEval preprocessors segment sentences from reference (RSUM) and evaluation (ESUM) summaries into clause-like units, then convert them to latent vectors. EDUA constructs a pyramid from RSUM vectors (lower left): the horizontal bands of the pyramid represent SCUs of decreasing weight (shaded squares). WMIN matches SCUs to ESUM segments to produce a raw score, and three normalized scores.

Data (size)	ELMo	USE	GloVe	WTMF
WIM (20)	0.3873	-0.0290	0.7149	**0.8525**
TAC 09 (54)	0.0515	0.2672	0.1713	**0.4961**
STS-14 (3750)	0.1636	0.5757	0.6129	**0.7257**

Table 1: Comparison of phrase embedding methods on correlation to manual pyramd (WIM, TAC09) or correlation to human similarity judgements (STS-14).

those in the VP and subject are reinserted in their original order. Every sentence has at least one default segmentation corresponding to the full sentence, possibly with one or more alternative segmentations of at least two segments each. It performs well for most cases apart from sentences with coordinate structures, which are notoriously difficult for conventional parsers. Figure 3 illustrates a sentence segmentation, with three alternatives.[3]

4.2 Semantic Vectors for Segments

The second PyrEval preprocessing step converts segments to semantic vectors. We chose to avoid semantic representation that requires training, to make PyrEval a lightweight, standalone tool. Although recent contextualized representations perform very well on a variety of NLP tasks, they are typically intended as the basis for a transfer learning approach, or to initialize further task-specific

[3]Segmentation 1.6.2 is the one EDUA-G selects for the pyramid.

Christopher Shake, the director of the London art gallery, suggests that this is not the case and that many different companies of different natures not just technology related are getting involved with cryptocurrencies.

neural training (e.g., (Pagliardini et al., 2018; Peters et al., 2018; Devlin et al., 2018; Vaswani et al., 2017)). The most practical way to rely on completely pre-trained representations is to use word embeddings along with a method to combine them into phrase embeddings. Here we report on a comparison of ELMo (Peters et al., 2018) and the Universal Sentence Encoder for English (USE) (Cer et al., 2018) with two conventional word embedding methods, GloVe (Pennington et al., 2014) and WTMF (Guo and Diab, 2012).[4]

ELMo is character-based rather than word-based, relies on a many-layered bidirectional LSTM, and incorporates word sequence (language model) information. It was trained on billions of tokens of Wikipedia and news text. To create meaning vectors for strings of words, we use pre-trained ELMo vectors, taking the weighted sum of 3 output layers as the word embeddings, then applying mean pooling.[5] USE is intended for transfer learning tasks, based on Transformer (Vaswani et al., 2017) or the (Iyyer et al., 2015) deep averaging network (DAN). We create meaning vectors for word strings with the USE-DAN pretrained encoder.[6] We use the GloVe download for 100D vec-

[4]We do not show results for Word2Vec (Mikolov et al., 2013), where performance was similar to GloVe.

[5]We use ELMo module from https://github.com/allenai/allennlp/.

[6]https://tfhub.dev/google/universal-sentence-encoder/2.

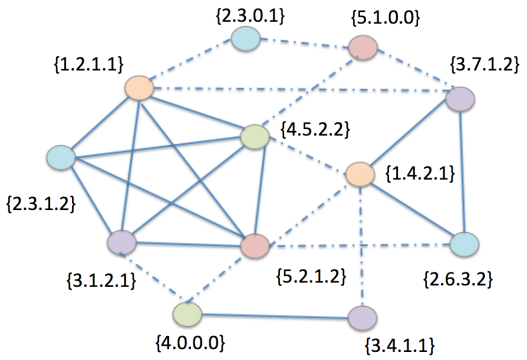

Figure 4: Part of an EDUA solution graph. Each vertex is a segment vector from a reference summary, indexed by **Summary.ID** (s_i)**, Sentence.ID** (s_{ij})**, Segmentation.ID** (s_{ijk})**, Segment.ID** (s_{ijkm}). All segments of all reference summaries have a corresponding node. All edges connect segments from different summaries with similarity $\geq t_{edge}$. This schematic representation of a partial solution contains three fully connected subgraphs with attraction edges (solid lines), each representing an SCU, whose weight is the number of vertices (segments).

1. Given a set of n reference summaries R, a preprocessing function (described in subsections 4.1-4.2) SEG returns segments as vectors: $\forall R_i \in R$, SEGS$(R_i) = \{seg_{ijk1}, seg_{ijk2}, \ldots, seg_{ijkm}\}$ where seg_{ijkm} is the mth segment of the kth segmentation of the jth sentence in the ith summary.
2. A graph G is constructed from SEGS(R_i), where an edge connects segments $seg_{ijkm}, seg_{i'j'k'm'}$ if $(i \neq i', seg_{ijkm} \neq seg_{i'j'k'm}$, cosine$(seg_{ijkm}, seg_{i'j'k'm}) \geq t_{edge})$. Every fully connected subgraph (clique) is a candidate scu whose size is the number of nodes, which has a maximum of n.
3. The attraction score of an $scu^z, \mathcal{AS}(scu^z) = \frac{1}{\binom{|scu^z|}{2}} \sum_{seg_{ijkm}, seg_{i'j'k'm} \in scu^z, seg_{ijkm} \neq seg_{i'j'k'm'}}$ cosine$(seg_{ijkm}, seg_{i'j'k'm'})$ if $z > 1$, else $= 1$.
4. A candidate pyramid P is a set of equivalence classes SCU^x that is a covering of all sentences in R (meaning only one segmentation per sentence belongs to any P), $\forall\ x \in [1,n] : (\exists\ SCU^x \in P) \rightarrow (x \in [1,n], \forall scu^z \in SCU^x, x = z)$. An SCU^x has an attraction class score $\mathcal{AC}(SCU^x) = \frac{1}{|SCU^x|} \sum_{scu^z \in SCU^x} \mathcal{AS}(SCU^z)$.
5. Finally, a pyramid P has an attraction score $\mathcal{AP}(P) = \sum_{SCU^x \in P} \mathcal{AS}(SCU^x)$.
6. The optimal pyramid(R) = $\mathcal{P}$ that maximizes $\mathcal{AP}$.

Figure 5: Formal specification of EDUA's input graph G consisting of all segments from all segmentations of reference summary sentences (item 2), the objective (item 6), and three scores for defining the objective function that are assigned to candidate SCUs (item 3), sets of SCUs of the same weight (item 4), and a candidate pyramid (item 5).

tors trained on the 840B Common Crawl.[7] To combine the GloVe word vectors into a phrase vector, we use the weighted averaging method from (Arora et al., 2016). WTMF is a matrix factorization method. We use WTMF matrices trained on the Guo and Diab (2012) corpus (393K sentences, 81K vocabulary size) that consists of WordNet, Wiktionary, and the Brown corpus.

We compare the four embedding methods on three datasets. Because our goal is to select a method that performs well on pyramid annotation, the first two datasets are human and machine summaries with manual pyramid annotations, with correlation of the manual pyramid and PyrEval scores as the metric. WIM (for *What is Matter*) is a dataset of student summaries with pyramid annotation from (Passonneau et al., 2018) with 20 student summaries on one topic. Note that PyrEval achieved a correlation of 0.85 on this data, compared with 0.82 for PEAK (Passonneau et al., 2018). We also use a subset of data from the NIST TAC 2009 summarizer challenge. We use summaries from all 54 peer systems on 14 of the 44 topics. We also use the STS-14 benchmark dataset of semantic similarity judgements (3750 sentence pairs), as in (Guo and Diab, 2012).

Table 1 shows WTMF to perform best on the three tasks by a large margin. We speculate this results from two factors. The lower dimensionality of WTMF vectors compared to ELMo or USE-DAN leads to higher maximum cosine values, thus better contrast between similar and dissimilar pairs. WTMF differs from similar matrix reduction methods in assigning a small weight to non-context words, which improves robustness for short phrases (fewer context words) Guo and Diab (2012). The authors also claimed that a training corpus largely consisting of definitional statements leads to co-occurrence data that is less noisy than sentences found in the wild.

4.3 EDUA

EDUA (Emergent Discovery of Units of Attraction) is a restricted set partition algorithm. It constructs an optimal pyramid to achieve the highest attraction (semantic similarity of segments) in all SCUs. Figure 4 schematically represents the input graph to EDUA (see also item 1 in Fig-

[7] https://nlp.stanford.edu/projects/glove/.

ure 5), whose nodes consist of the segment vectors described in the preceding section, and whose edges connect segments from different summaries whose cosine similarity $\geq t_{edge}$.[8] A candidate SCU is a fully connected subgraph (clique; item 2 in Figure 5). Every candidate SCU has an attraction score $\mathcal{AS}$ equal to the average of the edge scores (item 3 in Figure 5). A candidate pyramid is a set of SCUs that constitute a covering of all the sentences in the input reference summaries, with all segments for a given sentence coming from only one of its segmentations. The SCU weights for a pyramid, which are in $[1, n]$ for n reference summaries, form a partition over its segments, and each equivalence class (all SCUs of the same weight) has a score $\mathcal{AC}$ that is the average of its SCU scores (item 4 in Figure 5). The score for a candidate pyramid $\mathcal{AP}$ is the sum of its $\mathcal{AC}$ scores (item 5 in Figure 5). We use the sum rather than the average for $\mathcal{AP}$ to favor the equivalence classes for higher weight SCUs. The optimal pyramid maximizes $\mathcal{AP}$ (item 6 in Figure 5).

EDUA has two implementations. EDUA-C implements a complete solution based on depth first search (DFS) of candidate SCUs that guarantees the global optimum (max $\mathcal{AP}$). EDUA-G is a greedy approximation.[9]

4.4 EDUA-C

EDUA-C constructs an adjacency list that for each clique (candidate SCU) in the input graph, identifies all the other SCUs that satisfy two constraints: 1) for any given sentence, all SCUs reference the same segmentation; 2) all segments in all SCUs are distinct. DFS search proceeds through the adjacency list, ordering the SCUs by weight, until a path is found through all SCUs that meets the constraints. The solution has the highest $\mathcal{AP}$, or in the case of ties, the path found first.

Figure 6 illustrates a toy EDUA-C DFS tree. Each node depicts a candidate SCU clique, labelled by the number of nodes in the clique (SCU weight). No child node has a higher weight than its parent nodes. A child node is added to a search path (solid nodes) if it violates no constraints. Each of the six paths in the figure would receive an $\mathcal{AP}$ score. After DFS finds all legal paths, the one with highest $\mathcal{AP}$ is selected as the solution.

[8] The value of t_{edge} is automatically set to the 83rd percentile of all pairwise cosine similarities in the input data.

[9] See Appendix A for EDUA-G.

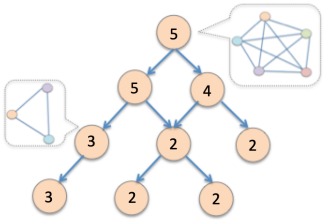

Figure 6: A directed Depth First Search tree for EDUA-C. Nodes are cliques representing candidate SCUs, as illustrated in Figure 4, labeled by their weights. Each DFS path is a partition over one way to segment all the input summaries and group all segments into SCUs. The solution is the path with the highest $\mathcal{AP}$.

4.5 Comparison of EDUA variants

Table 2 compares the distribution of SCUs by weight of the two EDUA variants with manual pyramids on the student summary dataset discussed in the next section. EDUA-C produces a more skewed distribution than EDUA-G. Both variants suffer from the coarse-grained segmentation output from the decomposition parser, but EDUA-G compensates by enforcing the Zipfian distribution observed in most pyramids (see appendix A for details).

To evaluate speed, we tested both variants on datasets with different numbers and lengths of reference summaries. TAC 2010 reference summaries (4 per topic) have on average 46 segments each, and 321 candidate SCUs. Pyramid construction for TAC 2010 takes less than 10 seconds with either variant on an Ubuntu machine with 4 Intel i5-6600 CPUs. EDUA-G's greater efficiency is more apparent for larger input. DUC 2005 has seven reference summaries per topic, and longer summaries than in TAC 2010; on five, EDUA-C takes 211 seconds, while EDUA-G is still only about ten seconds; on six, EDUA-C takes 20 minutes, compared to 5 minutes for EDUA-G.

Topic	Variant	All	w=5	w=4	w=3	w $\leq$ 2
CC	Manual	34	0	3	5	26
	G	31	1	2	4	24
	C	39	1	1	1	36
AV	Manual	41	0	6	2	33
	G	29	0	1	4	24
	C	35	1	1	1	32

Table 2: Comparison of distributions of SCUs by weight from pyramids produced manually, by two EDUA variants (G and C), for the two topics CC and AV.

4.6 WMIN Scoring

For automatic matching of phrases in evaluation summaries to SCUs in a manual pyramid, Passonneau et al. (2018) found good performance with WMIN (Sakai et al., 2003), a greedy maximum weighted independent set algorithm. Because EDUA pyramids are analogous to manual pyramids, PyrEval also uses WMIN. The input to WMIN is a graph where each node is a tuple of a segmentation of an ESUM sentence with the sets of SCUs that give the highest average cosine similarity for that sentence. The node weight is the sum of SCU weights. Graph edges enforce constraints that only one segmentation for a sentence can be selected, and each pyramid SCU can be matched to an ESUM sentence at most once. WMIN selects the nodes that result in the maximum sum of SCU weights for the ESUM.

Score computation is a function of the matched SCUs, as illustrated by the ESUM in the lower right of Figure 2. This ESUM has five SCUS: two of weight 5, one of weight 4, one of weight 2, and one that does not match the pyramid (zero weight). The sum of SCU weights is 16. The original pyramid score, a precision analog, normalizes the raw sum by the maximum sum for the same SCU count given by the pyramid – $(3 \times 5) + (2 \times 4)$ – indicating the degree to which the summary SCUs are as high weighted as possible. Following (Passonneau et al., 2018), we use the term quality score. The average number of SCUs in the reference summaries is 15, whose maximum weight from this pyramid is 53. Normalizing the raw sum by 53 gives a coverage score of 0.30 (a recall analog). The harmonic mean of these scores gives an F score analog referred to as a comprehensive score.

5 Student Summaries

As part of a collaboration with a researcher in educational technology, we collected a new data set of student summaries that were assigned in fall 2018 to computer science freshman in a university in the United Kingdom (Gao et al., 2019). Our immediate goal is to see how PyrEval could support instructors who assign summaries by providing an automated assessment that could be later corrected, but which provides scores and score justifications. PyrEval scores correlate well with manual pyramid scores on content, and the log output it produces provides a clear trace of score computation (see below).

Topic	Variant	Raw/Cov.	Qual.	Comp.	R2
AV	EDUAG	**0.66**	0.48	0.56	0.61
	EDUAC	0.55	0.50	0.53	
CC	EDUAG	**0.72**	0.63	0.69	0.66
	EDUAC	0.55	0.48	0.51	

Table 3: Pearson correlation of manual pyramid and PyrEval on four scores (raw/coverage, quality and comprehensive) compared with ROUGE-2 on coverage.

The class was an academic skills class that included instruction in academic reading and writing. For one assignment, they were instructed to select one of two current technology topics (three readings per topic), then to **summarize** it in 150 to 250 to words. The two topics are shown below, with the number of student summaries per reading, and average number of words.

1. Autonomous Vehicles (AV): 42 summaries, average words = 237.76
2. Cryptocurrency (CC): 37 summaries, average words = 245.84

To write reference summaries for both topics, the instructor recruited advanced students who had done well in her academic skills class in previous years. Three trained annotators applied manual pyramid annotation to the student summaries. As noted in section 2, pyramid annotation is highly reliable. Annotations of the student summaries were performed in two passes by different annotators.

Table 3 reports the correlation between the manual pyramid scores and the PyrEval scores on the two sets of student summaries. For both AV and CC, EDUA-G performs better than EDUA-C and ROUGE-2, the best ROUGE variant on TAC10 (see below), and ROUGE-2 performs better than EDUA-C. We attribute the lower correlations on the quality score, and the lower performance on this dataset compared to WIM (see Table 1), to the greater challenges of the new dataset. WIM students read a single, middle school text, and average summmary length was 109.02 words. For the new dataset, students read three advanced texts, and produced summaries that were over twice the length (see above). Error analysis shows complex sentence structure for the AV and CC data, with many constructions such as conjunctions and lists, that the decomposition parser cannot handle. As noted above, EDUA-G compensates due to a Zipfian constraint on the pyramid shape.

Figure 1 compares a PyrEval SCU with a manual one for the cryptocurrency topic, and

Single PyrEval SCU (W=3) about the relation of "car accidents" to "insurance cost"	
RSUM1	Also, as most collisions are due to human error, costs of insurance for self driving cars could fall by up to <NUM>.
RSUM2	The cars themselves would also reduce insurance premiums; <NUM> percent of road accidents are caused by human error
RSUM3	Shankleman does well to balance out the positives such as lower insurance , reduced traffic , savings on mechanical costs and lower chance of road accidents .

	Single manual SCU (W=4) on "high car accidents"	Single manual SCU (W=4) on "lower insurance"
RSUM1	Also, as most collisions are due to human error	costs of insurance for self-driving cars could fall by up to 50%
RSUM2	90 percent of road accidents are caused by human error	The cars themselves would also reduce insurance premiums
RSUM3	. . . lower chance of road accidents . . .	. . . lower insurance . . .
RSUM4	. . . he claims that over 90 percent of road traffic accidents occur as a result of human error	*this* would result in lower insurance premium for owners of autonomous vehicles by up to 50 percent.

Student IDs	Segments correctly matching this PyrEval SCU to students' summaries (from PyrEval log output)
A	The **insurance industry is also going to experience great changes** as the director insurer of AXA SA explains that more than <NUM> percent of **road accidents are caused by human error**.
B	as <NUM> of the **accidents are caused by human errors**, also reducing the number of human drivers will contribute to **cheap insurance premiums** and efficient transport
C	Shankleman explains how problems with modern day transport such as high **crash statistics and extortionate insurance costs will be eradicated** with such computing capabilities.

Figure 7: Alignment of an PyrEval SCU of weight 3 to segments from student summaries on autonomous vehicle.

also illustrates issues that might explain the relatively poorer performance of ROUGE. We show a phrase that both the manual annotator and PyrEval matched to the SCU from one of the student summaries, where the student used near synonyms for terms in the articles and reference summaries: *craftmanship* exhibition for *art gallery*, and *inn* for *hotel*. ROUGE cannot match synonyms, and does not distinguish differences in content importance.

Figure 7 shows an excerpt from PyrEval's log output on autonomous vehicle to illustrate the alignment of an SCU to three student summaries and comparison to two manual SCUs.[10] The PyrEval SCU captures a causal relation between "car accidents due to human error" and "lower insurance costs." The two manual SCUs, however, show that the human annotators split this content into two SCUs, because the content is expressed in distinct clauses in RSUM1 and RSUM2. The same content is supported by the implicit contexts for the shorter RSUM3 contributing phrases. The RSUM4 contributor in the manual SCU about "lower insurance" illustrates another issue that PyrEval preprocessing cannot handle: resolution of the deictic pronoun subject in "this would result . . . ".

[10] Preprocessing replaces numeric character strings with tags.

6 TAC 2010 Summaries

NIST summarization challenges dealt exclusively with news, which is also the most prevalent genre for automated summarizers in our survey of 2013-2018 ACL publications (23/39 summarizers; see above). To evaluate ROUGE, NIST used two human gold standards in yearly challenges from 2005 through 2011, one of which was manual pyramid. Annotation was performed by volunteers among the challenge participants, using guidelines developed for DUC 2006.[11] In this section, we apply a method NIST helped develop to evaluate ROUGE against manual pyramid in an evaluation of PyrEval against manual pyramid. We selected TAC 2010 because summarizer performance was less good in the earlier years.

TAC 2010 had two 100-word summarization tasks on 10 documents for 46 topics. Task A summarization was guided by a query. Task B was an update to A, based on additional input. On inspection of the 92 pyramids (46 each for Tasks A and B), we found that roughly 27% had poor quality pyramids that did not follow the guidelines mentioned above. We assembled a team of five people familiar with manual pyramid to manually redo the twelve pyramids that were independently identified as the lowest quality.[12]

Tests of the correlation of human scores as-

[11] http://www1.cs.columbia.edu/~becky/DUC2006/2006-pyramid-guidelines.html; we followed these guidelines for annotating the student

System	Task A			Task B		
	Mean Acc. (sdev)	95% CI	Acc. on 46 (delta)	Mean Acc. (sdev)	95% CI	Acc. on 46
R1	0.70 (0.04)	(0.69, 0.71)	*0.73 (0.03)*	0.61 (0.04)	(0.60, 0.62)	*0.69 (0.08)*
R2	**0.72 (0.03)**	(0.72, 0.73)	*0.80 (0.08)*	**0.70 (0.05)**	(0.69, 0.71)	*0.78 (0.08)*
EDUA-C	0.57 (0.04)	(0.57, 0.58)	0.65 (0.08)	0.56 (0.05)	(0.55, 0.57)	0.62 (0.06)
EDUA-G	0.57 (0.03)	(0.56, 0.57)	0.60 (0.04)	0.60 (0.03)	(0.59, 0.60)	0.63 (0.04)

Table 4: Mean accuracy, standard deviation and 95% confidence intervals on TAC 2010 Wilcoxon results for ROUGE-1, ROUGE-2 and PyrEval, using 100 bootstrapped samples of 41 of the 46 topics.

signed to automated summaries with ROUGE (and other automated metrics) were found to be unreliable, because of high score variance resulting as much from properties of the input texts as from differences in summarization systems (Nenkova, 2005; Nenkova and Louis, 2008). Analyses of over a decade of NIST data from automated summarizers that evaluate ROUGE against manual pyramid and another manual score led to a solution to this problem (Rankel et al., 2013; Owczarzak et al., 2012a,b; Rankel et al., 2011). The solution is to use Wilcoxon signed rank tests, so that pairs of systems are compared on matched input in a way that tests for statistical significance. The outcome is either that one of the systems is significantly better than the other, or that the difference between them is not statistically significant. To determine if the automated metric accurately reflects the gold standard scores, the same Wilcoxon tests are performed using the manually assigned scores on all pairs of systems, matching each pair on the same inputs. A given automated metric is then compared to the human gold standard to determine how accurately the automated metric leads to the same set of significant differences between all pairs of systems.

Table 4 presents bootstrapped accuracy results for ROUGE and PyrEval using 41 topics per bootstrap sample, along with absolute accuracy on all 46 topics. Each selection of 41 topics gives a gold standard set of system differences against which to compare a given metric. ROUGE 2 has the highest average accuracy on both Task A and B. ROUGE 1 performs nearly as well on Task A. PyrEval performs less well on average accuracy for all tasks, but similarly to ROUGE 1 in Task B. ROUGE-2 has greater sensitivity to topics, as shown by the higher deltas between the bootstrapped accuracy on 41 topics versus the accuracy on all 46. The differences in Table 4 between the bootstrapped averages across 41 topics, and the accuracy scores on all 46 topics, confirms the sensitivity of evaluation results to topics noted in (Nenkova, 2005; Nenkova and Louis, 2008).

7 Conclusion

PyrEval outperforms previous automated pyramid methods in accuracy, efficiency, score normalization, and interpretability. It correlates with manual pyramid better than ROUGE on a new dataset of student summaries, and produces output that helps justify the scores (similar to the examples for Figures 1 and 7). While it does not perform as well as ROUGE on extractive summarization, we speculate it would outperform ROUGE on abstractive summarizers. It relies on EDUA, a novel restricted set partition algorithm, that expects semantic vectors of sentence segments as input. The current rule-based method that identifies sentence substrings (the decomposition parser) is limited by the output of the constituency and dependency parsers it relies on. We are currently working on a neural architecture that simultaneously identifies simple clauses and produces semantic representations that could provide better input for both EDUA and WMIN, and thus improve PyrEval.

8 Acknowledgements

This work was supported in part by a Fellowship from Teaching and Learning with Technology, Penn State University, and by NSF award IIS-1847842. We thank two Penn State undergraduate research assistants for their contributions to the code base: Andrew Warner, and Purushartha Singh. Brent Hoffert, who recently graduated from Penn State, developed the wrapper that simplifies the use of PyrEval. Several additional Penn State undergrads helped correct the TAC 10 pyramids: Brent Hoffert, Alex Driban, Sahil Mishra, Xuannan Su, and Kun Wang. Finally, we thank the reviewers for their helpful suggestions.

summaries.

[12]We plan to ask NIST if we can make this data available through them.

A EDUA-G

EDUA-G (*Greedy*) is a greedy approximation to EDUA-C with a backtracking algorithm adjusting the allocation of candidate SCUs, and enforcing the constraints. In this appendix, we use the same notation as in section 4.3. Instead of finding the solution globally with maximum $\mathcal{AP}$ across all possible pyramids, EDUA-G works on achieving the maximum $\mathcal{AS}$ for each set of SCUs of a given size locally, starting with the set C_n with highest weight (number of nodes per subgraph c), then the rest in descending order. In addition to the constraints 1 and 2 in EDUA-C (mentioned in section 4.4), EDUA-G has a capacity constraint for each set C_r during search, limiting the number of SCUs committed to the class. This constraint is determined by the length of all the reference summaries and exploits an empirical observation of pyramids: that SCUs have a Zipfian distribution of frequency across reference summaries: a few have the highest weight, and for each lower weight there are more in number, with a very long tail of SCUs of weight 1.

To enforce the capacity constraint during search, we define the maximum number of SCUs y_n of each equivalence class C_n as:

$$y_n = \alpha\left(\frac{1}{n}\right)^{\beta} \tag{1}$$

where n is the index of the equivalence class, α is a constant related to the total number of segments from all reference summaries, and β is a scaling parameter (Clauset et al., 2009). Thus in addition to t_{edge}, EDUA-G has the hyperparameters α and β. The capacities of the equivalence classes are monotone increasing as n decreases:

$$|C_n| \leq |C_{n-1}| \tag{2}$$

Summing over $|C_n|$ gives the size of the pyramid:

$$\sum_{i}^{N} |C_n| \leq \sum_{i}^{N} y_i \tag{3}$$

Algorithm 1 presents EDUA-G.

Initialization Similar to EDUA-C, a segment pool $SP = SEGS(R_1) \cup \ldots \cup SEGS(R_n)$ is first constructed from all the reference summaries to store segments and two status flags. The pool is accessible globally. For every segment seg_{ijkm}, two status flags are set:

Algorithm 1: EDUA-G

Data: Number of reference summaries n; a list CU of candidate SCUs ordered by weight r where $1 \leq r \leq n$, then by attraction score $\mathcal{AS}(CU^r)$; capacity of each equivalence class $y_1 \ldots y_n$ by formula 1; a segment pool SP, residuals L_1

Result: Pyramid P with equivalence classes $C_1 \ldots C_n$

1 Initialize $r = n$,
2 $C_r = \emptyset$, $P = \emptyset$, D_r as empty stack,
3 **while** $(r > 1) \wedge (|C_r| \leq y_r)$ **do**
4 push all candidate CU^r selected from CU into D_r sorted by attraction score in ascending order ;
5 **while** D_r *is not empty* **do**
6 pop e from D_r with maximum $\mathcal{AS}$;
7 **if** *notConflict*(C_r, e), *and* $\forall\ seg_{ijkm} \in e$ $seg_{ijkm}.commit == True$ *or* $seg_{ijkm}.commit == NotValid$, *and* $seg_{ijkm}.used == False$ **then**
8 Commit(C_r, e, SP) ;
9 **end**
10 **end**
11 **if** *P fails to meet any of the constraints* **then**
12 BackTrack$(C_r, y_r, C_{r+1}, P, SP)$
13 **else**
14 $P \leftarrow P \cup C_r$;
15 **end**
16 $r \leftarrow r - 1$;
17 Initialize new stack D_r and repeat line 3
18 **end**
19 **foreach** $segs_{ijkm} \in L_1$ **do**
20 **if** $segs_{ijkm}.commit == True$ *or* $segs_{ijkm}.commit == NotValid$ **then**
21 $C_1 \leftarrow C_1 \cup segs_{ijkm}$;
22 $segs_{ijk*}.commit = True$ in SP;
23 **end**
24 **end**
25 $P \leftarrow P \cup C_1$

1. segmentation status, denoted as $seg_{ijkm}.commit$: for all $seg \in SP$, $seg.commit$ will be initialized as $NotValid$; during EDUA-G, if a sentence is first used by a segmentation seg_{ijk}, all segments $seg_{ijk*}.commit$ are set to True, and all other $seg_{ijk'*}$ from this sentence seg_{ij} are set to as False

2. segment status, denoted as $seg_{ijkm}.used$: when initialized, $seg_{ijkm}.used$ is set to False; if segment seg_{ijkm} is used in an SCU, the status $seg_{ijkm}.used$ is set to True

A graph G is constructed from all segments. A list of candidate SCUs (fully connected subgraph) with weights r from n to 2 is exhaustively extracted from G. All the leftover segments with weight as 1 are stored as residuals denote as L_1, at default sorted by the index.

Allocation The allocation process proceeds top-down, iterating over descending values of r from

Algorithm 2: BackTrack

Input: Current set C_r that fails constraints, its size constraint y_r, equivalence class C_{r+1}, current result P, segment pool SP
Result: Adjusted pyramid P with equivalence classes $C_1 \dots C_n$

Initialize $l_{r+1} \leftarrow$C$_{r+1}$, $l_r = \emptyset$;
while $|C_r| \leq y_r$ **do**
  Sort $l_r + 1$ by $\mathcal{AS}$ in ascending order;
  pop e' from $l_r + 1$;
  decompose e' into CU_r where $CU_r = \{CU_{r1}, \dots, CU_{r\binom{r+1}{r}}\}$;
  $l_r \leftarrow l_r \cup CU_r$;
  foreach $e \in l_r$ **do**
    if *notConflict*(C_r, e), $\forall\ seg_{ijkm} \in e$ $seg_{ijkm}.commit == True$ *or* $seg_{ijkm}.commit == NotValid$, *and* $seg_{ijkm}.used == False$ **then**
      Commit(C_r, e, SP) ;
    end
  end
  Update P with new C_r;
  Update C_{r+1} by removing all CU_{r+1}s that have overlapping segments with SCUs in C_r ;
  Update P with new C_{r+1}, reset segment and segmentation status in SP;
  if *P fails to meet any of the constraints* **then**
    BackTrack(C_{r+1}, y_{r+1},C_{r+1+1},P, SP)
  end
  Break ;
end

Algorithm 3: notConflict

Input: current set C_r, a candidate SCU e,
foreach *segment* $seg_{ijkm} \in e$ **do**
  if $\exists\ c \in C_r$ *where* $seg_{ijkm} \in c$ **then**
    return False
  end
end
return True

n to 2. All candidate SCUs are ordered first by weight, then by descending $\mathcal{AS}$. Each set C_r is filled with all candidate SCUs of size r, where maximum $\mathcal{AS}(SCU^r)$ is selected greedily, until the capacity constraint is satisfied. Every SCU committed to C_r requires the segment status to be checked and updated. Then the residual segments are allocated to C_1 as in EDUA-C if the status of the segments permits. For $1 < r < n$, if the provisional pyramid violates any constraints, backtracking considers a provisional revision of C_{r+1} based on reallocating all the segments in each subset of C_{r+1} of size q, for q from 1 to the size of C_{r+1}, considering reallocations in order of descending values of $\mathcal{AP}$. The algorithm terminates when all the constraints are satisfied, no segments remain whose segmentation status is True and whose segment status is False.

Algorithm 4: Commit

Input: current set C_r, a candidate SCU e, segment pool SP
$C_r \leftarrow C_r \cup e$;
foreach $seg_{ijkm} \in e$ **do**
  Set $seg_{ijkm}.used = True$ in SP ;
  Set $seg_{ijkm}.commit = True$ in SP ;
end

Backtracking The backtracking algorithm proceeds bottom-up, from the current set C_r to C_n. Recall from section 4.3, every pair of segments in an SCU has an edge $\geq t_{edge}$; therefore an SCU with $r+1$ contributors can be decomposed into $\binom{r+1}{r}$ SCUs with r contributors. We utilize this property to ensure every set C_r satisfies the constraints. During the emergent search and allocation of SCUs, if a set C_r does not meet the capacity constraint, the backtracking process will be initiated for re-allocation by re-using the segments committed to SCUs in C_{r+1}, to compose new SCUs in C_r. As shown in Algorithm 2, while the allocation process selects SCUs with maximum attraction scores greedily, the backtracking takes a conservative approach of re-doing the commit decision by decomposing one SCU at a time in C_{r+1} with the least $\mathcal{AS}(SCU^r)$, and composing new SCUs with weight r for C_r. It proceeds recursively from r to n until the resulting P satisfies the constraints. This is because every SCU in C_{r+1} has higher importance than in C_r, and this minimizes the impact of the re-allocation step on $\mathcal{AP}$. The backtracking algorithm terminates after all the constraints are satisfied.

B Grid Search on Hyperparameters

Grid search was used to tune the EDUA-G hyperparameters. On DUC 2005 data, we used α in the range [|seg|+10,|seg|+50] where |seg| is the number of input segments, and $\beta \in [1, 3]$. To set t_{edge}, we compute pairwise similarities of all segment pairs from different summaries, and take t_{edge} as the value at percentile N, for $N \in [60, 87]$. The performance metric was correlation with manual pyramid on individual summarization tasks.

Table 5 of ANOVA on the hyperparameters shows that β and t_{edge} have strong impact, while α does not (we select $\alpha = 10$). A contour plot of all combinations of β and t_{edge} (Figure 8) gives two regions of high correlation: $\beta \in [2.5, 3]$, and

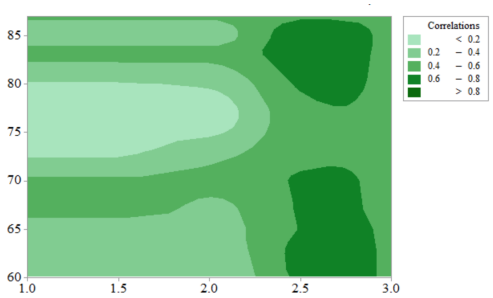

Figure 8: Contour plot for score correlations with β (X-axis) and t_{edge} (Y-axis).

Parameters	**DF**	**F-value**	**P-value**
α	4	0.31	0.872
β	4	104.31	0.000
t_{edge}	11	6.56	0.000

Table 5: One-way ANOVA for hyperparameters, with degrees of freedom (DF), F value and P-value (significance level α=0.05, sample size N=300).

$t_{edge} \in [60, 70]$, or $[80, 87]$. Higher t_{edge} yields fewer edges in the graph, so for efficiency, we select $\beta = 2.5$, and $N = 83$. (Depending on the dataset this corresponds to cosine similarities t_{edge} of about 0.15 to 0.35.)

A Case Study on Combining ASR and Visual Features for Generating Instructional Video Captions

Abstract

Instructional videos get high-traffic on video sharing platforms, and prior work suggests that providing time-stamped, subtask annotations (e.g., "heat the oil in the pan") improves user experiences. However, current automatic annotation methods based on visual features alone perform only slightly better than constant prediction. Taking cues from prior work, we show that we can improve performance significantly by considering automatic speech recognition (ASR) tokens as input. Furthermore, jointly modeling ASR tokens and visual features results in higher performance compared to training individually on either modality. We find that unstated background information is better explained by visual features, whereas fine-grained distinctions (e.g., "add oil" vs. "add olive oil") are disambiguated more easily via ASR tokens.

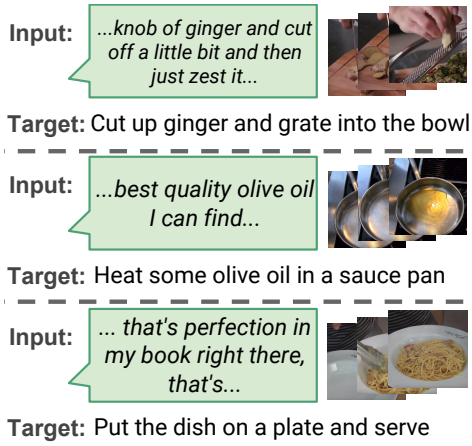

Figure 1: Illustration of a multimodal dense instructional video captioning task. Models are given access to both video frames and ASR tokens, and must generate a recipe instruction step for each video segment. The speaker in the video *sometimes* (but not always) references literal objects and actions.

1 Introduction

Instructional videos increasingly dominate user attention on online video platforms. For example, 86% of YouTube users report using the platform often to learn new things, and 70% of users report using videos to solve problems related to work, school, or hobbies (O'Neil-Hart, 2018).

Prior work in user experience has investigated the best way of presenting instructional videos to users. Kim et al. (2014), for example, compare two options; first: presenting users with the video alone, and second: presenting the video with an additional *structured* representation, including a timeline populated with task subgoals. Users interacting with the structured video representation reported higher satisfaction, and external judges rated the work they completed using the videos as having higher quality. Margulieux et al. (2012) and Weir et al. (2015) similarly find that presenting explicit subgoals alongside how-to videos improves user experiences. Thus, presenting instructional videos with additional structured annotations is likely to benefit users.

These studies rely on human annotation of time-stamped subtask goals, e.g., timed captions created through crowdsourcing. However, human-in-the-loop annotation is infeasible to deploy for popular video sharing platforms like YouTube that receive hundreds of hours of uploads per minute. In this work, we address the task of *automatically* producing captions for instructional videos at the level of video segments. Ideally, generated captions provide a literal, imperative description of the procedural step occurring for a given video segment, e.g., in the cooking context we consider, "add the oil to the pan."

Producing segment-level captions is a sub-task of dense video captioning, where prior work has mostly focused on visual-only models. Dense captioning is a difficult task, particularly in the

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 419–429
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

instructional video domain, as fine-grained distinctions may be difficult or impossible to make with visual features alone. Visual information can be ambiguous (e.g., distinguishing between "olive oil" vs. "vegetable oil") or incomplete (e.g., preparation steps may occur off-camera). In our study, a first important finding is that, for the dataset considered, current state-of-the-art, visual-features–only models only slightly outperform a constant prediction baseline, e.g., by 1.5 BLEU/METEOR points.

To improve performance in this difficult setting, we consider the *automatic speech recognition* (ASR) tokens generated by YouTube. These publicly available tokens are an ASR model's attempts to map words spoken in videos into text. However, while a promising potential source for signal, it is not always trivial to transform even accurate ASR into the desired imperative target: while there are cases of clear correspondence between the literal actions in the video and the ASR tokens, in other cases, the mapping is imperfect (Fig. 1). For example, when finishing a dish, a user says "that's perfection in my book right there" rather than "put the dish on a plate and serve." There are also cases where no ASR tokens are available at all. Despite these potential difficulties, previous work has demonstrated that ASR can be informative in a variety of instructional video understanding tasks (Naim et al., 2014, 2015; Malmaud et al., 2015; Sener et al., 2015; Alayrac et al., 2016; Huang et al., 2017); though less work has focused on instructional caption *generation,* which is known to be difficult and sensitive to input perturbations (Chen et al., 2018).

We find that incorporating ASR-token–based features significantly improves performance over visual-features–only models (e.g., CIDEr improves 0.53 $\Rightarrow$ 1.0, BLEU-4 improves 4.3 $\Rightarrow$ 8.5). We also show that *combining* ASR tokens and visual features results in the highest performing models, suggesting that the modalities contain complementary information.

We conclude by asking: what information is captured by the visual features that *is not* captured by the ASR tokens (and vice versa)? Auxiliary experiments examining performance of models in predicting the presence/absence of individual word types suggest that visual signals are superior for identifying unspoken, implicit aspects of scenes; for instance, in order to mix ingredients, they must be placed in a bowl — and although bowls are often visually present in the scene, "bowl" is often not explicitly mentioned by the speaker. Conversely, ASR features readily disambiguate between fine-grained entities, e.g., "olive oil" vs."vegetable oil", a task that is difficult (and sometimes impossible) for visual features alone.

2 Related Work

Narrated instructional videos. While several works have matched audio and video signals in an unconstrained setting (Arandjelovic and Zisserman, 2017; Tian et al., 2018), our work builds upon previous efforts to utilize accompanying speech signals to understand online *instructional* videos, specifically. Several works focus on learning video-instruction alignments, and match a fixed set of instructions to temporal video segments (Regneri et al., 2013; Naim et al., 2015; Malmaud et al., 2015; Hendricks et al., 2017; Kuehne et al., 2017). Another line of previous work uses speech to extract and align language fragments, e.g., verb-noun pairs, with instructional videos (Gupta and Mooney, 2010; Motwani and Mooney, 2012; Alayrac et al., 2016; Huang et al., 2017, 2018; Hahn et al., 2018). Sener et al. (2015), as part of their parsing pipeline, train a 3-gram language model on segmented ASR token inputs to produce recipe steps.

Dense Video Captioning. Recent work in computer vision addresses dense video captioning (Krishna et al., 2017; Li et al., 2018; Wang et al., 2018), a supervised task that involves (i) segmenting the input video, and, (ii) generating a natural language description for each segment. Here, we focus on the second subtask of generating descriptions given a ground-truth segmentation; this setting isolates the language generation part of the modeling process.[1] Most related to the present work are several dense captioning approaches that have been applied to instructional videos (Zhou et al., 2018b,c). Zhou et al. (2018c) achieve state-of-the-art performance on the dataset we consider; their model is video-only, and combines a region proposal network (Ren et al., 2015) and a Transformer (Vaswani et al., 2017) decoder.

Multimodal Video Captioning. Several works

[1] We find that state-of-the-art models perform poorly even for just this subtask (see § 3.2), so we reserve the full task for future work.

have employed multimodal signals to caption the MSR-VTT dataset (Xu et al., 2016), which consists of 2K video clips from 20 general categories (e.g., "news", "sports") with an average duration of 10 seconds per clip. In particular, Ramanishka et al. (2016); Xu et al. (2017); Hori et al. (2017); Shen et al. (2017); Chuang et al. (2017); Hao et al. (2018) all report small performance gains when incorporating audio features on top of visual features. However — we suspect that instructional video domain is significantly different than MSR-VTT (where the audio information does not necessarily correspond to human speech), as we find that ASR-only models significantly surpass the state-of-the-art video model in our case. Palaskar et al. (2019) and Shi et al. (2019), contemporaneous with the submission of the present work, also examine ASR as a source of signal for generating how-to video captions.

3 Dataset

We focus on YouCook2 (Zhou et al., 2018b), the largest human-captioned dataset of instructional videos publicly available.[2] It contains 2000 YouTube cooking videos, for a total of 176 hours, and spans 89 different recipes. Each video averages at 5.26 minutes, and is annotated with an average of 7.7 temporal segments (i.e., start/end points) corresponding to semantically distinct recipe steps. Each segment is associated with an imperative caption, e.g., "add the oil to the pan", for an average of 8.8 words per caption.

At the time of analysis (June 2018), over 25% of the YouCook2 videos had been removed from YouTube, and therefore we do not consider them. As a result, all our experiments operate on a *subset* of the YouCook2 data. While this makes direct comparison with previous and future work more difficult, our performance metrics can be viewed as lower bounds, as they are trained on less data compared to, e.g., (Zhou et al., 2018c). Unless noted otherwise, our analyses are conducted over 1.4K videos and the 10.6K annotated segments contained therein.

3.1 A Closer Look at ASR tokens

We collected the ASR tokens automatically generated by YouTube (available through the YouTube Data API[3] with trackKind = ASR), which are then mapped to their temporally corresponding video segments. We start by asking the following questions: How much narration do users provide for instructional videos? And: can YouTube's ASR system detect that speech?

Not surprisingly, speakers in videos tend to be more verbose than the annotated groundtruth captions: we find the length distribution of ASR tokens per segment to be roughly log-normal, with mean/median length being 42/28 tokens respectively (compared to a mean of 9 tokens/segment for captions). Over the 10.6K available segments, only 1.6% of them have zero associated tokens. Furthermore, based on automatic language identification provided by the YouTube API and some manual verification, we estimated that less than 1% of videos contain completely non-English speech (but we do not discard them from our experiments).

We also investigate the words-per-minute (WPM) ratio, based on the video segment length. The mean value of 134 WPM is slightly lower than, but comparable to, previously reported figures of English speaking rates (Yuan et al., 2006), which indicates that, for this set of video segments, words are being detected at rates comparable to everyday English speech.

3.2 A Closer Look at the Generation Task

To better understand the generation task, we computed lower and upper bounds for generation performance using a constant-prediction baseline and human performance, respectively.

Lower bound: constant. For all segments at test time, we predict "heat some oil in a pan and add salt and pepper to the pan and stir." This sentence is constructed by examining the most common n-grams in the corpus and pasting them together.

Upper bound: human estimate. We conducted a small-scale experiment to estimate human performance for the segment-level captioning task. Two of the authors of this paper, after being trained on segment-level captions from three videos, attempted to mirror that style of annotation for the segments of 20 randomly sampled videos, totalling over 140 segment annotations each.[4] Both human annotators report low-confidence with the

[2] How2 (Sanabria et al., 2018) tackles the different task of predicting video uploader-provided descriptions/captions, which are not always appropriate summarizations.

[3] https://developers.google.comyoutube/v3/docs/captions

[4] These preliminary experiments are not meant to provide a definitive, exact measure of inter-annotator agreement.

task, in particular, they found it difficult to maintain a consistent level of specificity in terms of how many factual details to include (e.g., "mix together" vs. "mix the peppers and mushrooms together.")

Results: We compute corpus-level performance statistics using four standard generation evaluation metrics: ROUGE-L (Lin, 2004), CIDEr (Vedantam et al., 2015), BLEU-4 (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005) (higher is better in all cases).

Note that our evaluation is micro-averaged at the segment level, and differs slightly from prior work on this dataset, which has mostly reported metrics macro-averaged at the video level. We switched the evaluation because some metrics like BLEU-4 exhibit undesirable sparsity artifacts when macro-averaging, e.g., any video without a correct 4-gram gets a zero BLEU score, even if there are many 1/2/3-grams correct. Segment-level averaging, the standard evaluation practice in fields like machine translation, is insensitive to this sparsity concern, and (we believe) provides a more robust perspective on performance.

	BLEU-4	METEOR	ROUGE-L	CIDEr
Constant Prediction	2.70	10.3	21.7	.15
Zhou et al. (2018c)	3.84	11.6	27.4	.38
Sun et al. (2019b)	4.07	11.0	27.5	.50
Sun et al. (2019a)	4.31	11.9	29.5	.53
Human Estimate	15.2	25.9	45.1	3.8

Table 1: The performance of several state-of-the-art, video-only models, with lower (constant prediction) and upper (human estimate) bounds.

This comparison highlights the gap that remains between the simplest possible baseline, several computer vision based models, and (roughly) how well humans perform at this task. Given that Sun et al. (2019a) is a highly tuned computer vision model transfer learned from a corpus of over 300K cooking videos, from the perspective of building video captioning systems in practice, we suspect that incorporating additional modalities like ASR is more likely to result in performance gains versus building better computer vision models.

4 Models

In addition to the constant prediction baseline, we explore a series of ASR-based baseline methods:

ASR as the Caption (ASC) This baseline returns the test-time ASR token sequence as the caption. While the result is not a coherent, imperative step, performance of this method offers insight into the extent of word overlap between the ASR sequence and the target groundtruth, as measured by the captioning metrics.

Filtered ASR (FASC) Given that the ASR token sequences are much longer than groundtruth captions (§ 3.1), the performance of ASC incurs a length (or precision-based) penalty for several metrics. The FASC baseline strengthens ASC by removing word types that are less likely to appear in groundtruth captions, e.g., "ah", "he", "hello," or "wish". Specifically, we only keep words with high $\frac{P(w \mid GT)}{P(w \mid ASR)}$ values, i.e., words that would be indicative of the groundtruth class if we were to build a Naive-Bayes classifier with add-one smoothing; probabilities are computed only over the training set to reduce the risk of overfitting. This baseline produces outputs that are shorter compared to ASC, but it is unlikely to yield fluent, readable text.

ASR-based Retrieval (RET) This retrieval baseline memorizes the recipe steps in the training set, and represents them each as tf-idf vectors. At test-time, the ASR sequence is converted into a tf-idf vector and compared to each training-set caption via cosine similarity.[5] The training caption that is most similar to the test-time ASR according to this metric is returned as the "generated" caption. Note that, although a memorization-based technique, this baseline method produces de-facto captions as outputs.

4.1 Transformer-based Neural Models

We explore neural encoder-decoder models based on Transformer Networks (Vaswani et al., 2017). In contrast to RNNs, Transformers abandon recurrence in favor of a mix of different types of feed-forward layers, e.g., in the case of the Transformer decoder, self-attention layers, cross-attention layers (attending to the encoder outputs), and fully connected feed-forward layers. We explore two variants of the Transformer, corresponding to different hypotheses about what information might be useful for captioning instructional videos.

ASR Transformer (AT) This model learns to map ASR-token sequences directly to captions using

[5] We tried several variants of this method, e.g., comparing test ASR to train ASR, but found that comparing test ASR to train captions performed the best.

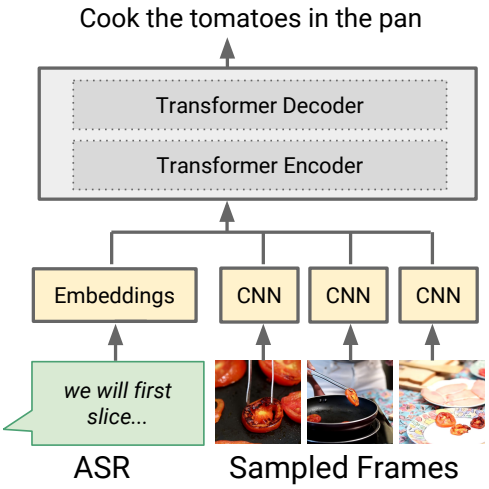

Figure 2: The AT+Video model. Both the encoder and decoder layers perform cross-modal attention.

Table 2: Caption generation performance: AT+Video is a multimodal model that adds visual frame features to AT. A bolded value in a column indicates a statistically-significant improvement, whereas an underline indicates a statistical tie for best ($p < .01$).

a standard sequence-to-sequence Transformer architecture. The model's parameters are optimized to maximize the probability of the ground-truth instructions, conditioned on the input ASR sequences.

Multimodal model (AT+Video) We incorporate video features into the ASR transformer (Fig 2). For ease of comparison with prior and future work, we use features extracted from ResNet34 (He et al., 2016) pretrained on the ImageNet classification task; these features are provided in the YouCook2 data release. Each video is initially uniformly sampled at 512 frames, with an average of 30 frames per captioned-segment.

To represent each video segment, first, k frames are randomly sampled with replacement. The sampled frames are temporally sorted to preserve ordering information, and their corresponding ResNet34 feature vectors are projected to the Transformer encoder hidden dimension via a width-1 1D convolution. We use $k = 10$ for all our experiments. The encoder self-attention layers perform *cross-modal attention* operations between the visual features and the ASR-token–based features. For each output token, the decoder attends to previously predicted tokens, and encoder outputs for all input frames / ASR tokens.

5 Experiments

We perform 10-fold cross-validation with randomly sampled 80/10/10 train/dev/test splits (split at the video-level), using the same splits for all models. After discarding the videos that were deleted at the time of data collection, each split contains roughly 1.1K training videos (averaging 8.3K training segments). We report mean performance over these splits according to four standard captioning accuracy metrics, introduced in §3.2. ROUGE-L, CIDEr, BLEU-4, and METEOR. We perform both Wilcoxon signed-rank tests (Demšar, 2006) and two-sided corrected resampled t-tests (Nadeau and Bengio, 2000) to estimate statistical significance. To be conservative and reduce the chance of Type I error, we take whichever p-value is larger between these two tests.

Transformer-based model details. For each cross-validation split, we use a batch size of 128, tie the Transformer model's feed forward and model dimensions $d_{ffn} = d_{model}$, and optimize regularized cross-entropy loss using Adam (Kingma and Ba, 2015) with $lr = .001$. We train models for 100K steps, storing checkpoint files periodically. For each split, we train 8 model variants, conducting a grid search over model dimension, number of encoder/decoder layers, and L2 regularization: we consider all model parameter settings in $(d_{model}, N_{layer}, \lambda_{reg}) \in \{128, 256\} \times \{2, 3\} \times \{.0005, .001\}$ for each cross-validation split independently, and select the highest performing, checkpointed model according to ROUGE-L over the development set for that fold. Transformer models are implemented using `tensor2tensor` (Vaswani et al., 2018) and `Tensorflow` (Abadi et al., 2015). The vocabulary (average size 800) is determined separately using the training data for each cross-validation split. Words are considered if they occur at least 5 times in the ground-truth of the current training set.[6] This leads to an OOV rate of ~60% in the input. We truncate inputs at 80 tokens (~10-15%

[6]Different vocabulary creation schemes, e.g., sub-word tokenization, led to small performance decreases.

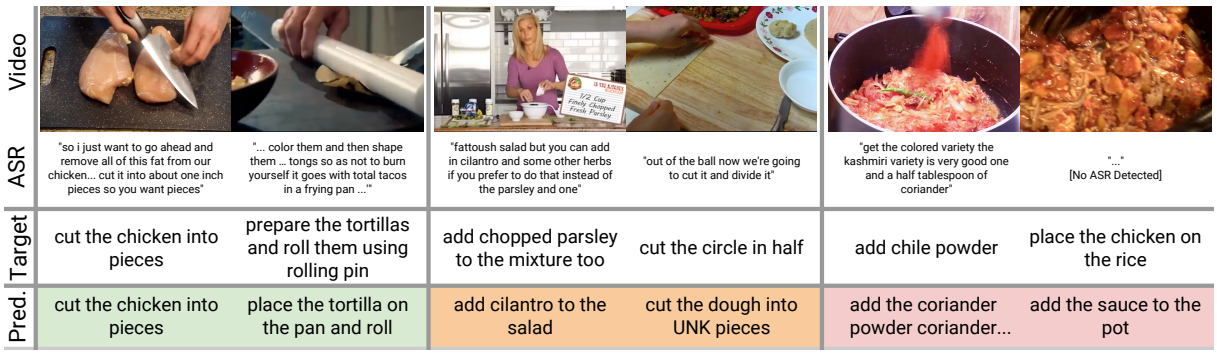

Figure 3: Example generations from AT+Video in cases where it performs **well**, **okay**, and **poorly**.

of transcripts are truncated in this process). For simplicity, decoding is done greedily in all cases.

Generation Experiment Results. Table 2 reports the performance of each model. For unimodal models, simple baselines like FASC (filtered ASR) and RET (training-caption retrieval) outperform the state-of-the-art video-only model of Sun et al. (2019a), according to the four automatic evaluation metrics. Overall, AT yields the best unimodal performance. Combining ASR and visual signals into a multimodal representation performs even better: the AT+Video model tends to outperform AT (and Sun et al. (2019a)), according to ROUGE-L, CIDEr, and METEOR ($p < .01$). Since AT and AT+Video have identical architectures and differ only in the available inputs, this result provides strong evidence that it is indeed the *multimodality* of AT+Video that leads to the (statistically significant) performance gains over the strongest unimodal models. We present some output examples in Fig. 3.

5.1 Diversity of Generated Captions

In addition to the automatic quality metrics, we measure how diverse the generated caption are for each model, using the following metrics: vocabulary coverage (the percent of vocabulary that was predicted at test-time by each algorithm at least once); proportion not copied (the percent of generated captions that do not appear in the training set verbatim); and output uniqueness (the percent of generated captions that are unique). These metrics are useful because they can highlight undesirable, degenerate behavior for models.[7] As an upper-bound, we compute these metrics for the ground-truth (GT) test-time targets. Note that even the ground-truth targets do not achieve 100% in these diversity metrics: for vocabulary coverage, not all vocabulary items appear in the ground-truth captions for a given cross-validation split; similarly, for proportion not copied/output uniqueness, because there are repeated captions in the label set.

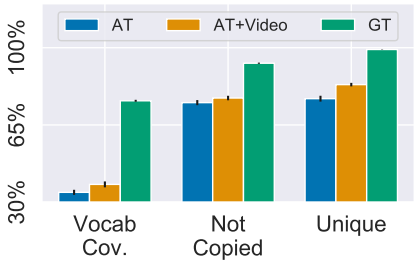

Figure 4: The multimodal model AT+Video produces slightly more diverse captions than its unimodal counterparts.

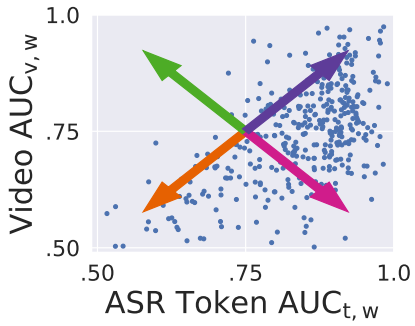

According to all metrics, AT+Video outputs are slightly more diverse compared to the AT outputs (Fig. 4). This observation suggests that the multimodal model is not simply exploiting a degeneracy to achieve its performance improvements.

6 Complementarity of Video and ASR

We now turn to the question of *why* multimodal models produce better captions: what type of signal does video contain that speech does not (and vice versa)? Our initial idea was to quantitatively compare the captions generated by AT versus AT+Video; however, because the dataset is relatively small, we were unable to make observations about the generated captions that were statistically significant.[8]

[7] For instance, the constant prediction baseline we consider would score low in both vocab coverage and uniqueness.

[8] In general, making concrete statements about the causal link between inputs and outputs of sequence-to-sequence models is challenging, even in the text-to-text case, see Alvarez-Melis and Jaakkola (2017).

Figure 5: Per-word classification results using ASR and/or Video features. Each point in the scatterplot represents a different word-type; x-coordinate values show how well a word is predicted by ASR-token features; y-coordinate values show how well a word is predicted by video features. Tables (a)-(d) show word types that are easy, universally difficult, better-predicted-by-ASR, and better-predicted-by-video, respectively.

Instead, we examine properties of the ASR-token–based and visual features directly. Following a procedure inspired from (Lu et al., 2008; Berg et al., 2012; Dai et al., 2018; Mahajan et al., 2018), we consider the auxiliary task of predicting presence/absence of unigrams in the ground truth captions from features extracted from corresponding segments. We train two unimodal classifiers, one using ASR-token–based features and one using visual features, and measure their relative capacity to predict different word types; the goal is to measure which word types are most-predictable from the ASR tokens and, conversely, which ones are most-predictable from the visual features.

For each segment, we predict the unigram distribution of its corresponding caption using a unimodal softmax classifier: for simplicity, we use a 2-layer, residual deep averaging network (Iyyer et al., 2015) for both the visual and ASR-based classifier. We measure per-word-type performance using AUC, which is word-frequency independent.

Specifically — for each word type w (e.g., w = `beer`) we measure how well w is predicted by the classifier based on ASR / spoken tokens AUC$_{t,w}$ (e.g., AUC$_{t,beer}$ = 98) and, conversely, how well w is predicted by the visual classifier AUC$_{v,w}$ (AUC$_{v,beer}$ = 68). For a given word type, we measure its overall difficulty by averaging AUC$_{t,w}$ and AUC$_{v,w}$; we call this AUC$_{\mu,w}$ (AUC$_{\mu,beer}$ = 83). Similarly, we measure the difference in difficulty by subtracting AUC$_{t,w}$ and AUC$_{v,w}$ to give AUC$_{\Delta,w}$ (AUC$_{\Delta,beer}$ = 30) with higher values indicating that a word type is predicted better by the spoken-token features compared to the visual features. We plot AUC$_{t,w}$ versus AUC$_{v,w}$ for 382 words in Fig. 5 (results are averaged over 10 cross-val splits).

Absolute Performance. Points in the upper-right quadrant of Fig. 5 represent words that are easy for both visual and ASR-token–based features to predict, whereas points in the lower-left represent words that are more difficult. Specific ingredients, e.g., "nori" and "mozzarella," are often easy to detect, as are actions closely associated with particular objects (e.g., "dough" is almost always the object being "knead"-ed). Conversely, pronouns (e.g., "it") and conjunctions (e.g., "or") are universally difficult to predict.

Visual vs. ASR-token–based features. In general, ASR-token–based features carry greater predictive power, as evidenced by the skew towards the bottom right in the scatterplot in Fig. 5. One pattern in the cases where speech features perform better (Fig. 5c) is that words are often modifiers, e.g., *white* (pepper), *sea* (salt), *dried* (chilies), *olive* (oil), etc. Indeed, small, detailed distinctions may be often difficult to make from visual features, e.g., "vegetable oil" and "olive oil" may look identical in most YouTube videos.

Nonetheless, there are types better predicted by video features (Fig. 5d). Often, these are cases that require unstated, background knowledge, i.e., references to objects not explicitly stated by the speaker(s). To quantify this observation, for each word type we compute the likelihood that it is *stated* by the speaker in the video, given that it appears in the ground-truth caption, i.e., $P(w \in \texttt{ASR} \mid w \in \texttt{GT})$. Aside from trivial cases (e.g., words misspelled in the GT never appear in the ASR), words that are often unstated include action words (e.g., "place", "crush") and cookware (e.g., "pan", "wok", "pot"). Words that are often stated include specific ingredients (e.g., "honey", "coconut", "ginger"). In contrast to word frequency (which is uncorrelated with AUC$_{\Delta,w}$, Spearman

$\rho \approx 0$), stated rate *is* correlated with $\text{AUC}_{\Delta,w}$ ($\rho = 0.44, p < .01$).

7 Oracle Object Detection

The results in Table 2 indicate that, while adding visual information yields statistically significant improvements to the ASR-only model, the improvements are not large in magnitude. This leaves open the question of whether (a) any visual information simply does not provide much additional information on top of ASR, or (b) we need better visual modeling. We take a first step in addressing this question by experimenting with an "oracle" object detector that provides perfect-precision predictions.[9] If even oracle object detection does not help, then the answer is more likely (a) rather than (b) above.

As part of a YouCook2 data release, bounding box annotations for selected objects in the recipe text (Zhou et al., 2018a) were provided. Unfortunately, while these could have served as an oracle, the actual annotations are only available for a small fraction of the data. Instead, we consider the set of 62 object labels made available. We simulate a high-precision, oracle object detector by identifying – per video segment – the overlap between (morphology-normalized) groundtruth caption mentions and the 62 object labels available.[10] For instance, for the groundtruth caption "put the mushrooms in the pan", the oracle object detector yields "mushroom" and "pan". 89% of segments receive at least one oracle object. The oracle object detections are then fed into the Transformer encoder (in random order), either by themselves (Oracle) or along with the ASR token sequence (AT+Oracle). We perform the same cross-validation experiments as described in §5, and report the average ROUGE-L (we observe similar trends with other metrics):

	AT	AT+Video	Oracle	AT+Oracle
ROUGE-L	35.5	36.7	40.8	**45.5**

Because the AT+Oracle model achieves large improvements over AT+Video, we suspect that building higher-quality visual representations is a promising avenue for future work.

[9] High-precision object detectors are gaining popularity in the computer vision community because the training data is easier to annotate, e.g., Krasin et al. (2017).

[10] This oracle is unlikely to be achievable, as it assumes 100% precision for the 62 objects considered (which also implies modeling *which* objects to talk about, a non-trivial task in itself (Berg et al., 2012)).

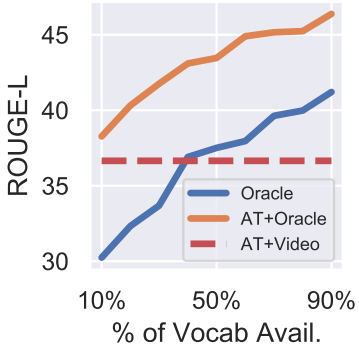

Figure 6: The performance of the oracle methods increases as they are given access to an increasing number of object types.

How weak of an oracle can still produce high performance? Fig. 6 shows performances of models using *subsets* of the 62 objects (most frequent 10% of objects through 90%) over one cross-validation fold. AT+Oracle gives better performance than AT+Video by detecting *just 6 object types,* and the oracle by-itself (which is only given access to object sets) achieves comparable performance to AT+Video with 30 object types. These results suggest that, at least for this task, the Transformer decoder is likely not the main performance bottleneck, as it is able to paste-together unordered object detections into captions effectively.

8 Conclusion

In this work, we demonstrate the impact of incorporating both visual and ASR-token–based features into instructional video captioning models. Additional experiments investigate the complementarity of the visual and speech signals.

Our oracle experiments suggest that performance bottlenecks likely derive from the input encoding, as the decoder is able to paste-together even simple sets of object detections into high-quality captions. Future work would thus be well-suited to investigate better models of input data. Given the small size of the dataset, transfer learning may prove fruitful, e.g., pre-training the encoder with an unsupervised, auxiliary task; work contemporaneous with our submission from the computer vision community suggests that transfer learning indeed is a promising direction (Sun et al., 2019b,a; Miech et al., 2019).

Abstract

Grounding referring expressions to objects in an environment has traditionally been considered a one-off, ahistorical task. However, in realistic applications of grounding, multiple users will repeatedly refer to the same set of objects. As a result, past referring expressions for objects can provide strong signals for grounding subsequent referring expressions. We therefore reframe the grounding problem from the perspective of coreference detection and propose a neural network that detects when two expressions are referring to the same object. The network combines information from vision and past referring expressions to resolve which object is being referred to. Our experiments show that detecting referring expression coreference is an effective way to ground objects described by subtle visual properties, which standard visual grounding models have difficulty capturing. We also show the ability to detect object coreference allows the grounding model to perform well even when it encounters object categories not seen in the training data.

1 Introduction

Grounding referring expressions to objects in an environment is a key *Artificial Intelligence* challenge spanning computer vision and natural language processing. Past work in referring expression grounding has focused on understanding the ways a human might resolve ambiguity that arises when multiple similar objects are in a scene – for example, by referring to visual properties or spatial relations (Nagaraja et al., 2016; Hu et al., 2017). However, most previous work treats it as an *ahistorical* task: a user is presented with an image and a referring expression and only features from the current referring expression are used to determine which object is being referred to. However, in many scenarios where a grounding system can be deployed, grounding is not an isolated one-off task. Instead, users will repeatedly refer to the same set of objects. In a household environment, a robot equipped with a grounding system will repeatedly be asked to retrieve objects by the people who live there. Similarly, during a cooperative assembly task, a robot will repeatedly be asked for various parts or tools. Even in non-embodied systems, such as conversational agents, a user will repeatedly refer to different relevant entities.

Utterances from a User:
(1) The open text book.
(2) Page with a dark border and images of two people at the bottom.
(3) The open book with typed pages.
(4) Pages of handwritten notes under the open book.

Figure 1: An example where a single user repeatedly refers to objects in the same scene. The color identifies which bounding box is being referred to.

These scenarios present new challenges and opportunities for grounding referential expressions. When people in the same environment commonly interact with each other (as in a household or workplace), *lexical entrainment* will likely occur (Brennan and Clark, 1996). That is, users of the system will come to refer to objects in similar ways to how they have been referred to in the past.

[*] Equal contribution.

Thus, it is important that the grounding system can adapt to the vocabulary used where it is deployed.

Even if each object is being repeatedly referred to by a set of people who do not interact with each other, the agent can still learn general information about the objects by remembering how they have been referred to in the past. This is useful as it provides a way for the model to learn properties of objects that are otherwise hard to detect such as subtle visual properties which cannot easily be captured by standard visual grounding systems.

To include past referring expressions in a grounding model, we formulate grounding as a type of coreference resolution – are a new phrase and a past phrase (known to identify a specific object) referring to the same object? To compare a new referring expression with past referring expressions, we need to learn a type of compatibility metric that tells us whether two expressions can both describe the same object. Detecting object coreference involves distinguishing between mutually exclusive object attributes, recognizing taxonomic relations, and permitting unrelated but possibly co-existing properties.

Our contribution is to demonstrate that grounding accuracy can be improved by incorporating a module that has been trained to perform coreference resolution to previous referring expressions. We introduce a neural network module that learns to identify when two referring expressions describe the same object. By jointly training the system with a visual grounding module, we show how grounding can be improved using information from both linguistic and visual modalities.

We evaluate our model on a dataset where users repeatedly refer to objects in the same scene (see Figure 1). Given the same amount of training data, our coreference grounding model achieves an overall increase of 15% grounding accuracy when compared to a state-of-the-art visual grounding model (Hu et al., 2017). We show that the coreference grounding model can better generalize to object categories and their descriptions not seen during training – a common difficulty of visual grounding models. Finally, we show that jointly training the coreference model with a visual grounding model allows the joint model to use object properties not stated in previous referring expressions. As an example application, we demonstrate how the coreference grounding paradigm can be used with a robotic platform.[1]

2 Technical Approach

The task of grounding referring expressions is to identify which object is being described by a query referring expression, Q. The input to this problem is a set of N objects, $O = \{o_1, o_2, \ldots, o_N\}$.[2] Each object, o_i, is represented by its visual features, v_i (i.e., pixels from the object's bounding box), and a referring expression, r_i, that was previously used to refer to that object (r_i may not always be available). The grounding problem can then be modelled as estimating the distribution over which object is being referred to: $p(x|Q, v_{1:N}, r_{1:N})$ where x is a random variable with domain O.

There has been a lot of work in grounding referring expressions (Hu et al., 2017), many of which use only visual features and no interaction history. Most of the proposed models have the form:

$$p(x = o_i|Q, v_{1:N}) = \mathcal{S}\left(\mathrm{W}_{vis} \cdot f_{vis}\left(Q, v_{1:N}\right)\right)_i = \frac{\exp\left(\mathrm{W}_{vis} \cdot f_{vis}\left(Q, v_i\right)\right)}{\sum_{j=1}^{N} \exp\left(\mathrm{W}_{vis} \cdot f_{vis}\left(Q, v_j\right)\right)}$$

where $f_{vis}\left(Q, v_i\right)$ is a low dimensional representation of the visual features v_i and the query Q, W_{vis} is a learned linear transformation, and $\mathcal{S}(\cdot)_i$ is the ith entry of the softmax function output.

We introduce a similar model for coreference grounding which uses past referring expressions to decide which object o_i is being referred to:

$$p\left(x = o_i|Q, r_{1:N}\right) = \mathcal{S}\left(\mathrm{W}_{coref} \cdot f_{coref}\left(Q, r_{1:N}\right)\right)_i$$

where $f_{coref}\left(Q, r_i\right)$ is an embedding of a past referring expression and the query expression, and W_{coref} is a learned linear transformation.

Finally, we introduce a joint model which fuses representations f_{vis} and f_{coref} by a function g:

$$p\left(x = o_i|Q, v_{1:N}, r_{1:N}\right) = \mathcal{S}\left(g\left(f_{coref}\left(Q, r_{1:N}\right), f_{vis}\left(Q, v_{1:N}\right)\right)\right)_i \quad (1)$$

Note that f_{vis} can come from any visual grounding model that associates text to visual features extracted from the objects' bounding boxes.

[1] The dataset, code, and demonstration videos can be found at https://mike-n-7.github.io/coreference-grounding.html.

[2] Object proposal networks (e.g., Faster R-CNN) can be used to extract object bounding boxes from an image.

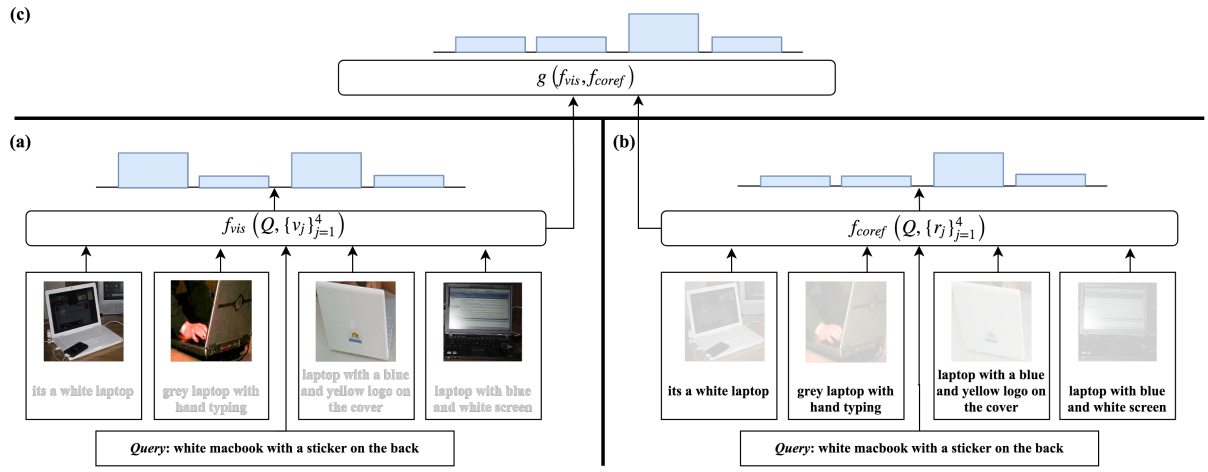

Figure 2: (a) A visual grounding model only takes in images to resolve the query expression and outputs a categorical distribution over the objects. (b) We propose a model that uses past referring expressions to resolve the new expression. (c) These models can be combined to fuse visual and linguistic information.

Our contributions are the coreference and joint grounding models. Both models learn to ground a new referring expression by computing compatibility with past referring expressions of candidate objects. We describe f_{coref} in detail in Section 2.1 and the joint model in Section 2.2. For a visualization of the model, see Figure 2.

2.1 Coreference Grounding Model

Given a query referring expression Q and an expression r_i for each object (each represented by a sequence of M words: $\{w_1, w_2, \ldots, w_M\}$), we define a joint representation of these two expressions, f_{coref}, as follows:

$$f_{coref}(Q, r_i) = f_{enc}(Q) \odot f_{enc}(r_i)$$

where f_{enc} produces referring expression embeddings for the given phrase of dimension $l \times 1$, and $\odot$ is the elementwise multiplication operator. Note the same encoder is used to embed both r_i and Q. In Section 4.3, we evaluate various referring expression embedding methods described below.

LSTM Embeddings The final output state of an LSTM (Hochreiter and Schmidhuber, 1997) is used as the referring expression embedding.

BiLSTM Embeddings For the bidirectional LSTM, forward and backward LSTMs are run over the input sequence, and their outputs for each word are concatenated. An expression embedding is computed by the dimension-wise max across words (Collobert and Weston, 2008).

Attention Embeddings Attention encoders (Lin et al., 2017) learn a weighted average of BiLSTM outputs as the referring expression representation. They output an attention score that is used to compute a weighted average of the BiLSTM outputs.

InferSent Embeddings Recently, *InferSent* (Conneau et al., 2017) was proposed as a *general purpose* sentence embedding method. *InferSent* is similar to the BiLSTM model but was trained using the *Natural Language Inference* task with the intuition that this task would require the sentence embeddings to contain semantically meaningful information. The authors showed that their sentence representation generalized well to other tasks. The pretrained encoder from the *InferSent* model is used to embed a referring expression.

2.2 Integrating Vision and Coreference

The coreference model can learn the complexities of coreference with past expressions, but if certain properties are not mentioned in a previous expression, the model will have difficulty deciding which object is being referred to. If the referenced property could have been learned by a visual grounding model, we would like to include this representation in our model. In this section, we show how we can take an existing visual grounding model and combine it with a coreference grounding model. We generate representations f_{vis} from an existing grounding model, and f_{coref} from our coreference grounding model. These representations are fused using a function $g(\cdot)$, which is used to compute the most likely referred object using Equation 1. We experiment with two choices of g, which we describe in the following subsections.

2.2.1 Addition

One approach is to take the sum of the scores of component visual and coreference grounding models. The function $g(\cdot)$ can be written as (arguments of functions removed for brevity):

$$g = \mathrm{W}_{vis} \cdot f_{vis}(\cdot) + \mathrm{W}_{coref} \cdot f_{coref}(\cdot)$$

where $\mathrm{W}_{vis}, \mathrm{W}_{vis} \in \mathbb{R}^{1 \times l}$ are learned parameters which transform their respective feature vectors of size l into scalar scores.

2.2.2 Concatenation

Simple addition might not capture all interdependencies between different modalities. We propose an approach where we concatenate the representations f_{vis} and f_{coref}, and add a two layer feed forward network to output the final score,

$$g = \mathrm{W}_{c1}(\mathrm{ReLU}(\mathrm{W}_{c2}(\mathrm{ReLU}([f_{vis} f_{coref}]).$$

For our visual grounding model, we use the *Compositional Modular Network* (Hu et al., 2017), which is one of the top performing models in several benchmark referring expressions datasets. We train the joint model end-to-end so that it can learn how to properly merge the visual and coreference information.

3 Dataset

Our goal is to ground a referring expression to an object in the environment using past referring expressions and visual features. Existing referring expression datasets do not contain at least two referring expressions for each object. Since this is a requirement to learn and evaluate models that can utilize past expressions, we create two new datasets for the task – a large *Diagnostic* dataset where past expressions are algorithmically assigned, and a smaller *Episodic* dataset created to capture more realistic interaction scenarios.

3.1 Diagnostic Dataset

In this dataset, artificial scenes are created by grouping similar objects, and each referring expression for an object is collected independently. This form of dataset allows us to easily scale up the amount of data used for training and capture more descriptive language by introducing category-level ambiguity into the scene. We use images from the MSCOCO dataset (Lin et al., 2014), which contains bounding boxes for each object in an image. We randomly group together four object images from the same category. We randomly label one object as the goal object and the remaining three as distractor objects. Annotators from the *Figure Eight* platform[3] are shown these images with the goal object labeled by a red bounding box. They are asked to write an English expression to refer to the goal object so that it can be easily distinguished. Two expressions are collected for each object, each time with different distractor objects.

To ensure the model can distinguish between objects of different categories, we randomly select half the data, and replace two distractor objects in the group with two objects from a different category. Since these objects are from a different category, we expect the referring expression to still be able to correctly identify the goal object.

Each instance, or dataset sample, now consists of four objects (represented by images) with a query expression referring to the goal object. To associate each object with a *past expression*, we use expressions that were used to reference that object in other instances. Each instance now has a set of objects associated with a past expression and an image. In addition, the goal object is labeled and a query referring expression is provided for the goal. We randomly split the data into train, development and test sets in a 60/20/20 ratio. We refer to this split as STANDARD.

To evaluate the ability of grounding models to disambiguate objects from categories not seen during training, we create an alternative split of the *Diagnostic* dataset. This split ensures that no object category in the test set is present in the training or development splits. We refer to this split as HARD. More details of dataset construction and verification are present in the supplementary material.

3.2 Episodic Dataset

The *Diagnostic* dataset uses cropped images of objects from MSCOCO images and programmatically assigned past expressions. In order to capture nuances of realistic interaction, we collect a smaller *Episodic* dataset where annotators are shown a full scene and repeatedly asked to refer to objects within that scene. We select scenes from the MSCOCO dataset which have three to six objects of the same category. We prune ob-

[3] https://www.figure-eight.com/

ject bounding boxes with area less than 5% or over 50% of the image area. Extremely small objects are often not distinguishable, and large bounding boxes often correspond to a cluster of objects rather than a single object in cluttered scenes.

Each annotator is shown the same scene 10 times in a row. Each time one of the ambiguous objects is marked with a red bounding box. The annotator is asked to provide an English referring expression to uniquely identify the marked object. Our interface does not allow the user to view referring expressions once it has been entered. As a result, if the same object is marked again in the series, the user will have no way to look up what they had written before. This process simulates how a user will refer to objects in the same environment over a period of time. As the annotators do not communicate with each other, the dataset will not capture between-user entrainment. For each image, we collect two such series of 10 expressions from two different users. We create examples for the *Episodic* dataset in two ways:

SAME USER: For each scene and annotator, we order the expressions in the same order they were provided by the annotator. Each expression forms an example where it is the respective query expression and the candidate objects are all the objects in the scene. All previous referring expressions for this scene and annotator are assigned to the respective objects as past referring expressions. These examples capture the scenario where the interaction history is provided by a single user.

ACROSS USERS: Similar to the SAME USER dataset, we create a new example each time the annotator refers to an object. However, the past expressions come from the other annotator who was displayed the same scene. These examples represent cases where interaction history is acquired from people who do not interact with each other.

We create train and development sets with both types of examples. For testing, we create one set corresponding to each of the previously mentioned types. Validation details are in the supplementary material.

The statistics for both datasets are given in Table 1. We report a metric called *Lexical Overlap* to denote the extent of similarity between training and test data. The *Lexical Overlap* is the fraction of word types in the test set that also appear in the training set. As seen in Table 1, the HARD split has lower Lexical Overlap compared to STANDARD.

Dataset	Diagnostic		Episodic	
	STANDARD	HARD	SAME USER	ACROSS USERS
# Train	10133	9855	2656	2656
# Dev	3889	4170	714	714
# Test	3796	3793	1686	1686
Objects per Example	4.0	4.0	5.64	5.64
Expressions per Object	0.47	0.47	0.5	1.94
Lexical Overlap	0.71	0.63	0.47	0.47

Table 1: Statistics for the various datasets used. Unless otherwise mentioned, the numbers are reported from the test set. Low lexical overlap for HARD indicates more unseen words in the test set. The ACROSS USERS test set of Episodic dataset has more past expressions for each object compared to other splits.

This means that a greater number of novel words appear in the HARD dataset.

4 Experiments

We run multiple experiments to evaluate the proposed grounding models and characterize the advantages of using coreference along with visual features for grounding. Specifically, we consider the following questions:

1. Which method performs best for coreference grounding and the joint model? (Section 4.3)
2. How does grounding with different types of information (visual, coreference) transfer to new object categories? (Section 4.4)
3. How does grounding performance vary when past expressions are acquired from the same (or entrained) users, as opposed to users unknown to each other? (Section 4.5)

All quantitative evaluation can be found in Table 2. As our datasets contain examples where the object being referred to may or may not have a previous referring expression, we report overall test set accuracy (*All*), as well as accuracy grouped by the number of past referring expressions belonging to the ground truth object (*0, 1, or, 2*). This allows us to more accurately evaluate the coreference models as they are not expected to perform well without a previous referring expression.

We show how coreference grounding is used in practice by demonstrating its use on the Baxter robot. Namely, we show how a system can keep track of past referring expressions and associate them with objects.

4.1 Model Descriptions

We compare against the following unsupervised coreference baselines (i.e., not trained on the referring expression task). All these methods use a

similarity score between the input expression and the past referring expression to make a prediction.

Word Overlap Baseline: Compute the *Jaccard* similarity between two expressions.
Word Averaging Baseline: Each expression is represented by the average of the word vectors of constituent words. Similarity is computed as cosine similarity between vectors.
Paragram Phrase: Uses the paraphrase model proposed by Wieting et al. (2016) to compute similarity between past and input expressions.
InferSent Unsupervised: Each expression is represented by its pretrained *InferSent* embedding and similarity is computed as cosine similarity.

We also consider supervised models for the referring expression grounding task:

Vision: The *Compositional Modular Network* (Hu et al., 2017) which grounds an input expression to a bounding box's visual features.
Coreference: The proposed model that grounds an expression to objects represented by previous referring expressions. We evaluate the LSTM, BiLSTM-Max, Attention, and InferSent Encoders.
Joint: Jointly trains the *Vision* and *Coreference* components of the model. This model uses only the InferSent encoder. We evaluate both addition and concatenation methods for information fusion.

4.2 Implementation Details

Since the *Episodic* dataset is much smaller in size, all models (except joint with concatenation) are first trained on the *Diagnostic* training set until the validation error stops decreasing, and then trained on the *Episodic* train set. For the joint model with concatenation, we found that tuning only the fusion parameters, while holding the others fixed, on the *Episodic* data performs better.

The large *Diagnostic* dataset contains at most one past expression for each object. We cannot expect our models trained on the *Diagnostic* data to handle multiple past referring expressions. As a result, when an object is associated with multiple past expressions, we only consider the expression most similar to the query expression according to the Unsupervised InferSent model.

The models are implemented in *PyTorch* (Paszke et al., 2017). All models for the *Diagnostic* dataset are trained with the *Adam* optimizer (Kingma and Ba, 2015), and the best model is selected based on the performance on the development set. We use GloVe vectors (Pennington et al., 2014) and a pretrained VGG19 model to extract visual features (Simonyan and Zisserman, 2015).

4.3 Coreference and Joint Model Evaluation

We evaluate the performance of the coreference and joint models on the STANDARD split of the *Diagnostic* dataset (see column STANDARD of Table 2). First, we observe that all unsupervised coreference methods perform poorly when the goal object does not have past referring expressions. However, when past expressions are present, all the coreference baselines outperform the vision model. Coreference using pretrained InferSent embeddings performs the best among the unsupervised methods, possibly because InferSent embeddings have been pretrained on the SNLI dataset. SNLI was created from image captions, making the domain similar to that of referring expressions.

Learned models of coreference start performing better on cases where the goal object has no past referring expression. Note that in the 0-column, the 0 only refers to the ground-truth object not having a referring expression – the other objects may have expressions associated with them. Thus the supervised models can better determine when two expressions are incompatible, leading to the model choosing an object without any previous referring expression. However, when a past referring expression is present, they are typically informative and the *Word Overlap* model performs the best amongst unsupervised and supervised methods (see the 1-column). *InferSent (Unsupervised)* still achieves strong performance yet fine-tuning to the task still helps. We use the coreference model with the *InferSent* encoder for the joint models.

The jointly trained models achieve high accuracies in both cases where the ground truth object has previously been referred to (1-column) and those where it has not (0-column). This indicates that the models can successfully utilize information from both vision and coreference modalities. The concatenation fusion method outperform simple shallow addition of component scores.[4]

The joint model consistently outperforms the vision model. This is because people usually provide information relevant to how the object can be referred. If this information is available, which is

[4]Note that different objects in a scene might have different number of past expressions. At test time, we will not know the goal object, and hence, we cannot use the number of past expressions to determine which model to use at test time.

		Diagnostic						Episodic (*s. 4.5*)				
		STANDARD (*s. 4.3*)			HARD (*s. 4.4*)			SAME USER				ACROSS USERS
		0 57%	1 43%	All	0 56%	1 44%	All	0 49%	1 33%	2 15%	All	
	Vision	64.2	66.1	65.0	59.6	60.6	60.0	32.1	32.1	29.4	31.5	31.5
Unsupervised	Word Overlap	3.5	74.2	34.1	4.0	72.6	34.3	5.3	85.4	87.3	37.6	58.1
	Word Averaging	3.5	69.6	32.1	4.0	67.8	32.2	5.3	77.8	80.2	42.7	51.8
	Paragram Phrase	3.5	71.3	32.8	4.0	71.3	33.7	5.3	81.1	83.7	44.3	56.9
	InferSent	8.8	73.8	36.9	9.2	73.6	37.6	5.9	85.0	85.7	46.3	47.7
Supervised	LSTM	28.2	41.1	33.8	28.2	40.3	33.5	6.0	69.4	63.9	37.2	46.8
	BiLSTM-Max	30.0	60.8	43.3	27.0	57.8	40.6	7.0	75.7	74.6	41.8	53.1

Joint	Addition	65.3	69.4	67.1	62.0	62.3	62.1	22.3	63.8	60.3	42.6	48.7
	Concatenation	68.6	71.3	**69.8**	58.0	70.7	**63.6**	19.0	84.7	86.1	**52.7**	**62.7**

Table 2: Grounding accuracy under different conditions. Best scores in bold. The columns labeled **0**, **1**, and **2** correspond to test examples where the goal object has 0, 1 and 2 past expressions respectively (percentage indicates fraction of test examples applicable for that column). **All** refers to the score on the entire test set. Most examples in ACROSS USERS have large number of past expressions, so we only report score on the entire test set.

true in many realistic scenarios, it is beneficial to utilize coreference grounding.

With more data, the vision model could achieve higher performance. However, we argue that as ambiguity between objects increases, the properties that distinguish objects become more subtle and a large dataset would be necessary to learn these intricacies.

When does Joint perform better than Vision and Coreference? Our *Joint* model performs better than models trained on single modality (*Vision*, *Coreference*). The joint model can use visual features when the past referring expressions are not sufficient to discriminate between objects. In 25% of examples, the *Coreference* model predicts the wrong object whereas the *Joint* model selects the correct object. A majority of these cases are examples where the goal object has no past expression associated with it. In 8% of examples, the *Joint* and *Coreference* models are correct even though the *Vision* model is wrong. Finally, for only 7% of the examples, the *Joint* model predicts the correct object when both the *Vision* and *Coreference* models predict incorrectly. This indicates that the *Joint* model is primarily merging the gains of the *Vision* and *Coreference* models; most correct decisions of *Joint* correspond to correct decisions either from *Vision* or *Coreference*. Figure 3 shows a breakdown of how often the various models outperform each other. Figure 4 shows examples where Joint outperforms models trained on a single modality.

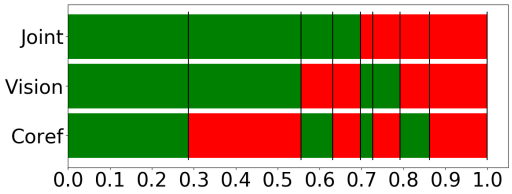

Figure 3: Proportion of examples of the STANDARD test set where different subsets of the systems ground correctly (green) or incorrectly (red). Instances are arranged along the x-axis.

4.4 Generalizing to New Object Categories

To evaluate how the various models handle generalization to unseen object categories, we use the HARD split of the *Diagnostic* dataset. The test set of this split contains object categories which have not explicitly been seen during training. We hypothesize that due to pretrained word embeddings (which include embeddings for words describing the unknown categories), the coreference models will be able to successfully ground to new object categories. On the other hand, the performance of the *Vision* model will decrease in the HARD split, because the pretrained visual features of the new objects are not well aligned with representations of unseen words. As seen in Table 2, this is indeed the case as the *Vision* model's performance drops between the STANDARD and HARD datasets. On the other hand, the coreference models' performance on the HARD split is comparable to those

of the STANDARD split. Although the aggregate performance is low, the coreference models perform strongly on examples where the goal object has past expressions (see 1-column). In particular, *Coref Supervised with InferSent* achieves 70.5% on the STANDARD split, which reduces only to 68.6% on the HARD split. This can be explained by observing that the representation of the object (its past referring expression) and a new referring expression are already aligned within the same vector space (pretrained InferSent embeddings).

4.5 Performance on Episodic Dataset

As the *Diagnostic* dataset is somewhat artificial in the way objects and properties are grouped, we also evaluate these models on the *Episodic* dataset. As described in Section 3.2, the key differences in this dataset are that all candidate objects in an example are from the *same* scene, and previous referring expressions are added sequentially as the user refers to more objects in the scene (thus a previous referring expression truly did occur *previously*).

We find similar trends in the performance on the *Episodic* dataset (see the *Episodic* columns of Table 2). Since the same user is referring to the same object multiple times, we expect expressions for the same object to be similar. This leads to the high performance of coreference models in the SAME USER split of the *Episodic* dataset (see the 1-column). Even the word-overlap model does particularly well due to the correlation between expressions from the same user (over 85% accuracy when the goal object has past expressions).

If the past expressions were not provided by the same user, but by users unknown to each other, we can still see improvement over not having any past expressions (see the ACROSS USERS column). In this split, past expressions are always associated with objects as we assume other users have interacted with the system. In the ACROSS USERS split, even though the *Coreference* models are less effective than in the SAME USER split, they still outperform the *Vision* model (e.g., the *Supervised InferSent* model achieves 61.3%, whereas a pure vision model achieves only 31.5%). This is because users unknown to each other still provide useful knowledge about the properties of objects.

The *Joint* models benefit from using both modalities, which is particularly important in realistic scenarios as most objects initially will not have any previous referring expressions. Note

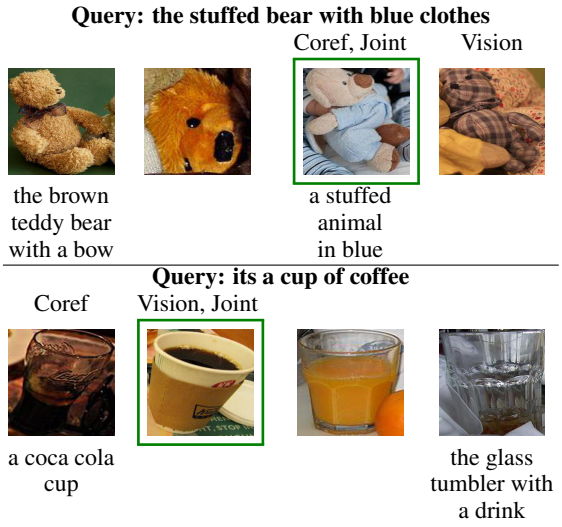

Figure 4: Examples where the Joint model accurately grounds the query, but either Vision or Coreference does not. The past expression is mentioned below each object image. The correct object has a green border and a model's name appears above its predicted object.

that the performance of the *Vision* model on the *Episodic* dataset is much lower than its performance on the *Diagnostic* dataset. This loss in performance is due to the images in the *Episodic* dataset being more cluttered and annotators often using spatial relationships to refer. As the *Diagnostic* training dataset does not contain spatial information, our models cannot handle these cases. We can train on existing referring expression datasets to learn spatial relationships, but we do not explore this as it is not central to this paper. More analysis is added to the appendix.

4.6 Robot Demonstration

One of the motivations of this work was to enable robots to use past referring expressions to aid grounding in human-robot interactions. In this section, we provide a demonstration of how our coreference grounding system can be integrated with the Baxter robotic platform. To benefit from coreference grounding, the system must have a natural way to keep track of past referring expressions of an object. We demonstrate such an interface in Figure 5.

We focus on a scenario where a human asks the robot to pick up specific objects. If the robot incorrectly identifies the object being referred to, on the next turn, the user can correct the robot by indicating the correct object (Figure 5b). The referring expression can then be associated with the correct

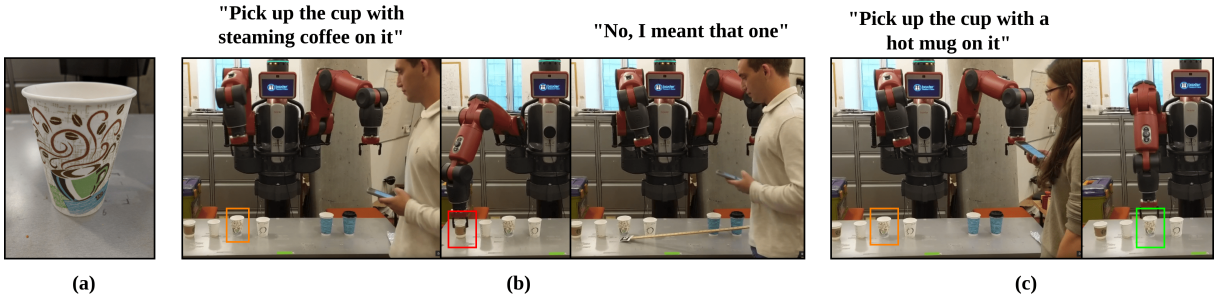

Figure 5: Demonstration of a coreference grounding system on the Baxter robot. (a) The cup being identified. (b) A user refers to the cup and the robot grounds incorrectly. The user corrects the robot and associates the referring expression with that object. (c) When a new user refers to the same object, the system's output is correct.

object and this association can be maintained with a tracking system. Future users (with no knowledge of the first user) can then successfully refer to the object (Figure 5c).

5 Related Work

Grounding Referring Expressions There has been a lot of recent work on resolving referring expressions to objects (Mao et al., 2016; Yu et al., 2016; Shridhar and Hsu, 2018; Nagaraja et al., 2016; Cirik et al., 2018). In contrast to these approaches which are static once trained, our model leverages past referring expressions, which permits an interface to add information during execution. Our task is related to *Visual Dialogue* (Das et al., 2017; Kottur et al., 2018), where an agent interactively answers questions about visual properties of a scene where the answers only exist in the image and not in the dialogue context. In contrast, we focus on using complementary knowledge from past referring expressions. There has also been work to learn a compatibility metric dictating whether two words can refer to the same object (Kruszewski and Baroni, 2015). Our work focuses on coreference between entire referring expressions instead of atomic words.

Lexical Choice in Interactions A large body of work in psycholinguistics (Clark and Wilkes-Gibbs, 1986; Brennan and Clark, 1996; Pickering and Garrod, 2004) show that participants in a conversation collaboratively come up with lexical terms to refer to objects and consequently, get *entrained* with each other and start using similar expressions to refer to objects. These works form the motivation for our problem formulation. Recently, the *PhotoBook Dataset* has been proposed to investigate shared dialogue history in conversation (Haber et al., 2019). The dataset differs from ours in that expressions refer to entire scenes instead of objects within a scene. The authors' conclusions support our findings that using past expressions is useful for resolving referring expressions.

Interaction History for Human Robot Interaction Paul et al. (2017) maintains knowledge provided by users, using a closed set of predicates. In constrast, we use raw past referring expressions to handle an open domain of knowledge. There has been work on grounding in dialogue for robots (Tellex et al., 2014; Whitney et al., 2017; Thomason et al., 2017; Padmakumar et al., 2017). In contrast to our work, they focus on refinement or clarification, and hence past expressions only help within the same dialogue episode.

6 Conclusion

In this work, we reformulated the grounding problem as a type of coreference resolution, allowing for the inclusion of past referring expressions that are typical in many real-world scenarios. We proposed a model that can use both linguistic features from past expressions and visual features of the object to ground to a new expression. We showed that this model outperforms a purely vision-based model as it can use past descriptions of salient features that the vision-based model may have difficulty learning with limited data. It further benefits from having a vision model that can fill in information not provided in past expressions.

Abstract

This paper addresses the problem of comprehending procedural commonsense knowledge. This is a challenging task as it requires identifying key entities, keeping track of their state changes, and understanding temporal and causal relations. Contrary to most of the previous work, in this study, we do not rely on strong inductive bias and explore the question of how multimodality can be exploited to provide a complementary semantic signal. Towards this end, we introduce a new entity-aware neural comprehension model augmented with external relational memory units. Our model learns to dynamically update entity states in relation to each other while reading the text instructions. Our experimental analysis on the visual reasoning tasks in the recently proposed RecipeQA dataset reveals that our approach improves the accuracy of the previously reported models by a large margin. Moreover, we find that our model learns effective dynamic representations of entities even though we do not use any supervision at the level of entity states.[1]

1 Introduction

A great deal of commonsense knowledge about the world we live is procedural in nature and involves steps that show ways to achieve specific goals. Understanding and reasoning about procedural texts (*e.g.* cooking recipes, how-to guides, scientific processes) are very hard for machines as it demands modeling the intrinsic dynamics of the procedures (Bosselut et al., 2018; Dalvi et al., 2018; Yagcioglu et al., 2018). That is, one must be aware of the entities present in the text, infer relations among them and even anticipate changes in the states of the entities after each action. For example, consider the cheeseburger recipe presented in Fig. 1. The instruction "*salt and pepper each patty and cook for 2 to 3 minutes on the first side*" in Step 5 entails mixing three basic ingredients, the *ground beef*, *salt* and *pepper*, together and then applying heat to the mix, which in turn causes chemical changes that alter both the appearance and the taste. From a natural language understanding perspective, the main difficulty arises when a model sees the word *patty* again at a later stage of the recipe. It still corresponds to the same entity, but its form is totally different.

Over the past few years, many new datasets and approaches have been proposed that address this inherently hard problem (Bosselut et al., 2018; Dalvi et al., 2018; Tandon et al., 2018; Du et al., 2019). To mitigate the aforementioned challenges, the existing works rely mostly on heavy supervision and focus on predicting the individual state changes of entities at each step. Although these models can accurately learn to make local predictions, they may lack global consistency (Tandon et al., 2018; Du et al., 2019), not to mention that building such annotated corpora is very labor-intensive. In this work, we take a different direction and explore the problem from a multimodal standpoint. Our basic motivation, as illustrated in Fig. 1, is that accompanying images provide complementary cues about causal effects and state changes. For instance, it is quite easy to distinguish raw meat from cooked one in visual domain.

In particular, we take advantage of recently proposed RecipeQA dataset (Yagcioglu et al., 2018), a dataset for multimodal comprehension of cooking recipes, and ask whether it is possible to have a model which employs dynamic representations of entities in answering questions that require multimodal understanding of procedures. To this end, inspired from (Santoro et al., 2018), we propose Procedural Reasoning Networks (PRN) that incorporates entities into the comprehension process and al-

Figure 1: A recipe for preparing a cheeseburger (adapted from the cooking instructions available at https://www.instructables.com/id/In-N-Out-Double-Double-Cheeseburger-Copycat). Each basic ingredient (entity) is highlighted by a different color in the text and with bounding boxes on the accompanying images. Over the course of the recipe instructions, ingredients interact with each other, change their states by each cooking action (underlined in the text), which in turn alter the visual and physical properties of entities. For instance, the *tomato* changes it form by being *sliced up* and then *stacked* on a *hamburger bun*.

lows to keep track of entities, understand their interactions and accordingly update their states across time. We report that our proposed approach significantly improves upon previously published results on visual reasoning tasks in RecipeQA, which test understanding causal and temporal relations from images and text. We further show that the dynamic entity representations can capture semantics of the state information in the corresponding steps.

2 Visual Reasoning in RecipeQA

In our study, we particularly focus on the visual reasoning tasks of RecipeQA, namely *visual cloze*, *visual coherence*, and *visual ordering* tasks, each of which examines a different reasoning skill[2]. We briefly describe these tasks below.

Visual Cloze. In the visual cloze task, the question is formed by a sequence of four images from consecutive steps of a recipe where one of them is replaced by a placeholder. A model should select the correct one from a multiple-choice list of four answer candidates to fill in the missing piece. In that regard, the task inherently requires aligning visual and textual information and understanding temporal relationships between the cooking actions and the entities.

Visual Coherence. The visual coherence task tests the ability to identify the image within a sequence of four images that is inconsistent with the text instructions of a cooking recipe. To succeed in this task, a model should have a clear understanding of the procedure described in the recipe and at the same time connect language and vision.

Visual Ordering. The visual ordering task is about grasping the temporal flow of visual events with the help of the given recipe text. The questions show a set of four images from the recipe and the task is to sort jumbled images into the correct order. Here, a model needs to infer the temporal relations between the images and align them with the recipe steps.

3 Procedural Reasoning Networks

In the following, we explain our Procedural Reasoning Networks model. Its architecture is based on a bi-directional attention flow (BiDAF) model (Gardner et al., 2018)[3], but also equipped with an explicit reasoning module that acts on entity-specific rela-

[2]We intentionally leave the textual cloze task out from our experiments as the questions in this task does not necessarily need multimodality.

[3]Our implementation is based on the implementation publicly available in AllenNLP (Gardner et al., 2018).

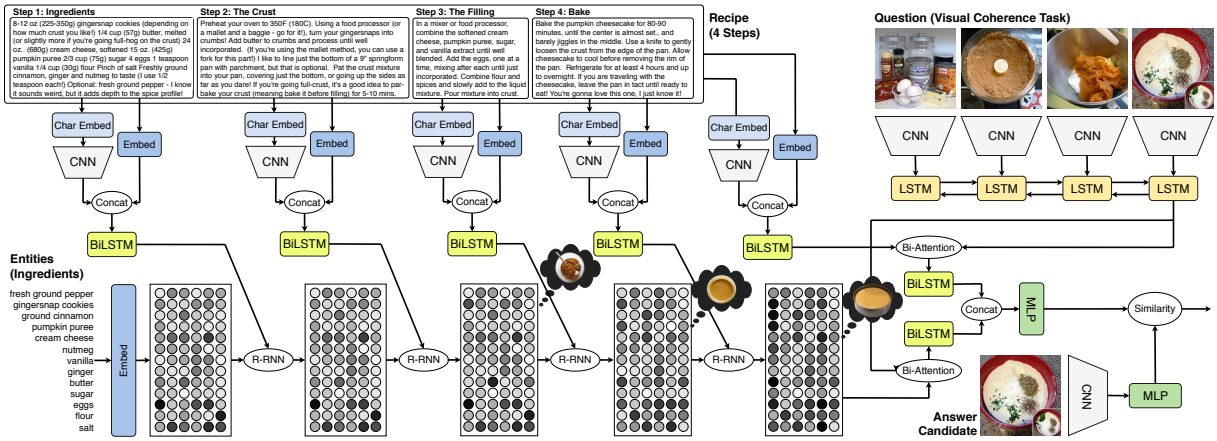

Figure 2: An illustration of our Procedural Reasoning Networks (PRN). For a sample question from visual coherence task in RecipeQA, while reading the cooking recipe, the model constantly performs updates on the representations of the entities (ingredients) after each step and makes use of their representations along with the whole recipe when it scores a candidate answer. Please refer to the main text for more details.

tional memory units. Fig. 2 shows an overview of the network architecture. It consists of five main modules: An input module, an attention module, a reasoning module, a modeling module, and an output module. Note that the question answering tasks we consider here are multimodal in that while the context is a procedural text, the question and the multiple choice answers are composed of images.

1. **Input Module** extracts vector representations of inputs at different levels of granularity by using several different encoders.
2. **Reasoning Module** scans the procedural text and tracks the states of the entities and their relations through a recurrent relational memory core unit (Santoro et al., 2018).
3. **Attention Module** computes context-aware query vectors and query-aware context vectors as well as query-aware memory vectors.
4. **Modeling Module** employs two multi-layered RNNs to encode previous layers outputs.
5. **Output Module** scores a candidate answer from the given multiple-choice list.

At a high level, as the model is reading the cooking recipe, it continually updates the internal memory representations of the entities (ingredients) based on the content of each step – it keeps track of changes in the states of the entities, providing an entity-centric summary of the recipe. The response to a question and a possible answer depends on the representation of the recipe text as well as the last states of the entities. All this happens in a series of implicit relational reasoning steps and there is no need for explicitly encoding the state in terms of a predefined vocabulary.

3.1 Input Module

Let the triple $(\mathbf{R}, \mathbf{Q}, \mathbf{A})$ be a sample input. Here, $\mathbf{R}$ denotes the input recipe which contains textual instructions composed of N words in total. $\mathbf{Q}$ represents the question that consists of a sequence of M images. $\mathbf{A}$ denotes an answer that is either a single image or a series of L images depending on the reasoning task. In particular, for the visual cloze and the visual coherence type questions, the answer contains a single image ($L = 1$) and for the visual ordering task, it includes a sequence.

We encode the input recipe $\mathbf{R}$ at character, word, and step levels. Character-level embedding layer uses a convolutional neural network, namely Char-CNN model by Kim (2014), which outputs character level embeddings for each word and alleviates the issue of out-of-vocabulary (OOV) words. In word embedding layer, we use a pretrained GloVe model (Pennington et al., 2014) and extract word-level embeddings[4]. The concatenation of the character and the word embeddings are then fed to a two-layer highway network (Srivastava et al., 2015) to obtain a contextual embedding for each word in the recipe. This results in the matrix $\mathbf{R}' \in \mathbb{R}^{2d \times N}$.

On top of these layers, we have another layer that encodes the steps of the recipe in an individual manner. Specifically, we obtain a step-level con-

[4]We also consider pretrained ELMo embeddings (Peters et al., 2018) in our experiments but found out that the performance gain does not justify the computational overhead.

textual embedding of the input recipe containing T steps as $\mathcal{S} = (\mathbf{s}_1, \mathbf{s}_2, \ldots, \mathbf{s}_T)$ where $\mathbf{s}_i$ represents the final state of a BiLSTM encoding the i-th step of the recipe obtained from the character and word-level embeddings of the tokens exist in the corresponding step.

We represent both the question $\mathbf{Q}$ and the answer $\mathbf{A}$ in terms of visual embeddings. Here, we employ a pretrained ResNet-50 model (He et al., 2016) trained on ImageNet dataset (Deng et al., 2009) and represent each image as a real-valued 2048-d vector using features from the penultimate average-pool layer. Then these embeddings are passed first to a multilayer perceptron (MLP) and then its outputs are fed to a BiLSTM. We then form a matrix $\mathbf{Q}' \in \mathbb{R}^{2d \times M}$ for the question by concatenating the cell states of the BiLSTM. For the visual ordering task, to represent the sequence of images in the answer with a single vector, we additionally use a BiLSTM and define the answering embedding by the summation of the cell states of the BiLSTM. Finally, for all tasks, these computations produce answer embeddings denoted by $\mathbf{a} \in \mathbb{R}^{2d \times 1}$.

3.2 Reasoning Module

As mentioned before, comprehending a cooking recipe is mostly about entities (basic ingredients) and actions (cooking activities) described in the recipe instructions. Each action leads to changes in the states of the entities, which usually affects their visual characteristics. A change rarely occurs in isolation; in most cases, the action affects multiple entities at once. Hence, in our reasoning module, we have an explicit memory component implemented with relational memory units (Santoro et al., 2018). This helps us to keep track of the entities, their state changes and their relations in relation to each other over the course of the recipe (see Fig. 3). As we will examine in more detail in Section 4, it also greatly improves the interpretability of model outputs.

Specifically, we set up the memory with a memory matrix $\mathbf{E} \in \mathbb{R}^{d_E \times K}$ by extracting K entities (ingredients) from the first step of the recipe[5]. We initialize each memory cell $\mathbf{e}_i$ representing a specific entity by its CharCNN and pre-trained GloVe embeddings[6]. From now on, we will use the terms memory cells and entities interchangeably throughout the paper. Since the input recipe is given in the form of a procedural text decomposed into a number of steps, we update the memory cells after each step, reflecting the state changes happened on the entities. This update procedure is modelled via a relational recurrent neural network (R-RNN), recently proposed by Santoro et al. (2018). It is built on a 2-dimensional LSTM model whose matrix of cell states represent our memory matrix $\mathbf{E}$. Here, each row i of the matrix $\mathbf{E}$ refers to a specific entity $\mathbf{e}_i$ and is updated after each recipe step t as follows:

$$\phi_{i,t} = \text{R-RNN}(\phi_{i,t-1}, \mathbf{s}_t) \tag{1}$$

where $\mathbf{s}_t$ denotes the embedding of recipe step t and $\phi_{i,t} = (\mathbf{h}_{i,t}, \mathbf{e}_{i,t})$ is the cell state of the R-RNN at step t with $\mathbf{h}_{i,t}$ and $\mathbf{e}_{i,t}$ being the i-th row of the hidden state of the R-RNN and the dynamic representation of entity $\mathbf{e}_i$ at the step t, respectively. The R-RNN model exploits a multi-headed self-attention mechanism (Vaswani et al., 2017) that allows memory cells to interact with each other and attend multiple locations simultaneously during the update phase.

In Fig. 3, we illustrate how this interaction takes place in our relational memory module by considering a sample cooking recipe and by presenting how the attention matrix changes throughout the recipe. In particular, the attention matrix at a specific time shows the attention flow from one entity (memory cell) to another along with the attention weights to the corresponding recipe step (offset column). The color intensity shows the magnitude of the attention weights. As can be seen from the figure, the internal representations of the entities are actively updated at each step. Moreover, as argued in (Santoro et al., 2018), this can be interpreted as a form of relational reasoning as each update on a specific memory cell is operated in relation to others. Here, we should note that it is often difficult to make sense of these attention weights. However, we observe that the attention matrix changes very gradually near the completion of the recipe.

3.3 Attention Module

Attention module is in charge of linking the question with the recipe text and the entities present in the recipe. It takes the matrices $\mathbf{Q}'$ and $\mathbf{R}'$ from the input module, and $\mathbf{E}$ from the reasoning module

[5]The first steps of the recipes in RecipeQA commonly contain a list of ingredients.

[6]Multi-word entities (*e.g. minced garlic*) are represented by the average embedding vector of the words that they contain, and OOV words are expressed with the average word vector of all the words.

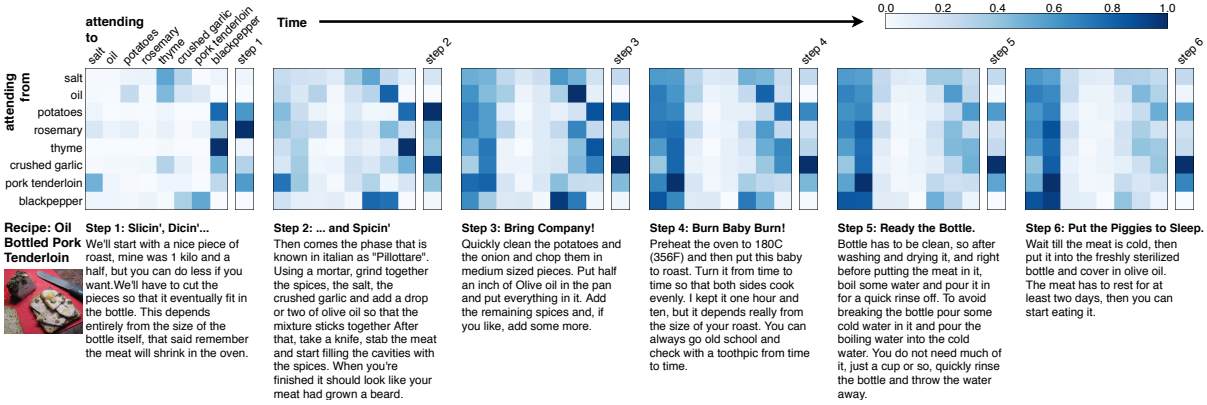

Figure 3: Sample visualizations of the self-attention weights demonstrating both the interactions among the ingredients and between the ingredients and the textual instructions throughout the steps of a sample cooking recipe from RecipeQA (darker colors imply higher attention weights). The attention maps do not change much after the third step as the steps after that mostly provide some redundant information about the completed recipe.

and constructs the question-aware recipe representation $\mathbf{G}$ and the question-aware entity representation $\mathbf{Y}$. Following the attention flow mechanism described in (Seo et al., 2017a), we specifically calculate attentions in four different directions: (1) from question to recipe, (2) from recipe to question, (3) from question to entities, and (4) from entities to question.

The first two of these attentions require computing a shared affinity matrix $\mathbf{S}^R \in \mathbb{R}^{N \times M}$ with $\mathbf{S}^R_{i,j}$ indicating the similarity between i-th recipe word and j-th image in the question estimated by

$$\mathbf{S}^R_{i,j} = \mathbf{w}_R^\top [\mathbf{R}'_i; \mathbf{Q}'_j; \mathbf{R}'_i \circ \mathbf{Q}'_j] \tag{2}$$

where $\mathbf{w}_R^\top$ is a trainable weight vector, $\circ$ and $[;]$ denote elementwise multiplication and concatenation operations, respectively.

Recipe-to-question attention determines the images within the question that is most relevant to each word of the recipe. Let $\tilde{\mathbf{Q}} \in \mathbb{R}^{2d \times N}$ represent the recipe-to-question attention matrix with its i-th column being given by $\tilde{\mathbf{Q}}_i = \sum_j \mathbf{a}_{ij} \mathbf{Q}'_j$ where the attention weight is computed by $\mathbf{a}_i = \mathrm{softmax}(\mathbf{S}^R_i) \in \mathbb{R}^M$.

Question-to-recipe attention signifies the words within the recipe that have the closest similarity to each image in the question, and construct an attended recipe vector given by $\tilde{\mathbf{r}} = \sum_i \mathbf{b}_i \mathbf{R}'_i$ with the attention weight is calculated by $\mathbf{b} = \mathrm{softmax}(\mathrm{max}_{col}(\mathbf{S}^R)) \in \mathbb{R}^N$ where max_{col} denotes the maximum function across the column. The question-to-recipe matrix is then obtained by replicating $\tilde{\mathbf{r}}$ N times across the column, giving $\tilde{\mathbf{R}} \in \mathbb{R}^{2d \times N}$.

Then, we construct the question aware representation of the input recipe, $\mathbf{G}$, with its i-th column $\mathbf{G}_i \in \mathbb{R}^{8d \times N}$ denoting the final embedding of i-th word given by

$$\mathbf{G}_i = [\mathbf{R}'_i; \tilde{\mathbf{Q}}_i; \mathbf{R}'_i \circ \tilde{\mathbf{Q}}_i; \mathbf{R}'_i \circ \tilde{\mathbf{R}}_i;] \ . \tag{3}$$

Attentions from question to entities, and from entities to question are computed in a way similar to the ones described above. The only difference is that it uses a different shared affinity matrix to be computed between the memory encoding entities $\mathbf{E}$ and the question $\mathbf{Q}'$. These attentions are then used to construct the question aware representation of entities, denoted by $\mathbf{Y}$, that links and integrates the images in the question and the entities in the input recipe.

3.4 Modeling Module

Modeling module takes the question-aware representations of the recipe $\mathbf{G}$ and the entities $\mathbf{Y}$, and forms their combined vector representation. For this purpose, we first use a two-layer BiLSTM to read the question-aware recipe $\mathbf{G}$ and to encode the interactions among the words conditioned on the question. For each direction of BiLSTM , we use its hidden state after reading the last token as its output. In the end, we obtain a vector embedding $\mathbf{c} \in \mathbb{R}^{2d \times 1}$. Similarly, we employ a second BiLSTM, this time, over the entities $\mathbf{Y}$, which results in another vector embedding $\mathbf{f} \in \mathbb{R}^{2d_E \times 1}$. Finally, these vector representations are concatenated and then projected to a fixed size representation using $\mathbf{o} = \varphi_o([\mathbf{c}; \mathbf{f}]) \in \mathbb{R}^{2d \times 1}$ where φ_o is a multilayer perceptron with $\tanh$ activation function.

3.5 Output Module

The output module takes the output of the modeling module, encoding vector embeddings of the question-aware recipe and the entities $\mathbf{Y}$, and the embedding of the answer $\mathbf{A}$, and returns a similarity score which is used while determining the correct answer. Among all the candidate answer, the one having the highest similarity score is chosen as the correct answer. To train our proposed procedural reasoning network, we employ a hinge ranking loss (Collobert et al., 2011), similar to the one used in (Yagcioglu et al., 2018), given below.

$$L = \max\{0, \gamma - \cos(\mathbf{o}, \mathbf{a}_+) + \cos(\mathbf{o}, \mathbf{a}_-)\} \quad (4)$$

where γ is the margin parameter, $\mathbf{a}_+$ and $\mathbf{a}_-$ are the correct and the incorrect answers, respectively.

4 Experiments

In this section, we describe our experimental setup and then analyze the results of the proposed Procedural Reasoning Networks (PRN) model.

4.1 Entity Extraction

Given a recipe, we automatically extract the entities from the initial step of a recipe by using a dictionary of ingredients. While determining the ingredients, we exploit Recipe1M (Marin et al., 2018) and Kaggle Whats Cooking Recipes (Yummly, 2015) datasets, and form our dictionary using the most commonly used ingredients in the training set of RecipeQA. For the cases when no entity can be extracted from the recipe automatically (20 recipes in total), we manually annotate those recipes with the related entities.

4.2 Training Details

In our experiments, we separately trained models on each task, as well as we investigated multi-task learning where a single model is trained to solve all these tasks at once. In total, the PRN architecture consists of ∼12M trainable parameters. We implemented our models in PyTorch (Paszke et al., 2017) using AllenNLP library (Gardner et al., 2018). We used Adam optimizer with a learning rate of 1e-4 with an early stopping criteria with the patience set to 10 indicating that the training procedure ends after 10 iterations if the performance would not improve. We considered a batch size of 32 due to our hardware constraints. In the multi-task setting, batches are sampled round-robin from all tasks, where each batch is solely composed of examples from one task. We performed our experiments on a system containing four NVIDIA GTX-1080Ti GPUs, and training a single model took around 2 hours. We employed the same hyperparameters for all the baseline systems. We plan to share our code and model implementation after the review process.

4.3 Baselines

We compare our model with several baseline models as described below. We note that the results of the first two are previously reported in (Yagcioglu et al., 2018).

Hasty Student (Yagcioglu et al., 2018) is a heuristics-based simple model which ignores the recipe and gives an answer by examining only the question and the answer set using distances in the visual feature space.

Impatient Reader (Hermann et al., 2015) is a simple neural model that takes its name from the fact that it repeatedly computes attention over the recipe after observing each image in the query.

BiDAF (Seo et al., 2017a) is a strong reading comprehension model that employs a bi-directional attention flow mechanism to obtain a question-aware representation and bases its predictions on this representation. Originally, it is a span-selection model from the input context. Here, we adapt it to work in a multimodal setting and answer multiple choice questions instead.

BiDAF w/ static memory is an extended version of the BiDAF model which resembles our proposed PRN model in that it includes a memory unit for the entities. However, it does not make any updates on the memory cells. That is, it uses the static entity embeeddings initialized with GloVe word vectors. We propose this baseline to test the significance of the use of relational memory updates.

4.4 Results

Table 1 presents the quantitative results for the visual reasoning tasks in RecipeQA. In single-task training setting, PRN gives state-of-the-art results compared to other neural models. Moreover, it achieves the best performance on average. These results demonstrate the importance of having a dynamic memory and keeping track of entities extracted from the recipe. In multi-task training set-

Impatient Reader	27.36	28.08	26.74	27.39	–	–	–	–
BIDAF	53.95	48.82	62.42	55.06	44.62	36.00	**63.93**	48.67
BIDAF w/ static memory	51.82	45.88	60.90	52.87	**47.81**	40.23	62.94	**50.59**
PRN	**56.31**	53.64	**62.77**	**57.57**	46.45	**40.58**	62.67	50.17

* Taken from the RecipeQA project website, based on 100 questions sampled randomly from the validation set.

Table 1: Quantitative comparison of the proposed PRN model against the baselines.

ting where a single model is trained to solve all the tasks at once, PRN and BIDAF w/ static memory perform comparably and give much better results than BIDAF. Note that the model performances in the multi-task training setting are worse than single-task performances. We believe that this is due to the nature of the tasks that some are more difficult than the others. We think that the performance could be improved by employing a carefully selected curriculum strategy (McCann et al., 2018).

In Fig. 4, we illustrate the entity embeddings space by projecting the learned embeddings from the step-by-step memory snapshots through time with t-SNE to 3-d space from 200-d vector space. Color codes denote the categories of the cooking recipes. As can be seen, these step-aware embeddings show clear clustering of these categories. Moreover, within each cluster, the entities are grouped together in terms of their state characteristics. For instance, in the zoomed parts of the figure, chopped and sliced, or stirred and whisked entities are placed close to each other.

Fig. 5 demonstrates the entity arithmetics using the learned embeddings from each entity step. Here, we show that the learned embedding from the memory snapshots can effectively capture the contextual information about the entities at each time point in the corresponding step while taking into account of the recipe data. This basic arithmetic operation suggests that the proposed model can successfully capture the semantics of each entity's state in the corresponding step[7].

5 Related Work

In recent years, tracking entities and their state changes have been explored in the literature from a variety of perspectives. In an early work, Henaff et al. (2017) proposed a dynamic memory based network which updates entity states using a gating mechanism while reading the text. Bansal et al. (2017) presented a more structured memory augmented model which employs memory slots for representing both entities and their relations. Pavez et al. (2018) suggested a conceptually similar model in which the pairwise relations between attended memories are utilized to encode the world

[7]We used Gensim for calculating entity arithmetics using cosine distances between entity embeddings.

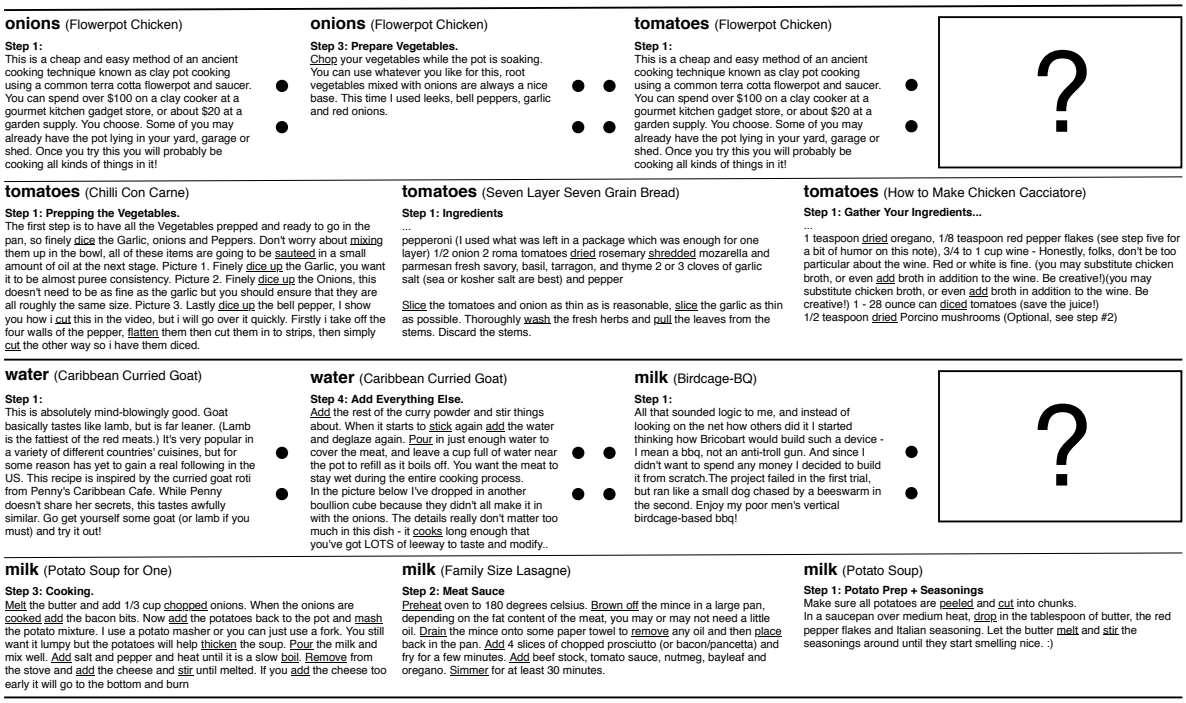

Figure 5: Step-aware entity representations can be used to discover the changes occurred in the states of the ingredients between two different recipe steps. The difference vector between two entities can then be added to other entities to find their next states. For instance, in the first example, the difference vector encodes the chopping action done on onions. In the second example, it encodes the pouring action done on the water. When these vectors are added to the representations of raw tomatoes and milk, the three most likely next states capture the semantics of state changes in an accurate manner.

state. The main difference between our approach and these works is that by utilizing relational memory core units we also allow memories to interact with each other during each update.

Perez and Liu (2017) showed that similar ideas can be used to compile supporting memories in tracking dialogue state. Wang et al. (2017) has shown the importance of coreference signals for reading comprehension task. More recently, Dhingra et al. (2018) introduced a specialized recurrent layer which uses coreference annotations for improving reading comprehension tasks. On language modeling task, Ji et al. (2017) proposed a language model which can explicitly incorporate entities while dynamically updating their representations for a variety of tasks such as language modeling, coreference resolution, and entity prediction.

Our work builds upon and contributes to the growing literature on tracking states changes in procedural text. Bosselut et al. (2018) presented a neural model that can learn to explicitly predict state changes of ingredients at different points in a cooking recipe. Dalvi et al. (2018) proposed another entity-aware model to track entity states in scientific processes. Tandon et al. (2018) demonstrated that the prediction quality can be boosted by including hard and soft constraints to eliminate unlikely or favor probable state changes. In a follow-up work, Du et al. (2019) exploited the notion of label consistency in training to enforce similar predictions in similar procedural contexts. Das et al. (2019) proposed a model that dynamically constructs a knowledge graph while reading the procedural text to track the ever-changing entities states. As discussed in the introduction, however, these previous methods use a strong inductive bias and assume that state labels are present during training. In our study, we deliberately focus on unlabeled procedural data and ask the question: Can multimodality help to identify and provide insights to understanding state changes.

6 Conclusion

We have presented a new neural architecture called Procedural Reasoning Networks (PRN) for multimodal understanding of step-by-step instructions. Our proposed model is based on the successful BiDAF framework but also equipped with an explicit memory unit that provides an implicit mecha-

nism to keep track of the changes in the states of the entities over the course of the procedure. Our experimental analysis on visual reasoning tasks in the RecipeQA dataset shows that the model significantly improves the results of the previous models, indicating that it better understands the procedural text and the accompanying images. Additionally, we carefully analyze our results and find that our approach learns meaningful dynamic representations of entities without any entity-level supervision. Although we achieve state-of-the-art results on RecipeQA, clearly there is still room for improvement compared to human performance. We also believe that the PRN architecture will be of value to other visual and textual sequential reasoning tasks.

Abstract

One of the goals of natural language understanding is to develop models that map sentences into meaning representations. However, training such models requires expensive annotation of complex structures, which hinders their adoption. Learning to actively-learn (LTAL) is a recent paradigm for reducing the amount of labeled data by learning a policy that selects which samples should be labeled. In this work, we examine LTAL for learning semantic representations, such as QA-SRL. We show that even an *oracle* policy that is allowed to pick examples that maximize performance on the test set (and constitutes an upper bound on the potential of LTAL), does not substantially improve performance compared to a *random* policy. We investigate factors that could explain this finding and show that a distinguishing characteristic of successful applications of LTAL is the interaction between optimization and the oracle policy selection process. In successful applications of LTAL, the examples selected by the oracle policy do not substantially depend on the optimization procedure, while in our setup the stochastic nature of optimization strongly affects the examples selected by the oracle. We conclude that the current applicability of LTAL for improving data efficiency in learning semantic meaning representations is limited.

1 Introduction

The task of mapping a natural language sentence into a *semantic representation*, that is, a structure that represents its meaning, is one of the core goals of natural language processing. This goal has led to the creation of many general-purpose formalisms for representing the structure of language, such as semantic role labeling (SRL; Palmer et al., 2005), semantic dependencies (SDP; Oepen et al., 2014), abstract meaning representation (AMR; Banarescu et al., 2013), universal conceptual cognitive annotation (UCCA; Abend and Rappoport, 2013), question-answer driven SRL (QA-SRL; He et al., 2015), and universal dependencies (Nivre et al., 2016), as well as domain-specific semantic representations for particular users in fields such as biology (Kim et al., 2009; Nédellec et al., 2013; Berant et al., 2014) and material science (Mysore et al., 2017; Kim et al., 2019).

Currently, the dominant paradigm for building models that predict such representations is supervised learning, which requires annotating thousands of sentences with their correct structured representation, usually by experts. This arduous data collection is the main bottleneck for building parsers for different users in new domains.

Past work has proposed directions for accelerating data collection and improving data efficiency through multi-task learning across different representations (Stanovsky and Dagan, 2018; Hershcovich et al., 2018), or having non-experts annotate sentences in natural language (He et al., 2015, 2016). One of the classic and natural solutions for reducing annotation costs is to use *active learning*, an iterative procedure for selecting unlabeled examples which are most likely to improve the performance of a model, and annotating them (Settles, 2009).

Recently, learning to actively-learn (LTAL) has been proposed (Fang et al., 2017; Bachman et al., 2017; Liu et al., 2018), where the procedure for selecting unlabeled examples is *trained* using methods from reinforcement and imitation learning. In recent work by Liu et al. (2018), given a labeled dataset from some domain, active learning is simulated on this dataset, and a policy is trained to iteratively select the subset of examples that maximizes performance on a development set. Then, this policy is used on a target domain to select unlabeled examples for annotation. If the learned

Proceedings of the 23rd Conference on Computational Natural Language Learning, pages 452–462
Hong Kong, China, November 3-4, 2019. ©2019 Association for Computational Linguistics

policy generalizes well, we can reduce the cost of learning semantic representations. Liu et al. (2018) and Vu et al. (2019) have shown that such learned policies significantly reduce annotation costs on both text classification and named entity recognition (NER).

In this paper, we examine the potential of LTAL for learning a semantic representation such as QA-SRL. We propose an *oracle setup* that can be considered as an upper bound to what can be achieved with a learned policy. Specifically, we use an *oracle policy* that is allowed to always pick a subset of examples that maximizes its target metric on a development set, which has the same distribution as the *test set*. Surprisingly, we find that even this powerful oracle policy does not substantially improve performance compared to a policy that randomly selects unlabeled examples on two semantic tasks: QA-SRL span (argument) detection and QA-SRL question (role) generation.

To elucidate this surprising finding, we perform a thorough analysis, investigating various factors that could negatively affect the oracle policy selection process. We examine possible explanatory factors including: (a) the search strategy in the unlabeled data space (b) the procedure for training the QA-SRL model (c) the architecture of the model and (d) the greedy nature of the selection procedure. We find that for all factors, it is challenging to get consistent gains with an oracle policy over a random policy.

To further our understanding, we replicate the experiments of Liu et al. (2018) on NER, and compare the properties of a successful oracle policy in NER to the less successful case of QA-SRL. We find that optimization stochasticity negatively affects the process of sample selection in QA-SRL; different random seeds for the optimizer result in different selected samples. We propose a measure for quantifying this effect, which can be used to assess the potential of LTAL in new setups.

To conclude, in this work, we conduct a thorough empirical investigation of LTAL for learning a semantic representation, and find that it is difficult to substantially improve data efficiency compared to standard supervised learning. Thus, other approaches should be explored for the important goal of reducing annotation costs in building such models. Code for reproducing our experiments is available at https://github.com/koomri/LTAL_SR/.

2 Learning to Actively Learn

Classic pool-based active learning (Settles, 2009) assumes access to a small labeled dataset $\mathcal{S}_{\text{lab}}$ and a large pool of unlabeled examples $\mathcal{S}_{\text{unlab}}$ for a target task. In each iteration, a heuristic is used to select L unlabeled examples, which are sent to annotation and added to $\mathcal{S}_{\text{lab}}$. An example heuristic is *uncertainty sampling* (Lewis and Gale, 1994), which at each iteration chooses examples that the current model is the least confident about.

LTAL proposes to replace the heuristic with a learned policy π_θ, parameterized by θ. At *training time*, the policy is trained by simulating active learning on a labeled dataset and generating training data from the simulation. At *test time*, the policy is applied to select examples in a new domain. Figure 1 and Algorithm 1 describe this data collection procedure, on which we build our *oracle policy* (§3).

In LTAL, we assume a labeled dataset $\mathcal{D}$ which is partitioned into three disjoint sets: a small labeled set $\mathcal{S}_{\text{lab}}$, a large set $\mathcal{S}_{\text{unlab}}$ that will be treated as unlabeled, and an evaluation set $\mathcal{S}_{\text{eval}}$ that will be used to estimate the quality of models. Then, active learning is simulated for B iterations. In each iteration i, a model m^i_ϕ, parameterized by ϕ, is first trained on the labeled dataset. Then, K subsets $\{\mathcal{C}_j\}_{j=1}^K$ are randomly sampled from $\mathcal{S}_{\text{unlab}}$, and the model m^i_ϕ is fine-tuned on each candidate set, producing K models $\{m^i_{\phi_j}\}_{j=1}^K$. The performance of each model is evaluated on $\mathcal{S}_{\text{eval}}$, yielding the scores $\{s(\mathcal{C}_j)\}_{j=1}^K$. Let the candidate set with highest accuracy be $\mathcal{C}^i_t$. We can create training examples for π_θ, where $(\mathcal{S}_{\text{lab}}, \mathcal{S}_{\text{unlab}}, m^i_\phi, \{s(\mathcal{C}_j)\}_{j=1}^K)$ are the inputs and $\mathcal{C}^i_t$ is the label. Then $\mathcal{C}^i_t$ is moved from $\mathcal{S}_{\text{unlab}}$ to $\mathcal{S}_{\text{lab}}$.

Simulating active learning is a computationally expensive procedure. In each iteration we need to train K models over $\mathcal{S}_{\text{lab}} \cup \mathcal{C}_j$. However, a trained network can potentially lead to a policy that is better than standard active learning heuristics.

3 An Oracle Active Learning Policy

Our goal is to examine the potential of LTAL for learning a semantic representation such as QA-SRL. Towards this goal, we investigate an *oracle policy* that should be an upper bound for what can be achieved with a learned policy π_θ.

The oracle policy is allowed to use Algorithm 1

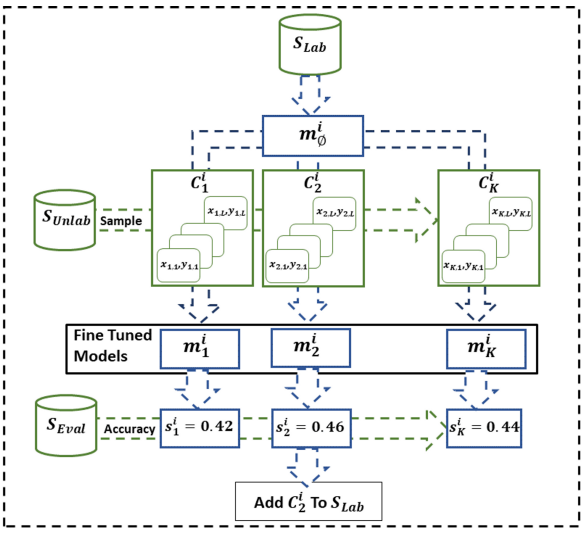

Figure 1: A single iteration of LTAL, where examples are sampled from $\mathcal{S}_{\text{unlab}}$, trained with examples in $\mathcal{S}_{\text{lab}}$, and performance on $\mathcal{S}_{\text{eval}}$ is used to select examples to annotate. See §2 for details.

Algorithm 1: Simulating active learning

Input: $\mathcal{S}_{\text{lab}}, \mathcal{S}_{\text{unlab}}, \mathcal{S}_{\text{eval}}$

1 **for** $i \in \{1 \dots B\}$ **do**
2 $\quad m^i_\phi \leftarrow \text{Train}(\mathcal{S}_{\text{lab}})$
3 $\quad \mathcal{C}^i_1, \dots, \mathcal{C}^i_K = \text{SampleCandidates}(\mathcal{S}_{\text{unlab}})$
4 $\quad$ **for** $j \in \{1, \dots, K\}$ **do**
5 $\quad\quad m^i_{\phi_j} \leftarrow \text{FineTune}(m^i_\phi, \mathcal{S}_{\text{lab}} \cup \mathcal{C}^i_j)$
6 $\quad\quad s^i_j \leftarrow \text{Accuracy}(m^i_{\phi_j}, \mathcal{S}_{\text{eval}})$
7 $\quad t \leftarrow \underset{j \in \{1,\dots,K\}}{\text{argmax}}\ s^i_j$
8 $\quad \text{CreateTrainEx}((\mathcal{S}_{\text{lab}}, \mathcal{S}_{\text{unlab}}, m^i_\phi, \{\mathcal{C}^i_j\}^K_{j=1}), \mathcal{C}^i_t)$
9 $\quad \mathcal{S}_{\text{lab}} \leftarrow \mathcal{S}_{\text{lab}} \cup \mathcal{C}^i_t, \mathcal{S}_{\text{unlab}} \leftarrow \mathcal{S}_{\text{unlab}} \setminus \mathcal{C}^i_t$
10 **return** $\mathcal{S}_{\text{lab}}$

at test time (it does not create training examples for π_θ, thus Line 8 is skipped). Put differently, the oracle policy selects the set of unlabeled examples that maximizes the target metric of our model on a set sampled from the *same distribution* as the test set. Therefore, the oracle policy enjoys extremely favorable conditions compared to a trained policy, and we expect it to provide an upper bound on the performance of π_θ. Despite these clear advantages, we will show that an oracle policy struggles to substantially improve performance compared to a random policy.

While the oracle policy effectively "peeks" at the label to make a decision, there are various factors that could explain the low performance of a model trained under the oracle policy. We now list several hypotheses, and in §5.4 and §6 methodologically examine whether they explain the empirical results of LTAL.

- **Training**: The models $m^i_{\phi_j}$ are affected by the training procedure in Lines 2 and 5 of Alg. 1. Different training procedures affect the performance of models trained with the oracle policy.
- **Search space coverage**: Training over all unlabeled examples in each iteration is intractable, so the oracle policy randomly samples K subsets, each with L examples. Because $K \cdot L << |\mathcal{S}_{\text{unlab}}|$, it is possible that randomly sampling these sets will miss the more beneficial unlabeled examples. Moreover, the parameter L controls the diversity of candidate subsets, since as L increases the similarity between the K different subsets grows. Thus, the hyper-parameters K and L might affect the outcome of the oracle policy.
- **Model architecture**: The model architecture (e.g., number of parameters) can affect the efficacy of learning under the oracle policy.
- **Stochasticity:** The oracle policy chooses an unlabeled set based on performance after training with stochastic gradient descent. Differences in performance between candidate sets might be related to this stochasticity, rather than to the actual value of the examples (especially when $\mathcal{S}_{\text{lab}}$ is small).
- **Myopicity:** The oracle policy chooses the set $\mathcal{C}^i_j$ that maximizes its performance. However, the success of LTAL depends on the *sequence* of choices that are made. It is possible that the greedy nature of this procedure results in suboptimal performance. Unfortunately, improving search through beam search or similar measures is intractable in this already computationally-expensive procedure.

We now describe QA-SRL (He et al., 2015), which is the focus of our investigation, and then describe the experiments with the oracle policy.

4 QA-SRL Schema

QA-SRL was introduced by He et al. (2015) as an open variant of the predefined role schema in traditional SRL. QA-SRL replaces the predefined set of *roles* with the notion of *argument questions*. These are natural language questions centered around a target predicate, where the answers to the given question are its corresponding arguments. For example, for the sentence *"Elizabeth Warren decided to **run** for president"*, traditional SRL will label *"Elizabeth Warren"* as `ARG0` of the **run** predicate (the agent of the predicate, or the entity running in this case), while QA-SRL

*Elizabeth Warren **announced** her candidacy at a rally in Massachusetts.*

Argument	QA-SRL role	PropBank role
Elizabeth Warren	Who **announced** something?	ARG0
her candidacy	What did someone **announce**?	ARG1
at a rally in Massachusetts	Where did someone **announce** something?	ARGM-LOC

Table 1: Example of QA-SRL versus traditional SRL annotation for a given input sentence (top). Each line shows a single argument, and its role in QA-SRL (in question form) followed by its traditional SRL role, using PropBank notation. Roles in QA-SRL have a structured open representation, while SRL assigns discrete roles from a predefined set.

will assign the more subtle question *"who might run?"*, indicating the uncertainty of this future event. Questions are generated by assigning values to 7 pre-defined slots (where some of the slots are potentially empty). See Table 1 for an example QA-SRL annotation of a full sentence.

Recently, FitzGerald et al. (2018) demonstrated the scalability of QA-SRL by crowdsourcing the annotation of a large QA-SRL dataset, dubbed QA-SRL bank 2.0. It consists of 250K QA pairs over 64K sentences on three different domains (Wikipedia, news, and science). Following, this large dataset has enabled the development a neural model which breaks QA-SRL into a pipeline of two tasks, given a target predicate in an input sentence. First, a *span detection* algorithm identifies arguments of the predicate as continuous spans in the sentence (e.g., *"Elizabeth Warren"* in the previous example), then a *question generation* model predicts an appropriate role question (e.g., *"who might run?"*).

We find that QA-SRL is a good test-bed for active learning of semantic representations, for several key reasons: (1) it requires semantic understanding of the sentence, beyond syntactic or surface-level features (e.g., identifying the factuality of a given predicate), (2) adopting the formulation of FitzGerald et al. (2018), it consists of two semantic tasks, allowing us to test active learning on both of them, (3) we can leverage the large QA-SRL dataset to simulate active learning scenarios, and lastly (4) QA-SRL's scalability is attractive for the application of active learning policies, as they may further reduce costs for researchers working on developing specialized semantic representations in low-resource domains (e.g., medical, biological, or educational domains).

5 Experimental Evaluation

We now perform a series of experiments comparing the performance of an oracle policy to a random policy. We describe the experimental settings (§5.1), tasks and models (§5.2), present the main results (§5.3), and conclude by investigating factors that might affect our empirical findings (§5.4).

5.1 Experimental Settings

We evaluate the potential of the oracle policy on QA-SRL Bank 2.0 (FitzGerald et al., 2018). We use the training set of the *science* domain as $\mathcal{D}$, randomly split it into $\mathcal{S}_{\text{lab}}$, $\mathcal{S}_{\text{unlab}}$, and $\mathcal{S}_{\text{eval}}$. We evaluate the success of a model m^i_ϕ trained with the oracle policy by periodically measuring performance on the development set of the *science* domain. Unless mentioned, all results are an average of 3 experiments, where a different split of $\mathcal{D}$ was performed. Each experiment used K threads of a 40-core 2.2GHz Xeon Silver 4114 machine.

We compare the results of a base oracle policy (BASEORACLE) corresponding to the best policy we were able to obtain using the architecture from FitzGerald et al. (2018) to the following baselines:

- RANDOM: One of the candidate sets $\mathcal{C}^i_j$ is chosen at random and added to $\mathcal{S}_{\text{lab}}$.
- LONGEST: The set $\mathcal{C}^i_j$ with the maximal average number of tokens per sentence is added to $\mathcal{S}_{\text{lab}}$.
- UNCERTAINTY: For each candidate set, we use m^i_ϕ to perform predictions over all of the sentences in the set, and choose the set $\mathcal{C}^i_j$ that has the maximal average entropy over the set of predictions.

5.2 Tasks and Models

We now describe the three tasks and corresponding models in our analysis:

Span Detection: Here we detect spans that are arguments of a predicate in a sentence (see Table 1). We start with a labeled set of size $|\mathcal{S}_{\text{lab}}| = 50$, and select examples with the oracle policy for $B = 460$ iterations. We set the number of candidate sets to $K = 5$, and the size of each set to $L = 1$,

thus the size of the final labeled set is 510 examples. We train the publicly available span detection model released by FitzGerald et al. (2018), which consumes as input a sentence $x_1, \ldots, x_n$, where x_i is the concatenation of the embedding of the ith word in the sentence and a learned embedding of a binary indicator for whether this word is the target predicate. This input is fed into a multi-layer encoder, producing a representation h_i for every token. Each span $x_{i:j}$ is represented by concatenating the respective hidden states: $s_{ij} = [h_i; h_j]$. A fully connected network consumes the span representation s_{ij}, and predicts a probability whether the span is an argument or not.

To accelerate training, we reduce the number of parameters to 488K by freezing the token embeddings, reducing the number of layers in the encoder, and by shrinking the dimension of both the hidden representations and the binary predicate indicator embedding. Following FitzGerald et al. (2018), we use GLoVe embeddings (Pennington et al., 2014).

Question Generation: We generate the question (role) for a given predicate and corresponding argument. We start with a labeled set of size $|\mathcal{S}_{\text{lab}}| = 500$ and perform $B = 250$ iterations, where in each iteration we sample $K = 5$ candidate sets each of size $L = 10$ (lower values were intractable). Thus, the final size of $\mathcal{S}_{\text{lab}}$ is 3,000 samples. We train the publicly available *local* question generation model from FitzGerald et al. (2018), where the learned argument representation s_{ij} is used to independently predict each of the 7 question slots. We reduce the number of parameters to 360K with the same modifications as in the span detector model. As a metric for the quality of question generation models, we use its official metric exact match (EM), which reflects the percentage of predicted questions that are identical to the ground truth questions.

Named Entity Recognition: To reproduce the experiments of Liu et al. (2018) we run the oracle policy on the CoNLL-2003 NER English dataset (Sang and De Meulder, 2003), replicating the experimental settings described in Liu et al. (2018) (as their code is not publicly available). We run the oracle policy for $B = 200$ iterations, starting from an empty $\mathcal{S}_{\text{lab}}$, and adding one example ($L = 1$) from $K = 5$ candidate sets in each iteration. We use a CRF sequence tagger from AllenNLP (Gardner et al., 2018), and experiment with two variants: (1) NER-MULTILANG: A BiLSTM CRF model (20K parameters) with 40 dimensional multi-lingual word embeddings (Ammar et al., 2016), and (2) NER-LINEAR: A linear CRF model which was originally used by Liu et al. (2018).

5.3 Results

Span Detection: Table 2 shows F_1 score (the official metric) of the QA-SRL span detector models for different sizes of $\mathcal{S}_{\text{lab}}$ for BASEORACLE and the other baselines. Figure 2 (left) shows the relative improvement of the baselines over RANDOM. We observe that the maximal improvement of BASEORACLE over RANDOM is 9% given 200 examples, but with larger $\mathcal{S}_{\text{lab}}$ the improvement drops to less than 5%. This is substantially less than the improvements obtained by Liu et al. (2018) on text classification and NER. Moreover, LONGEST outperforms BASEORACLE in most of the observed results. This shows that there exists a selection strategy that is better than BASEORACLE, but it is not the one chosen by the oracle policy.

Question Generation: To check whether the previous result is specific to span detection, we conduct the same experiment for question generation. However, training question generation models is slower compared to span detection and thus we explore a smaller space of hyper-parameters. Table 3 reports the EM scores achieved by BASEORACLE and LONGEST, and Figure 2 (center) shows the relative improvement. Here, the performance of BASEORACLE is even worse compared to span detection, as its maximal relative improvement over RANDOM is at most 5%.

Named Entity Recognition: Figure 2 (right) shows the relative improvement of NER-LINEAR and NER-MULTILANG compared to RANDOM. We observe that in NER-LINEAR, which is a replication of Liu et al. (2018), the oracle policy indeed obtains a large improvement over RANDOM for various sizes of $\mathcal{S}_{\text{lab}}$, with at least 9.5% relative improvement in performance. However, in NER-MULTILANG the relative gains are smaller, especially when the size of $\mathcal{S}_{\text{lab}}$ is small.

5.4 Extended Experiments

Surprisingly, we observed in §5.3 that even an oracle policy, which is allowed to pick the examples

# samples	100	150	200	250	300	350	400	450	500
BASEORACLE	42.7	**49.2**	52.9	54.2	**56.6**	**57.4**	58.4	**59.5**	59.9
RANDOM	42.8	47.2	48.3	52.4	53.3	56.1	57.0	57.5	58.5
LONGEST	**44.1**	49.1	**53.0**	**55.5**	56.4	**57.4**	**58.7**	58.6	**60.0**
UNCERTAINTY	42.8	47.0	50.1	51.3	52.2	54.4	55.1	55.6	56.9

Table 2: Span detection F_1 on the development set for all models across different numbers of labeled examples.

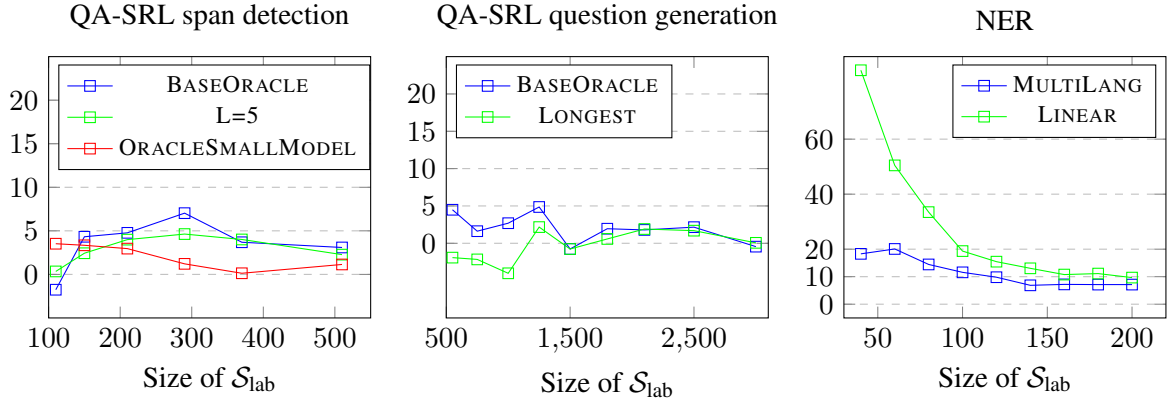

Figure 2: Relative improvement (in %) of different models compared to RANDOM on the development set. Note that the range of the y-axis in NER is different from QA-SRL.

that maximize performance on samples from the same distribution as the test set, does not substantially improve performance over a random policy. One possibility is that no active learning policy is better than random. However, LONGEST outperformed BASEORACLE showing that the problem is at least partially related to BASEORACLE itself.

We now examine the possible factors described in §3 and investigate their interaction with the performance of models trained with BASEORACLE. All modifications were tested on *span detection*, using the experimental settings described in §5.1.

Search space coverage We begin by examining the effect of the parameters K and L on the oracle policy. As K increases, we cover more of the unlabeled data, but training time increases linearly. As L increases, the subsets $\{\mathcal{C}_j\}_{j=1}^{K}$ become more similar to one another due to the fact that we are randomly mixing more examples from the unlabeled data. On the other hand, when L is small, the fine-tuning process is less affected by the candidate sets and more by $\mathcal{S}_{\text{lab}}$. In such case, it is likely that the difference in scores is also affected by stochasticity.

BASEORACLE uses $K = 5, L = 1$. We examine the performance of the oracle policy as these values are increased in Table 4. We observe that performance does not improve, and perhaps even decreases for larger values of K. We hypothesize that a large K increases the greediness of the procedure, and may result in selecting an example that seems promising in the current iteration but is suboptimal in the long run, similar to large beam sizes reducing performance in neural machine translation (Yang et al., 2018). A moderate K results in a more random and possibly beneficial selection.

Increasing the size of each candidate set to $L = 5$ or 20 results in roughly similar performance to $L = 1$. We hypothesize that there is a trade-off where as L increases the similarity between the different sets increases but training becomes more stable and vice versa, and thus performance for different L values does not vary substantially.

Training In Lines 2 and 5 of Alg. 1 we train on $\mathcal{S}_{\text{lab}}$ and then fine-tune on the union $\mathcal{S}_{\text{lab}} \cup \mathcal{C}_j^i$ until s_j^i does not significantly improve for 5 epochs. It is possible that fine-tuning from a fixed model reduces the efficacy of training, and training on $\mathcal{S}_{\text{lab}} \cup \mathcal{C}_j^i$ from random weights will improve performance. Of course, training from scratch will substantially increase training time. We run an experiment, termed INDEP., where Line 2 is skipped, and in Line 5 we independently train each of the candidate models from random weights. We find that this modification does not achieve better results than BASEORACLE, possibly because training a model from scratch for each of the candidates increases the stochasticity in the optimization.

# samples	550	750	1000	1250	1500	1800	2100	2500	3000

ORACLESMALLMODEL	53.8	56.6	58.9	60.3	61.5	63.3

Table 4: Span detection F_1 scores on the development set for different size of $\mathcal{S}_{\text{lab}}$. We highlight the best performing policy for the standard span detector architecture. (*) indicates that the results are for a single run.

In addition, we also experiment with fine-tuning on $\mathcal{C}_j$ only, rather than $\mathcal{S}_{\text{lab}} \cup \mathcal{C}_j$. As we expect, results are quite poor since the model uses only a few examples for fine-tuning and forgets the examples in the labeled set.

Lastly, we hypothesize that selecting a candidate set based on the target metric (F_1 for span detection) might not be sensitive enough and thus we run an experiment, termed LOSS-SCORE, where we select the set $\mathcal{C}_j$ that minimizes the loss on the development set. We find that this modification achieves lower results than RANDOM, especially when $\mathcal{S}_{\text{lab}}$ is small, reflecting the fact that the loss is not perfectly correlated with our target metric.

Model Architecture In §5.3 we observed that results on NER vary with the model architecture. To see whether this phenomenon occurs also for span detection we perform a modification to the model – we reduce the number of parameters from 488K to 26K by reducing the hidden state size and replacing GLoVe embeddings with multi-lingual embeddings (Ammar et al., 2016). We then compare an oracle policy (ORACLESMALLMODEL) with a random policy (RANDOMSMALLMODEL). Table 4 shows that while absolute F_1 actually improves in this setup, the oracle policy improves performance compared to a random policy by no more than 4%. Thus, contrary to NER, here architecture modifications do not expose an advantage of the oracle policy compared to the random one. We did not examine a simpler linear model for span detection, in light of recent findings (Lowell et al., 2019) that it is important to test LTAL with state-of-the-art models, as performance is tied to the specific model being trained.

Myopicity We hypothesized that greedily selecting an example that maximizes performance in a specific iteration might be suboptimal in the long run. Because non-greedy selection strategies are computationaly intractable, we perform the following two experiments.

First, we examine EPSILON-GREEDY-P, where in each iteration the oracle policy selects the set $\mathcal{C}_j$ that maximizes target performance with probability $1 - p$ and randomly chooses a set with probability p. This is meant to check whether adding random exploration to the oracle policy might prevent it from getting stuck in local optima. We find that when $p = 0.3$ its performance is comparable to BASEORACLE while reducing the computational costs.

Second, we observe that most of the gain of BASEORACLE compared to RANDOM is in the beginning of the procedure. Thus, we propose to use BASEORACLE in the first b iterations, and then transition to a random policy (termed ORACLE-B). We run this variation with $b = 100$ and find that it leads to similar performance.

To summarize, we have found that an oracle policy only slightly improves performance for QA-SRL span detection and question generation compared to a random policy, and that improvements in NER are also conditioned on the underlying model. Our results echo recent findings by Lowell et al. (2019), who have shown that gains achieved by active learning are small and inconsistent when modifying the model architecture.

We have examined multiple factors that might affect the performance of models trained with an oracle policy including the training procedure, model architecture, and search procedure, and have shown that in all of them the oracle policy

struggles to improve over the random one. Thus, a *learned policy* is even less likely to obtain meaningful gains using LTAL.

In the next section we analyze the differences between NER-LINEAR, where LTAL works well, and BASEORACLE, in order to better understand the underlying causes for this phenomenon.

6 When does LTAL Work?

A basic underlying assumption of active learning (with or without a learned policy), is that some samples in $\mathcal{S}_{\text{unlab}}$ are more informative for the learning process than others. In LTAL, the informativeness of a candidate example set is defined by the accuracy of a trained model, as evaluated on $\mathcal{S}_{\text{eval}}$ (Line 6 in Alg. 1). Thus, for active learning to work, the candidate set that is selected should not be affected by the stochasticity of the training process. Put differently, the ranking of the candidate sets by the oracle policy should be *consistent* and not be dramatically affected by the optimization.

To operationalize this intuition, we use Alg. 1, but run the for-loop in Line 4 twice, using two different random seeds. Let $\mathcal{C}_t^i$ be the chosen or *reference* candidate set according to the first run of the for-loop in iteration i. We can measure the consistency of the optimization process by looking at the ranking of the candidate sets $\mathcal{C}_1^i, \ldots \mathcal{C}_K^i$ according to the second fine-tuning, and computing the mean reciprocal rank (MRR) with respect to the reference candidate set $\mathcal{C}_t^i$ across all iterations:

$$\text{MRR} = \frac{1}{B}\sum_{i=1}^{B}\frac{1}{\text{rank}(\mathcal{C}_t^i)}, \qquad (1)$$

where $\text{rank}(\mathcal{C}_t^i)$ is the rank of $\mathcal{C}_t^i$ in the second fine tuning step. The only difference between the two fine-tuning procedures is the random seed. Therefore, an MRR value that is close to 1 means that the ranking of the candidates is mostly affected by the quality of the samples, while a small MRR hints that optimization plays a large role. We prefer MRR to other correlation-based measures (such as Spearman's rank-order correlation), because the oracle is only affected by the candidate set that is ranked first. We can now examine whether the MRR score correlates with whether LTAL works or not.

We measure the MRR in 3 settings: (1) NER-LINEAR, a linear CRF model for NER which replicates the experimental settings in (Liu et al., 2018), where LTAL works, (2) NER-MULTILANG, a BiLSTM-CRF sequence tagger from AllenNLP (Gardner et al., 2018) with 40 dimensional multi-lingual word embeddings of Ammar et al. (2016), and (3) BASEORACLE, the baseline model for span detection task. In all experiments the initial $\mathcal{S}_{\text{lab}}$ was empty and $B = 200$, following the experimental settings in which LTAL has shown good performance (Liu et al., 2018; Fang et al., 2017; Vu et al., 2019). Since the MRR might change as the size of $\mathcal{S}_{\text{lab}}$ is increasing, we compute and report MRR every 10 iterations.

Figure 3 (left) presents the MRR in the three experiments. We observe that in NER-LINEAR the MRR has a stable value of 1, while in NER-MULTILANG and BASEORACLE the MRR value is substantially lower, and closer to an MRR value of a random selection (~.46). The right side of Figure 3 shows that NER-LINEAR oracle policy outperforms a random policy by a much larger margin, compared to the other 2 experiments.

These results show that the ranking in NER-LINEAR is not affected by the stochasticity of optimization, which is expected given its underlying convex loss function. On the other hand, the optimization process in the other experiments is over a non-convex loss function and a small $\mathcal{S}_{\text{lab}}$, and thus optimization is more brittle. Interestingly, we observe in Figure 3 that the gains of the oracle policy in NER-LINEAR are higher than NER-MULTILANG, although the task and the dataset are exactly same in the two experiments. This shows that the potential of LTAL is affected by the model, where a more complex model leads to smaller gains by LTAL.

We view our findings as a guideline for future work: by tracking the MRR one can assess the potential of LTAL at development time – when the MRR is small, the potential is limited.

7 Related Work

Active learning has shown promising results on various tasks. The commonly used *uncertainty* criteria (Lewis and Catlett, 1994; Culotta and McCallum, 2005) is focused on selecting the samples on which the confidence of the model is low. Among other notable approaches, in *query by committee* (Seung et al., 1992) a disagreement between a set of trained models on the prediction of an example is used to select what samples to label.

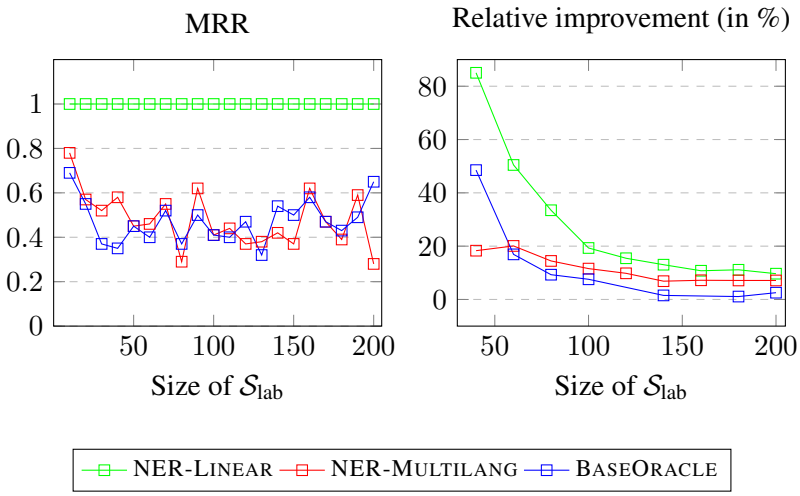

Figure 3: MRR (on the left) and relative improvement (in %) of different models compared to RANDOM on the development set.

In a large empirical study, Lowell et al. (2019) have recently shown other limitations in active learning. They investigate the performance of active learning across NLP tasks and model architectures, and demonstrate that it does not achieve consistent gains over supervised learning, mostly because the collected samples are beneficial to a specific model architecture, and does not yield better results than random selection when switching to a new architecture.

There has been little research regarding active learning of semantic representations. Among the relevant work, Siddhant and Lipton (2018) have shown that *uncertainty* estimation using dropout and Bayes-By-Backprop (Blundell et al., 2015) achieves good results on the SRL formulation. The improvements in performance due to LTAL approaches on various tasks (Konyushkova et al., 2017; Bachman et al., 2017; Fang et al., 2017; Liu et al., 2018) has raised the question whether learned policies can be applied also to the field of learning semantic representations.

8 Conclusions

We presented the first experimentation with LTAL techniques in learning parsers for semantic representations. Surprisingly, we find that LTAL, a learned method which was shown to be effective for NER and document classification, does not do significantly better than a random selection on two semantic representation tasks within the QA-SRL framework, even when given extremely favourable conditions. We thoroughly analyze the factors leading to this poor performance, and find that the stochasticity in the model optimization negatively affects the performance of LTAL. Finally, we propose a metric which can serve as an indicator for whether LTAL will fare well for a given dataset and model. Our results suggest that different approaches should be explored for the important task of building semantic representation models.

How does Grammatical Gender Affect Noun Representations in Gender-Marking Languages?

Abstract

Many natural languages assign grammatical gender also to inanimate nouns in the language. In such languages, words that relate to the gender-marked nouns are inflected to agree with the noun's gender. We show that this affects the word representations of inanimate nouns, resulting in nouns with the same gender being closer to each other than nouns with different gender. While "embedding debiasing" methods fail to remove the effect, we demonstrate that a careful application of methods that neutralize grammatical gender signals from the words' context when training word embeddings is effective in removing it. Fixing the grammatical gender bias yields a positive effect on the quality of the resulting word embeddings, both in monolingual and cross-lingual settings. We note that successfully removing gender signals, while achievable, is not trivial to do and that a language-specific morphological analyzer, together with careful usage of it, are essential for achieving good results.

1 Introduction

Work on distributional word embeddings focuses almost exclusively on English, or on cross-lingual and language-agnostic techniques. However, languages are diverse and different languages exhibit different linguistic phenomena, which may interact with the English-centric embedding learning algorithms. In this work we look into one such phenomenon—grammatical gender—and examine its effect on the learned representation.

Many languages have rich grammatical systems, that often include a complex gender system as well (Corbett, 1991). Languages with grammatical gender assign and morphologically mark gender not only to animate nouns (which have biological sex, e.g. man, woman, mother, father), but also to inanimate nouns (e.g. dream, book). This grammatical gender assignment is mostly arbitrary: the same inanimate concept can have different gender in different languages. For example, a *flower* is masculine in Italian (*fiore*) and feminine in German (*Blume*).

Languages often maintain an *agreement system* in which certain words agree on different morphological features with other words they relate to. For example, English present-tense verbs are inflected to agree with their nominal subject on the *number* feature. In other languages the agreement system is more elaborate, and in particular verbs, adjectives, determiners and other functions agree with nouns on many features, including gender (Corbett, 2006).[1]

Such grammatical agreement affects the distributional environment of nouns, as nouns of different gender become surrounded by different word forms: feminine nouns co-occur more with the feminine forms of words, while masculine nouns with the masculine forms. For example, the Italian word *viaggio* ("*journey*"-masc) will co-occur with *durato* ("*last*"-masc) and *lungo* ("*long*"-masc), while the word *gita* ("*trip*"-fem) will co-occur with *durata* ("*last*"-fem) and *lunga* ("*long*"-fem).

Such changes in the distributional environment may bias the learned distributional representations of inanimate nouns. Indeed, we see that the majority of the top-10 nearest neighbors of the word *gita* in Italian ("*trip*"-fem) are feminine words. Also, we notice that the word *viaggio* ("*journey*"-masc) is not on the list, while in English, for comparison, we can find *journey* in the top-10 nearest neighbors of *trip*.

In this work, we are interested in investigating, demonstrating and quantifying this effect beyond

[1]As the gender of nouns is fixed, the other elements are inflected to accommodate the agreement constraint. The nouns are said to *assign gender* to the other words.

the anecdotal level. We also explore methods for removing such unwanted biases.

We demonstrate that both in Italian and in German, the grammatical gender affects similarities between word representations (using words from SimLex-999 (Hill et al., 2015; Leviant and Reichart, 2015)): pairs of nouns with similar gender are closer to each other while pairs of nouns with different gender are farther apart.

After quantifying the effect, we explore several methods of reducing it. A popular choice would be to simply lemmatize all the words prior to feeding them to the embedding learning algorithm. However, full lemmatization can be destructive, in the sense that it will also remove morphological distinction that we may want to keep. We thus seek more surgical approaches. Interestingly, recent embedding debiasing approaches (Bolukbasi et al., 2016) do not work well. We instead look for methods that attempt to neutralize the gender signals from the training data. We find that such methods are effective in reducing the effect, but are also language specific and tricky to get right: we rely on language specific morphological analyzers while carefully accounting for their peculiarities and adjusting our use for each language. We take this work as a reminder that (a) linguistic resources such as lexicons and morphological analyzers are still relevant and useful (cf. (Zalmout and Habash, 2017)); (b) languages are diverse and different languages require different treatments; and (c) small details may matter a lot. In particular, existing tools and resources, either learned or human curated, should not be trusted blindly, but be carefuly adapted for the problem.

Finally, we show that reducing the effect of grammatical agreement also has a positive effect on the quality of the resulting word representations, both in monolingual and cross-lingual settings. We conclude that grammatical gender indeed has its imprints on the representations of inanimate nouns, and that this should be taken into account when working with gender-marking languages. Our code and debiased embeddings are available at `https://github.com/gonenhila/grammatical_gender`.

2 Background and Related Work

Word Embeddings Word embeddings have become an important component in many NLP models and are widely used for a vast range of downstream tasks. These models are based on the distributional hypothesis according to which words that occur in the same contexts tend to have similar meanings (Harris, 1954). Indeed, they aim to create word representations that are derived from their shared contexts, where the context of a word is essentially the words in its proximity (be it according to linear order in the sentence or according to syntactic relations) (Mikolov et al., 2013; Pennington et al., 2014; Levy and Goldberg, 2014).

Gender Biases in Word Embeddings Social gender bias was demonstrated to be consistent and pervasive across different word embeddings (Caliskan et al., 2017). Bolukbasi et al. (2016) show that using word embeddings for simple analogies surfaces many gender stereotypes. In addition, they define the gender bias of a word w by its projection on the "gender direction": $\overrightarrow{w} \cdot (\overrightarrow{he} - \overrightarrow{she})$, assuming all vectors are normalized. Positive bias stands for male-bias. For example, the bias of *manager* is 0.06, while the bias of *nurse* is -0.10[2].

Recently, some work has been done to reduce social gender bias in word embeddings, both as a post-processing step (Bolukbasi et al., 2016) and as part of the training procedure (Zhao et al., 2018). Bolukbasi et al. (2016) use a post-processing debiasing method. Given a word embedding matrix, they make changes to the word vectors in order to reduce the gender bias for all words that are not inherently gendered. They do that by zeroing the gender projection of each word on a predefined gender direction.[3]

In Zmigrod et al. (2019), the authors mitigate social gender bias in gender marking languages using counterfactual data augmentation. Gender-marking languages add several interesting dimensions to the story: words relating to animate concepts such as "nurse" or "cat" may have both masculine and feminine versions; the distributional environment of a word contains many more explicit gender cues; and inanimate concepts are also assigned gender. All of these factors interact in complicated ways. In this work we focus on purely grammatical gender—the gender that is assigned to inanimate nouns—and its effect on their resulting representations.

[2] in English word2vec embeddings (Mikolov et al., 2013) trained on Wikipedia.

[3] The gender direction is chosen to be the top principal component (PC) of ten gender pair difference vectors.

Grammatical Gender Bias in Word Embeddings Grammatical gender is manifested in a similar way to social bias. For example, when projected on the Italian gender direction $\overrightarrow{lui} - \overrightarrow{lei}$ (Italian equivalents of "he" and "she"), the word "secolo" (*century*, masculine) has positive bias of 0.073, while the word "zuppa" (*soup*, feminine) has negative bias of -0.079.[4]

We attribute this behavior to grammatical agreement. Since the context of different-gender nouns is expected to be very different because of the agreement of the surrounding words, and since the resulting representations are based on the context of the word, we expect grammatical gender to play a role in the representations—nouns with the same gender are expected to be closer together than nouns with different gender. For inanimate nouns, this behavior is undesired.

Word Embeddings and Morphology Word embeddings were shown to capture grammatical and morphological properties. Avraham and Goldberg (2017) show that standard training of word embeddings in Hebrew captures also morphological properties and that using the lemmas when composing the representations helps to better capture semantic similarities. Similarly, Basirat and Tang (2018) show that typical grammatical features are captured by Swedish word embeddings.

Cotterell et al. (2016) treat the sparsity problem of morphologically rich languages in word embedding. They present a Gaussian graphical model to smooth representations of observed words and extrapolate representations for unseen words using morphological resources. With similar motivation, Vulić et al. (2017) use morphological constraints in English in order to pull inflectional forms of the same word closer together and push derivational antonyms farther apart. Finally, Salama et al. (2018) enhance Arabic word embeddings by incorporating morphological annotations.

3 Grammatical Gender Affects Word Representations

As a first step, we aim to verify that the representation of inanimate nouns in gender-marking languages is indeed affected by their grammatical gender. Since English does not have grammatical gender, a natural approach would be to use it as a reference when measuring this phenomenon.

[4] in Italian word2vec embeddings (Mikolov et al., 2013) trained on Wikipedia.

3.1 Inanimate Noun Pairs from SimLex-999

We take the inanimate noun portion of the SimLex-999 dataset (Hill et al., 2015), a gold standard resource for evaluating distributional semantic models. This dataset has an English version, and also German and Italian versions (Leviant and Reichart, 2015), and includes both similar and dissimilar word pairs, with human-assigned similarity judgments for each pair. This gives us 529 pairs of English words, along with high quality translations to Italian and German. We manually associate the Italian and German words with their grammatical gender.

3.2 Differences in Similarities

We divide the pairs in the gender-marking (GM) language (be it German or Italian) into two sets: (1) pairs of nouns that have the same gender in the GM language; (2) pairs of nouns that have different gender in the GM language. The respective English pairs are split in the same way, according to the gender of the nouns in the GM language. Thus, we end up with two sets of pairs in a GM language and their translations to English. Note that the English sets are different when used as a reference for German and Italian, since the split depends on the gender in the respective language.

For each set we compute the average of the cosine similarity of all word pairs within it. If gender plays a role in the representation of words, and indeed brings same-gender words closer together while keeping different-gender words farther apart, we expect to see a significant difference between the average similarity of the set of same-gender nouns and the set of different-gender nouns. As mentioned above, we compute these averages for English as a reference, where we expect a low difference between the two sets. Table 1 shows the results for Italian and German, compared to English. Indeed, in both cases, the difference between the average of the two sets is much bigger.

3.3 Rank in Nearest Neighbor List

We take the same sets as before, and for each pair in them we compute the rank of the second word in the nearest neighbor list of the first word and vice versa. For example, for the pair "parola" (*word*) and "dizionario" (*dictionary*) in Italian, we compute the rank of "dizionario" in the list of nearest neighbor of "parola" and the rank of "parola" in

	Italian	En	German	En
Same Gender	0.442	0.424	0.491	0.446
Different Gender	0.385	0.415	0.415	0.403
difference	0.057	0.009	0.076	0.043

Table 1: Averages of similarities of pairs with same gender vs. different gender, along with the respective averages in English. The last row (difference) is the difference between the averages of the two sets.

the list of nearest neighbors of "dizionario".

We then compare the average ranking in each set, with English as the reference. If the gender affects the similarities between words, we expect same-gender pairs to have lower average than different-gender pairs (remember that the closest word is at the lowest rank: 1). Table 2 shows the results for Italian and German, compared to English. As expected, the average ranking of same-gender pairs is significantly lower than that of different-gender pairs, both for German and Italian, while the difference between the sets in English is much smaller.

4 Debiasing Methods do not Work

As mentioned above, grammatical gender bias shares some aspects with social gender bias. Keeping that in mind we first turn to use these existing methods of gender-debiasing in English word embeddings.

Bolukbasi's method (2016) requires sets of pairs that define the gender direction. For this we use their predefined pairs, since we target grammatical gender bias, which we have demonstrated to be similar to social gender bias. In addition, a predefined set of inherently-neutral words is also needed: these are the words that will be debiased by the algorithm. As a first step, and in order to estimate the feasibility of using this method for reducing the grammatical gender bias, we use the set of the inanimate nouns from SimLex-999 as our set of inherently-neutral words.[5]

The algorithm worked well in the sense that the bias of all inanimate nouns, when measured by their projection on the gender dimension, became zero. However, it also failed: the similarities between the inanimate nouns themselves hardly changed. Table 3 depicts the average similarities in Italian before and after debiasing.

This suggests that the information about the gender is deeply embedded in the representation and is not easy to remove in a post-processing phase. Specifically, zeroing the projection of a word's vector on the gender direction is not enough in order to remove all gender information from the word's representation. The fact that similarities between words hardly change implies that the projection on the gender direction is not the only indication of gender. These results align with the findings discussed in Gonen and Goldberg (2019).

We conclude that focusing on the projection of vectors on the gender direction is not the right way to go, and we opt to removing gender inflections from the context before training. We describe this in detail in the next section.

5 Removing Gender Inflection from the Context

As mentioned above, words in the surroundings of gender-marked nouns (e.g. articles, adjectives) are often inflected to agree with the gender of the noun they relate to. As we hypothesize that most of the effect shown in Section 3 is caused by this gender agreement, we try several schemes that aim to remove gender signals from the context.

A straight-forward approach would be to lemmatize all the words, which will remove all gender signals from the context of a word. However, this approach has two main downsides: 1) We would like to have a representation for all the words in the vocabulary, but changing also the target words will reduce the vocabulary size and result with missing words (we will no longer have different masculine and feminine forms for any word); 2) Lemmatization removes not only gender information, but also additional information (such as number and tense). While gender assignment is arguably arbitrary, and does not translate to an actual physical property of inanimate nouns in reality, other properties that agree with the noun, such as number, do hold in reality and signify actual properties of the target noun, which we prefer to preserve.

Thus, a better approach would be to neutralize gender signals from the context alone, keeping the target words intact. This way we do not change the resulting embedding vocabulary. This can be done using: 1) lemmatizing all the context words, where we lose additional information, as

[5] If this method doesn't mitigate the bias we showed in the previous section, then using inherently-neutral words extracted from the vocabulary automatically cannot possibly work as well.

	Italian			German		
	Same-gender	Diff-Gender	difference	Same-gender	Diff-Gender	difference
